Prokaryotes work together with eukaryotes in many ways. In fact, mitochondria and chloroplasts are descended from what were once free-living bacteria. Much later in evolutionary history, some plants formed associations with bacteria to form cooperative nitrogen-fixing nodules on their roots (see Chapter 36).

Many animals, including humans, harbor a variety of bacteria and archaea in their digestive tracts. Cows depend on prokaryotes to perform important steps in digestion. Like most animals, cows cannot produce cellulase, the enzyme needed to start the digestion of the cellulose that makes up the bulk of their plant food. However, bacteria living in a special section of the gut called the rumen produce enough cellulase to process the cow's daily diet. Humans use some of the metabolic products—especially vitamins B 12 and K—of bacteria living in our large intestine.

We are heavily populated, inside and out, by bacteria. Although very few of them are agents of disease, popular notions of bacteria as "germs" arouse our curiosity about those few. Let's briefly consider the roles of some bacteria as pathogens.

A small minority of bacteria are pathogens

The late nineteenth century was a productive era in the history of medicine—a time during which bacteriologists, chemists, and physicians proved that many diseases are caused by microbial agents. During this time the German physician Robert Koch laid down a set of rules for establishing that a particular microorganism causes a particular disease:

BACTERIA AND ARCHAEA: THE PROKARYOTIC DOMAINS 467

- ▶ The microorganism must always be found in individuals with the disease.
- ▶ The microorganism can be taken from the host and grown in pure culture.
- ▶ A sample of the culture produces the disease when injected into a new, healthy host.
- ▶ The newly infected host yields a new, pure culture of microorganisms identical to those obtained in the second step.

These rules—called Koch's postulates—were very important in a time when it was not widely accepted that microorganisms cause disease. Today, medical science makes use of other, more powerful diagnostic tools.

Only a tiny percentage of all prokaryotes are pathogens (disease-producing organisms), and of those that are known, all are bacteria. For an organism to be a successful pathogen, it must overcome several hurdles:

- ▶ It must arrive at the body surface of a potential host.
- ▶ It must enter the host's body.
- ▶ It must evade the host's defenses.
- ▶ It must multiply inside the host.
- ▶ It must infect a new host.

Failure to overcome any of these hurdles ends the reproductive career of a pathogenic organism. However, in spite of the many defenses available to potential hosts that we considered in Chapter 19, some bacteria are very successful pathogens.

For the host, the consequences of a bacterial infection depend on several factors. One is the invasiveness of the pathogen—its ability to multiply within the body of the host. Another is its toxigenicity—its ability to produce chemical substances (toxins) harmful to the tissues of the host. *Corynebacterium diphtheriae*, the agent that causes diphtheria, has low invasiveness and multiplies only in the throat, but its toxigenicity is so great that the entire body is affected. In contrast, *Bacillus anthracis*, which causes anthrax (a disease primarily of cattle and sheep), has low toxigenicity but an invasiveness so great that the entire bloodstream ultimately teems with the bacteria.

There are two general types of bacterial toxins: exotoxins and endotoxins. Endotoxins are released when certain Gram-negative bacteria lyse (burst). These toxins are lipo-polysaccharides that form part of the outer bacterial membrane. Endotoxins are rarely fatal; they normally cause fever, vomiting, and diarrhea. Among the endotoxin producers are some strains of *Salmonella* and *Escherichia*.

Exotoxins are proteins released by living, multiplying bacteria, and they may travel throughout the host's body. They are highly toxic—often fatal—to the host, but do not produce fevers. Exotoxin-induced human diseases include tetanus (from *Clostridium tetani*), botulism (from *Clostridium Botulinum*), cholera (from *Vibrio cholerae*) and plague (from *Yersinia pestis*).

Remember that in spite of our frequent mention of human pathogens, only a small minority of the known prokaryotic species are pathogenic. Many more species play

positive roles in our lives and in the biosphere. We make direct use of many bacteria and a few archaea in such diverse applications as cheese production, sewage treatment, and the industrial production of an amazing variety of antibiotics, vitamins, organic solvents, and other chemicals.

Prokaryote Phylogeny and Diversity

The prokaryotes comprise a diverse array of microscopic organisms. To explore this diversity, let's first consider how they are classified, and some of the difficulties involved in doing so; then we'll look at some specific examples.

Nucleotide sequences of prokaryotes reveal their evolutionary relationships

There are three primary motivations for classification schemes: to help identify unknown organisms, to reveal evolutionary relationships, and to provide universal names (see Chapter 23). Many scientists and medical technologists must be able to identify bacteria quickly and accurately—when the bacteria are pathogenic, lives may depend on it.

Until recently, taxonomists based their classification schemes for the prokaryotes on readily observable phenotypic characters such as color, motility, nutritional requirements, antibiotic sensitivity, and reaction to the Gram stain. Although such schemes have facilitated the identification of prokaryotes, they have not provided insights into how these organisms evolved—a question of great interest to microbiologists and to all students of evolution. The prokaryotes and the protists (see Chapter 27) have long been major challenges to those who attempted phylogenetic classifications. Only recently have systematists had the right tools for tackling this task.

Analyses of the nucleotide sequences of ribosomal RNA's provided us with the first apparently reliable measures of evolutionary distance among taxonomic groups. Ribosomal RNA (rRNA) is particularly useful for evolutionary studies of living organisms for several reasons:

- ▶ rRNA is evolutionarily ancient.
- ▶ No living organism lacks rRNA.
- ▶ rRNA plays the same role in translation in all organisms.
- ▶ rRNA has evolved slowly enough that sequence similarities between groups of organisms are easily found.

Let's look at just one of the approaches to the use of rRNA for studying evolutionary relationships.

Comparisons of rRNA's from a great many organisms showed that there are recognizable short base sequences characteristic of particular taxonomic groups. These signature sequences, approximately 6 to 14 bases long, appear at the same approximate positions in rRNA's from related groups. For example, the signature sequence AAACU-UAAAG occurs about 910 bases from one end of the RNA of the light subunit of ribosomes in 100 percent of the Archaea and Eukarya tested, but in none of the Bacteria tested. Several signature sequences distinguish each of the three domains. Similarly, the major groups within the bacteria and archaea possess unique signature sequences.

468 CHAPTER TWENTY-SIX

Common ancestor of all of today's organisms

These data sound promising, but things aren't as easy as we might wish. When biologists examined other genes and RNA's, contradictions began to appear. Analyses of different nucleotide sequences suggested different phylogenetic patterns. How could such a situation have arisen?

Lateral gene transfer muddied the phylogenetic waters

It is now clear that, from early in evolution to the present day, genes have been moving among prokaryotic species by lateral gene transfer. As we have seen, a gene from one species can become incorporated into the genome of another. Mechanisms of lateral gene transfer include transfer by plasmids and viruses and uptake of DNA by transformation. Such transfers are well documented, not just between bacterial species or archaean species, but also across the boundary between bacteria and archaea.

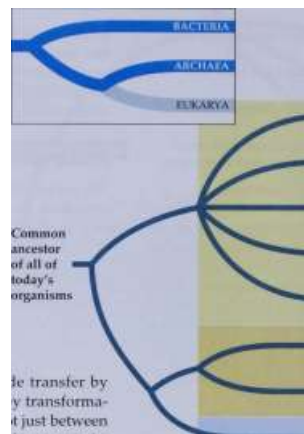

A gene that has been transferred will be inherited by the recipient's progeny and in time will be recognized as part of the normal genome of the descendants. Biologists are still assessing the extent of lateral gene transfer among prokaryotes and its implications for phylogeny, especially at the early stages of evolution.

There is great controversy now over prokaryotic phylogeny. Figure 26.11 is an overview of some major groups in the domains Bacteria and Archaea that we will discuss further in this chapter. Keep in mind that a new picture will likely emerge within the next decade, based on the addition of more nucleotide sequence data and on new information about the currently understudied archaea.

Mutations are the most important source of prokaryotic variation

Assuming that the prokaryote groups we are about to describe do indeed represent monophyletic groups, we discover that they are amazingly complex. A single group of bacteria or archaea may contain the most extraordinarily diverse species, and a species in one group may be phenotypically almost indistinguishable from one or many species in another group. What are the sources of this diversity?

Although prokaryotes can acquire new alleles by transformation, transduction, or conjugation, the most important source of genetic variation in populations of prokaryotes is probably mutation. Mutations, especially recessive mutations, are slow to make their presence felt in populations of humans and other diploid organisms. In contrast, a mutation in a prokaryote, which is haploid, has immediate consequences for that organism. If it is not lethal, it will be transmitted to and expressed in the organism's daughter cells—and in their daughter cells, and so forth. Thus, a beneficial mutant allele spreads rapidly.

26.11 Two Domains: A Brief Overview

An abridged summary classification of the domains Bacteria and Archaea shows their relationships to each other and to the Eukarya. The relationships among the many lineages of bacteria, not all of which are listed here, are unresolved at this time.

The rapid multiplication of many prokaryotes, coupled with mutation, selection, and genetic drift, allows rapid phenotypic changes within their populations. Important changes, such as loss of sensitivity to an antibiotic, can occur over broad

geographic areas in just a few years. Think how many significant metabolic changes could have occurred over even modest time spans in relation to the history of life on Earth. When we introduce the Proteobacteria, the largest group of bacteria, you will see that its different subgroups easily and rapidly adopted and abandoned metabolic pathways under selective pressure from their environments.

The Bacteria

The great majority of known prokaryotes are bacteria. Here we will describe bacterial diversity using a currently popular classification scheme that enjoys considerable support from nucleotide sequence data. More than a dozen monophyletic groups have been proposed under this scheme; we will describe just a few of them here. The higher-order relationships among these groups of prokaryotes are not known. Some biologists describe them as kingdoms, some as subkingdoms, others as phyla. Here we call them groups. We'll pay the closest attention to the Proteobacteria, Cyanobacteria, Spirochetes, Chlamydias, and Firmicutes (see Figure 26.11), but first we mention one property that is shared by members of three other groups.

Some bacteria are heat lovers

Three of the bacterial groups that may have branched out earliest during bacterial evolution are all thermophiles (heat lovers), as are the most ancient of the archaea. This observation supports the hypothesis that the first living organisms were thermophiles that appeared in an environment much hotter than those that predominate today.

The Proteobacteria are a large and diverse group

By far the largest group of bacteria, in terms of number of described species, is the Proteobacteria, sometimes referred to as the purple bacteria. Among the proteobacteria are many species of Gram-negative, bacteriochlorophyll-containing, sulfur-using photoautotrophs. However, this group also includes a dramatically diverse group of bacteria that bear no resemblance to the purple bacteria in phenotype. The mitochondria of eukaryotes were derived from proteobacteria by endosymbiosis.

No characteristic demonstrates the diversity of the proteobacteria more clearly than their metabolic pathways (Figure 26.12). The common ancestor of all the proteobacteria was probably a photoautotroph. Early in evolution, two groups of proteobacteria lost their ability to photosynthesize and have been chemoheterotrophs ever since. The other three groups still have photoautotrophic members, but in each group, some evolutionary lines have abandoned photoautotrophy and taken up other modes of nutrition. There are chemoautotrophs and chemoheterotrophs in all

three groups. Why? We can view each of the trends in Figure 26.12 as an evolutionary response to selective pressures encountered as these bacteria encountered new habitats that presented new challenges and opportunities.

Among the proteobacteria are some nitrogen-fixing genera such as *Rhizobium* (see Figure 34.10) and other bacteria that contribute to the global nitrogen and sulfur cycles. *E. coli*, one of the most studied organisms on Earth, is a proteobacterium. So, too, are many of the most famous human pathogens, such as *Yersinia pestis*, *Vibrio cholerae*, and *Salmonella typhimurium*, all mentioned in our discussion of pathogens.

Fungi cause most plant diseases, and viruses cause others, but about 200 plant diseases are of bacterial origin. Crown gall, with its characteristic tumors (Figure 26.13), is one of the most striking. The causal agent of crown gall is *Agrobacterium tumefaciens*, which harbors a plasmid used in recombinant DNA studies as a vehicle for inserting genes into new plant hosts (see Chapter 17).

A change of line color from green to red or blue indicates loss of the ability to photosynthesize.

26.12 The Evolution of Metabolism in the Proteobacteria

The common ancestor of all proteobacteria was probably a photoautotroph. As they encountered new environments, groups 1 and 2 lost the ability to photosynthesize; in the other three groups, some evolutionary lines became chemoautotrophs or chemoheterotrophs.

Crown gall is a plant disease caused by Gram-negative *Agrobacterium tumefaciens*.

470 CHAPTER TWENTY-SIX

The Cyanobacteria are important photoautotrophs

The Cyanobacteria (blue-green bacteria) require only water, nitrogen gas, oxygen, a few mineral elements, light, and carbon dioxide to survive. They use chlorophyll *a* for photosynthesis and liberate oxygen gas; many species also fix nitrogen. Their photosynthesis was the basis of the "oxygen revolution" that transformed Earth's atmosphere.

Cyanobacteria carry out the same type of photosynthesis that is characteristic of eukaryotic photosynthesizers. They contain elaborate and highly organized internal membrane systems called photosynthetic lamellae, or thylakoids (Figure 26.14). The chloroplasts of photosynthetic eukaryotes are derived from an endosymbiotic cyanobacterium.

Cyanobacteria may associate in colonies or live free as single cells. Depending on the species and on growth conditions, colonies of cyanobacteria may range from flat sheets one cell thick to spherical balls of cells.

Some filamentous colonies differentiate into three cell types: vegetative cells, spores, and heterocysts (Figure 26.15). Vegetative cells photosynthesize, spores are resting cells that can eventually develop into new filaments, and heterocysts are cells specialized for nitrogen fixation. All of the known cyanobacteria with heterocysts fix nitrogen. Heterocysts also have a role in reproduction: When filaments break apart to reproduce, the heterocyst may serve as a breaking point.

26.14 Thylakoids in Cyanobacteria

This cyanobacterium was prepared by the freeze-etch technique to emphasize the extensive system of internal membranes. These photosynthetic thylakoid membranes are present through most of the cytoplasm and clearly identify the specimen as a cyanobacterium, even though the exact species is not identified here.

26.75 Cyanobacteria

(a) *Anabaena* is a genus of colonial, filamentous cyanobacteria. The vegetative cells are photosynthetic. (b) A thin neck attaches a heterocyst to each of two other cells in a colony, (c) Cyanobacteria appear in enormous numbers in some environments. This California pond has experienced eutrophication: Phosphorus and other nutrients generated by human activity have accumulated in the pond, feeding an immense green mat—commonly referred to as "pond scum"—made up of several species of unicellular cyanobacteria.

Spirochetes look like corkscrews

Spirochetes are Gram-negative bacteria characterized by unique structures called axial filaments, fibrils running through the periplasmic space (see Figure 26.5a). The cell body is a long cylinder coiled into a spiral (Figure 26.16). The axial filaments begin at either end of the cell and overlap in

Treponema pallidum ..

26.76 A Spirochete

This corkscrew-shaped spirochete causes syphilis in humans.

the middle, and there are typical basal rings where they are attached to the cell wall. Many spirochetes live in humans as parasites. Others live free in mud or water.

Chlamydias are extremely small

Chlamydias are among the smallest bacteria (0.2-1.5 μm in diameter). They can live only as parasites within the cells of other organisms. These tiny spheres are unique prokaryotes because of their complex life cycle, which involves two different forms of cells (Figure 26.17). In humans, various strains of chlamydias cause eye infections (especially trachoma), sexually transmitted disease, and some forms of pneumonia.

Endospore

Clostridium tetani ''

1.2 μm

26.18 The Endospore: A Structure for Waiting Out

Bad Times

This firmicute, which causes tetanus, produces endospores as resistant resting structures.

Most Firmicutes are Gram-positive

The Firmicutes are sometimes referred to as the Gram-positive bacteria, but some firmicutes are Gram-negative, and some have no cell wall at all. Nonetheless, the firmicutes constitute a monophyletic group.

Some firmicutes produce endospores (Figure 26.18)—heat-resistant resting structures—when nutrients become scarce. The bacterium replicates its DNA and encapsulates one copy, along with some of its cytoplasm, in a tough cell wall heavily thickened with peptidoglycan and surrounded by a spore coat. The parent cell then breaks down, releasing the endospore. Endospore production is not a reproductive process; the endospore merely replaces the parent cell. The endospore can survive harsh environmental conditions, such as high or low temperatures or drought, because it is dormant—its normal activity is suspended. Later, if it encounters favorable conditions, the endospore becomes metabolically active and divides, forming new cells like the parent. Some endospores apparently can be reactivated even after more than a thousand years of dormancy.

Members of this endospore-forming group include the many species of *Bacillus* and *Clostridium*. The toxins produced by *C. botulinum* are among the most poisonous ever discovered; the lethal dose for humans is about one-millionth of a gram (1 µg).

The genus *Staphylococcus*—the staphylococci—includes firmicutes that are abundant on the human body surface; they are responsible for boils and

many other skin problems (Figure 26.19). *S. aureus* is the best-known human pathogen; it is found in 20 to 40 percent of normal adults (and in 50 to 70 percent of hospitalized adults). It can cause respiratory, intestinal, and wound infections, in addition to skin diseases.

Actinomycetes are firmicutes that develop an elaborately branched system of filaments (Figure 26.20). These bacteria closely resemble the filamentous bodies of fungi. Some actinomycetes reproduce by forming chains of spores at the tips of the filaments. In the species that do not form spores, the branched, filamentous growth ceases and the structure breaks up into typical cocci or rods, which then reproduce by fission.

The actinomycetes include several medically important bacteria. *Mycobacterium tuberculosis* causes tuberculosis. *Streptomyces* produces streptomycin, as well as hundreds of

Actinomyt

other antibiotics, including several dozen in general use. We derive most of our antibiotics from members of the actinomycetes.

Another interesting group of firmicutes, the mycoplasmas, lack cell walls, although some have a stiffening material outside the plasma membrane. Some of them are the smallest cellular creatures ever discovered—they are even smaller than chlamydias (Figure 26.21). The smallest mycoplasmas capable of growth have a diameter of about 0.2 μm , and they are small in another crucial sense: They have less than half as much DNA as do most other prokaryotes. It has been speculated that the amount of DNA in a mycoplasma may be the minimum amount required to code for the essential properties of a living cell.

The Archaea

The domain Archaea consists mainly of prokaryotic genera that live in habitats notable for characteristics such as extreme salinity (salt content), low oxygen concentration, high temperature, or high or low pH. On the face of it, the Archaea do not seem to belong together as a group; in fact, some evidence suggests that the domain Archaea is para-phyletic. One current classification scheme treats the domain as two kingdoms: Euryarchaeota and Crenarchaeota. In fact, we know very little about the phylogeny of archaea, in part because the study of archaea is still in its early stages. We do know that archaea share certain characteristics.

The Archaea share some unique characteristics

Two characteristics shared by all archaea are the absence of peptidoglycan in their cell walls and the presence of lipids of distinctive composition in their cell membranes (see Table 26.1). The base sequences of their ribosomal RNA's support a close evolutionary relationship among them. Their separation from the Bacteria and Eukarya was clari-

Long-chain hydrocarbons with glycerol at both ends span the membrane of some archaea.

Some archaean hydrocarbons fit the same membrane template as do the fatty acids of bacteria and eukaryotes.

26.22 Membrane Architecture in Archaea

The long-chain hydrocarbons of archaean membranes are branched, and may have glycerol at both ends. This structure still fits into a biological membrane, however; in fact, all three domains have similar membrane structures.

fied when biologists sequenced the first archaean genome: It consisted of 1,738 genes, more than half of which were unlike any genes ever found in the other two domains.

The unusual lipids in the membranes of archaea deserve some description. They are found in all archaea, and in no bacteria or eukaryotes. Most membrane lipids of bacteria and eukaryotes contain unbranched long-chain fatty acids connected to glycerol by ester linkages:

(see also Figure 3.19). In contrast, archaean membrane lipids contain long-chain hydrocarbons connected to glycerol by ether linkages:

In addition, the long-chain hydrocarbons are branched in the archaea. One class of these lipids contains glycerol at both ends of the hydrocarbons. This structure still fits in a biological membrane, as shown in Figure 26.22. In spite of the striking difference in membrane lipids, all three domains have lipid bi-layer membranes with similar overall structures, dimensions, and functions.

Most Crenarchaeota live in hot, acidic places

Most known Crenarchaeota are both thermophilic (heat-loving) and acidophilic (acid-loving). Members of the genus *Sulfolobus* live in hot sulfur springs at temperatures of 70-75°C. They die of "cold" at 55°C (131°F). Hot sulfur springs are also extremely acidic. *Sulfolobus* grows best in the pH range from 2 to 3, but it readily tolerates pH values as low as 0.9. Some acidophilic hyperthermophiles maintain an internal pH near 7 (neutral) in spite of the acidity of their environment. These and other hyperthermophiles thus thrive where very few other organisms can even survive (Figure 26.23).

The Euryarchaeota live in many amazing places

Some species of Euryarchaeota, once assigned to unrelated bacterial groups, share the property of producing methane (CH₄) by reducing carbon dioxide. All of these methane producers are obligate anaerobes, and methane production is the key step in their energy metabolism. Comparison of rRNA nucleotide sequences revealed a close evolutionary relationship among all these methanogens.

Methanogens release approximately 2 billion tons of methane gas into Earth's atmosphere each year, accounting for all the methane in our air, including that associated with mammalian belching. Approximately a third of this methane comes from methanogens in the guts of grazing herbivores such as cows.

26.23 Some Would Call It Hell; Archaea Call It Home

Masses of heat- and acid-loving archaea form an orange mat inside a volcanic vent on the island of Kyushu, Japan. Sulfurous residue is visible at the edges of the archaean mat.

26.24 Extreme Halophiles

Commercial seawater evaporating ponds, such as these in San Francisco Bay, are attractive homes for salt-loving archaea.

One methanogen, *Methanopyrus*, lives on the ocean bottom near blazing volcanic vents. *Methanopyrus* can survive and grow at 110°C. It grows best at 98°C and not at all at temperatures below 84°C.

Another group of Euryarchaeota, the extreme halophiles (salt lovers), lives exclusively in very salty environments. Because they contain pink carotenoids, they can be seen easily under some circumstances (Figure 26.24). Halophiles grow in the Dead Sea and in brines of all types: Pickled fish may sometimes show reddish pink spots that are colonies of halophilic archaea. Few other organisms can live in the saltiest of the homes that the strict halophiles occupy; most would "dry" to death, losing too much water to the hypertonic environment. Strict halophiles have been found in lakes with pH values as high as 11.5—the most alkaline environment inhabited by living organisms, almost as alkaline as household ammonia.

Some of the extreme halophiles have a unique system for trapping light energy and using it to form ATP—without using any form of chlorophyll—when oxygen is in short supply. They use the pigment retinal (also found in the vertebrate eye) combined with a protein to form bacteriorhodopsin, and form ATP by a chemiosmotic mechanism of the sort described in Figure 7.12.

Another member of the Euryarchaeota, *Thermoplasma*, has no cell wall. It is thermophilic and acidophilic, its metabolism is aerobic, and it lives in coal deposits. It has the smallest genome among the archaea, and perhaps the smallest (along with the mycoplasmas) of any free-living organisms—1,100,000 base pairs.

This chapter has provided a brief summary of two of the e domains of the living world. The world of the eukaryotes, both unicellular and multicellular, will be the subject of the next seven chapters.

Chapter Summary

Why Three Domains?

- Living organisms can be divided into three domains: Bacteria, Archaea, and Eukarya. Both the Archaea and the Bacteria are prokaryotic, but they differ from each other more radically than do the Archaea from the Eukarya, which constitute the rest of the living world.
- The evolutionary relationships of the three domains were first revealed by their rRNA sequences. The common ancestor of all three domains lived more than 3 billion years ago, and the common ancestor of the Archaea and Eukarya at least 2 billion years ago. Review Figure 26.2 and Table 26.1

General Biology of the Prokaryotes

- The prokaryotes are the most numerous organisms on Earth, and they occupy an enormous variety of habitats.
- Most prokaryotes are cocci, bacilli, or spiral forms. Some link together to form associations, but very few are truly multicellular. Review Figure 26.3
- Prokaryotes lack nuclei, membrane-enclosed organelles, and cytoskeletons. Their chromosomes are circular. They often contain plasmids. Some prokaryotes contain internal membrane systems. Review Figure 26.4
- Many prokaryotes move by means of flagella, gas vesicles, or gliding mechanisms. Prokaryotic flagella rotate rather than beat.
- Prokaryotic cell walls differ from those of eukaryotes. Bacterial cell walls generally contain peptidoglycan. Differences in peptidoglycan content result in different reactions to the Gram stain. Review Figure 26.7
- Prokaryotes reproduce asexually by fission, but also exchange genetic information.

► Prokaryotes have diverse metabolic pathways and nutritional modes. They include obligate anaerobes, facultative anaerobes, and obligate aerobes. The major nutritional types are photoautotrophs, photoheterotrophs, chemoautotrophs, and chemoheterotrophs. Some prokaryotes base their energy metabolism on nitrogen- or sulfur-containing ions. Review Figure 26.8 and Table 26.2

Prokaryotes in Their Environments

► Some prokaryotes play key roles in global nitrogen and sulfur cycles. Important players in the nitrogen cycle are the nitrogen fixers, nitrifiers, and denitrifiers. Review Figure 26.10

► Photosynthesis by cyanobacteria generated the oxygen gas that permitted the evolution of aerobic respiration and the appearance of present-day eukaryotes.

► Many prokaryotes live in or on other organisms, with neutral, beneficial, or harmful effects.

► A small minority of bacteria are pathogens. Pathogens vary with respect to their invasiveness and toxigenicity. Some produce endotoxins, which are rarely fatal; others produce exotoxins, which tend to be highly toxic.

Prokaryote Phylogeny and Diversity

► Phylogenetic classification of prokaryotes is now based on rRNA sequences and other molecular evidence.

► Lateral gene transfer among prokaryotes, which has occurred throughout evolutionary history, makes it difficult to infer prokaryote phylogeny.

► Evolution, powered by mutation, natural selection, and genetic drift, can proceed rapidly in prokaryotes because they are haploid and can multiply rapidly.

BACTERIA AND ARCHAEA: THE PROKARYOTIC DOMAINS 475

The Bacteria

► There are far more known bacteria than known archaea. One phylogenetic classification of the domain Bacteria groups them into more than a dozen groups.

► The most ancient bacteria, like the most ancient archaea, may be thermophiles, suggesting that life originated in a hot environment.

► All four nutritional types occur in the largest bacterial group, the Proteobacteria. Metabolism in different groups of proteobacteria has evolved along different lines. Review Figure 26.12

► Cyanobacteria, unlike other bacteria, photosynthesize using the same pathways plants use. Many cyanobacteria fix nitrogen.

► Spirochetes move by means of axial filaments.

► Chlamydias are tiny parasites that live within the cells of other organisms.

► Firmicutes are diverse; some of them produce endospores as resting structures that resist harsh conditions. Actinomycetes, some of which produce important antibiotics, grow as branching filaments.

► Mycoplasmas, the tiniest living things, lack conventional cell walls. They have very small genomes.

The Archaea

► Archaea have cell walls lacking peptidoglycan, and their membrane lipids differ from those of bacteria and eukaryotes, containing branched long-chain hydrocarbons connected to glycerol by ether linkages. Review Figure 26.22

► The domain Archaea can be divided into two kingdoms: Crenarchaeota and Euryarchaeota.

► Crenarchaeota are heat-loving and often acid-loving archaea.

► Methanogens produce methane by reducing carbon dioxide. Some methanogens live in the guts of herbivorous animals; others occupy high-temperature environments on the ocean floor.

► Extreme halophiles are salt lovers that often lend a pinkish color to salty environments; some halophiles also grow in extremely alkaline environments.

► Archaea of the genus *Thermoplasma* lack cell walls, are thermophilic and acidophilic, and have a tiny genome (1,100,000 base pairs).

For Discussion

1. Why do systematic biologists find rRNA sequence data more useful than data on metabolism or cell structure for classifying prokaryotes?

2. Why does lateral gene transfer make it so difficult to arrive at agreement on phylogeny?
3. Differentiate among the members of the following sets of related terms:
 - a. prokaryotic/eukaryotic
 - b. obligate anaerobe/facultative anaerobe/obligate aerobe
 - c. photoautotroph/photoheterotroph/chemoautotroph/ chemoheterotroph
 - d. Gram-positive/Gram-negative
4. Why are the endospores of firmicutes not considered to be reproductive structures?
5. Until fairly recently, the cyanobacteria were called blue-green algae and were not grouped with the bacteria. Suggest several reasons for this (abandoned) tendency to separate the bacteria and cyanobacteria. Why are the cyanobacteria now grouped with the other bacteria?
6. The actinomycetes are of great commercial interest. Why?
7. Hyperthermophiles are of great interest to molecular biologists and biochemists. Why? What practical concerns might motivate that interest?

21

Protists and the Dawn of the Eukarya

The Bacteria and the Archaea had the living world to themselves for more than a billion years. As we saw in Chapter 26, members of these two domains differ sharply in several important ways—but neither of these prokaryotes is like the single-celled organism shown here. What strikes you the most about this amoeba? Probably the most obvious visible difference between it and the prokaryotes is that the amoeba has numerous compartments—membrane-enclosed organelles.

What are compartments useful for? For one thing, they keep items separate—like keeping greasy tools away from clean socks by storing them in different cabinets. Compartments also keep things together when that makes sense, such as keeping all your socks in one drawer, or keeping all the files for your term paper in a single directory on your computer. Rooms are another example of compartments, and they can be specialized for different activities: One room in the Biological Sciences Building might be set up as a laboratory, while another room serves as a lecture hall, and still another contains special protective seals that prevent radiation or pathogens from escaping.

The single-celled amoeba is an example of an organism that compartmentalizes: It has a cytoskeleton, a nucleus enclosed by a nuclear envelope, and several kinds of organelles. Amoebas are members of the domain Eukarya, and they differ from members of the two prokaryotic domains in other important ways as well.

The flexibility and options that arose once the eukaryotic cell had evolved resulted in a profusion of body forms and myriad specialized functions. Eukaryotic evolution has produced great diversity, especially among the multicellular lineages, but even among the unicellular protists. In both multicellular and unicellular forms, however, there are also many cases of convergent evolution; for example, organisms with an amoeba-like body form arose several times.

Protists Defined

Many modern members of the Eukarya are familiar to us—trees, dogs, and mushrooms, not to mention our-

An Amoeba

is have several kinds of organelles (seen here as bubble-like compartments). Their flowing pseudopods are constantly changing shape as the amoeba moves and feeds.

selves. These members of the kingdoms Plantae, Animalia, and Fungi are not strange to us. However, amoebas and a dazzling assortment of other eukaryotes, mostly microscopic organisms, don't fit into these three kingdoms. We call all those eukaryotes that are neither plants, animals, nor fungi protists (Figure 27.1; Table 27.1). The protists are not a monophyletic group. Some protists are more closely related to the animals than they are to other protists. Some protists are motile, while others are stationary; some are photosynthetic, while others are heterotrophic; most are unicellular, while some giant kelps are not only multicellular but also huge, sometimes achieving lengths greater than that of a football field.

The origin of the eukaryotic cell was one of the pivotal events in evolutionary history. In this chapter on the protists we describe and celebrate the origin and early diversification of the eukaryotes and the complexity achieved by some single cells. We'll explore some of the diversity of protist body forms, and we'll try to give a sense of developing current views of the evolutionary relationships of some of the protists.

The Origin of the Eukaryotic Cell

The eukaryotic cell differs in many ways from prokaryotic cells. How did it originate? Given the nature of evolutionary processes, the differences cannot all have arisen simultaneously. We think we can make some reasonable guesses

about the important events, bearing in mind that the global environment underwent an enormous change—from anaerobic to aerobic—during the course of these events. As you read this chapter, keep in mind that the steps we sug-

gest are just that: guesses. This version of the story is one of a few under current consideration. We present it as a framework for thinking about this challenging problem, not as a set of facts.

478 CHAPTER TWENTY-SEVEN

Plasma membrane

Infolding of the plasma membrane adds surface area without increasing the cell's volume.

27.2 Membrane Infolding

The loss of the rigid prokaryotic cell wall allowed the plasma membrane to elaborate inward and create more surface area.

The modern eukaryotic cell arose in several steps

The essential steps in the origin of the eukaryotic cell include

- ▶ The origin of a flexible cell surface
- ▶ The origin of a cytoskeleton
- ▶ The origin of a nuclear envelope
- ▶ The appearance of digestive vesicles
- ▶ The endosymbiotic acquisition of certain organelles

what a flexible cell surface allows. Many ancient fossil prokaryotes look like rods, and we presume that they, like most present-day prokaryotic cells, had firm, cell walls. The first step toward the eukaryotic condition may have been the loss of the cell wall by an ancestral prokaryotic cell. This may not seem like an obvious first step, but consider the possibilities open to a flexible cell without a wall.

First, think of cell size. As a cell grows, its surface area-to-volume ratio decreases (see Figure 4.2). Unless the surface is flexible and can fold inward and elaborate itself, creating more surface area for gas and nutrient exchange (Figure 27.2), the cell volume will reach an upper limit. With a surface flexible enough to allow infolding, the cell can exchange materials with its environment rapidly enough to sustain a larger volume and more rapid metabolism. Further, a flexible surface can pinch off bits of the environment, bringing them into the cell by endocytosis (Figure 27.3).

o recall that the chromosome of a prokaryotic

is attached to a site on its plasma membrane (see

Figure 26.4). If that region of the plasma membrane

ne to fold into the cell, the first step would be taken

Ribosomes-Protective cell wall DNA-

27.3 From Prokaryotic Cell to Eukaryotic Cell

One possible evolutionary sequence is shown here. The exact sequence, of course, is not known.

PROTISTS AND THE DAWN OF THE EUKARYA 479

toward the evolution of a nucleus, the key feature of the eukaryotic cell.

CHANGES IN CELL STRUCTURE AND FUNCTION. Early Steps in

the evolution of the eukaryotic cell are likely to have included three advances: the formation of ribosome-studded internal membranes, some of which surrounded the DNA (see Figure 27.3); the appearance of a cytoskeleton and the evolution of digestive vesicles.

A cytoskeleton made up of actin fibers and microtubules would allow the cell to manage changes in shape, to distribute daughter chromosomes, and to move materials from one part of the now much larger cell to other parts. The origin of the cytoskeleton remains a mystery, heightened by the fact that the genes that encode the cytoskeleton are present in neither bacteria nor archaea. An intriguing and controversial suggestion is that a fourth domain of life, now long extinct, originated these genes and transferred them laterally to an ancestor of the early eukaryotes.

From an intermediate kind of cell, the next advance was probably to a cell that we could call a phagocyte—a motile cell that could prey on other cells by engulfing and digesting them. The first true eukaryote possessed a cytoskeleton and a nuclear envelope. It may have had an associated endoplasmic reticulum and Golgi apparatus, and perhaps one or more flagella of the eukaryotic type. Notice how much of the progress to this point was made possible by the loss of the cell wall and the elaboration of what was originally the plasma membrane.

endosymbiosis and organelles. While the processes already outlined were taking place, the cyanobacteria were very busy, generating oxygen gas as a product of photosynthesis. The increasing O_2 levels in the atmosphere had disastrous consequences for most other living things, because most living things of the time (archaea and bacteria) were unable to tolerate the newly aerobic, oxidizing environment. But some prokaryotes managed to cope, and—fortunately for us—so did some of the ancient phagocytes.

According to one hypothesis, the key to the survival of early phagocytes was the ingestion and incorporation of a prokaryote

that became symbiotic within the phagocyte and evolved into the peroxisomes of today (see Figure 27.3). These organelles were able to disarm the toxic products of oxygen action, such as hydrogen peroxide. This association may have been the first important endosymbiosis in the evolution of the eukaryotic cell.

In Chapter 4 we introduced the concept of endosymbiosis (organisms living together, one inside the other). A crucial endosymbiotic event in the history of the Eukarya was the incorporation of a proteobacterium that evolved into the mitochondrion. Upon completion of this step, the basic modern eukaryotic cell was complete. Some very important eukaryotes are the result of yet another endosymbiotic step, the incorporation of prokaryotes related to today's cyanobacteria, which became chloroplasts. We'll see how this happened later in the chapter.

This unicellular *Giardia* has two nuclei but no mitochondria.

Nuclei

27.4 *Giardia*: A Protist without Mitochondria

Current evidence indicates that *Giardia* is descended from an ancestor that possessed mitochondria.

"Archaezoa": The little kingdom that was

The hypothesis that the eukaryotic nucleus evolved before the mitochondrion gained early support from the existence of a few unicellular eukaryotes, such as *Giardia*, that lack mitochondria. *Giardia lamblia* is a familiar parasite that contaminates water supplies and causes the intestinal disease giardiasis (Figure 27.4). This tiny organism has no mitochondria, chloroplasts, or other membrane-enclosed organelles, but it contains two nuclei bounded by nuclear envelopes, and it has a cytoskeleton. Some biologists treated such eukaryotes without mitochondria as the modern descendants of a hypothetical ancient group, which they called "archaezoans." It was later learned that at least some archaezoans may have descended from eukaryotes that lost their mitochondria. Research sometimes takes surprising twists and turns! We no longer speak of a kingdom of archaezoans. However, the existence of such organisms today shows that eukaryotic life is feasible without mitochondria, and the eukaryotes that lack mitochondria are the focus of much attention.

Many uncertainties remain

Several uncertainties cloud our current understanding of the origins of eukaryotic cells. Lateral gene transfer complicates the study of eukaryotic origins just as it complicates the study of relationships among the prokaryote lineages. At the same time, it may not have been extensive enough to account for the fact that, as genetic studies advance, more and more genes of bacterial origin are being found in eukaryotes.

An endosymbiotic origin of mitochondria and chloroplasts accounts for the presence of bacterial genes encoding enzymes for energy metabolism (respiration and photosynthesis), but it does not explain the presence of many other bacterial genes. The eukaryotic genome clearly is a mixture of genes with two distinct origins. A recent suggestion is that the Eukarya might have arisen from the mutualistic fusion (not endosymbiosis) of a Gram-negative bacterium and an archaean. There are many interesting ideas about eukaryotic origins awaiting additional data and analysis.

480 CHAPTER TWENTY-SEVEN

We can expect that these and other questions will yield to additional research. Let's leave our speculations about the origin of the protists for the moment and examine what we do know about them.

General Biology of the Protists

Most protists are aquatic. Some live in marine environments, others in fresh water, and still others in the body fluids of other organisms. The slime molds inhabit damp soil and the moist, decaying bark of rotting trees. Many other protists also live in soil water, some of them contributing to the global nitrogen cycle by preying on soil bacteria and recycling their nitrogen compounds to nitrates.

Protists are strikingly diverse in their structure, but not so diverse in their metabolism as the prokaryotes—in fact, some of the eukaryotes' most important metabolic pathways were "borrowed" from bacteria through endosymbiosis. However, protists do display a number of nutritional modes. Some are autotrophs, some are heterotrophs, and some switch with ease between the autotrophic and heterotrophic modes of nutrition.

Some protists, formerly classified as animals, are sometimes referred to as protozoans, although biologists increasingly regard this term as inappropriate because it lumps together protist groups that are phylogenetically distant from one another. Most protozoans are ingestive heterotrophs. There are several kinds of photosynthetic protists that some biologists still refer to as algae (singular alga). Although these two terms—protozoans and algae—are useful in some contexts, they do not correspond with natural phy-

Contractile vacuole

Canals take up water from the cytoplasm.

Water moves from canals to the vacuole.

//\ Empty vacuole

The pore opens and the vacuole contracts. Contraction of the vacuole expels water from the cell.

27.5 Contractile Vacuoles Ball Out Excess Water

Water constantly enters freshwater protists by osmosis. A pore in the cell surface allows the contractile vacuole to expel the water it accumulates.

EXPERIMENT

Question: Where—and how—does *Paramecium* digest its food? METHOD Yeast cells are stained with Congo red, a pH indicator.

RESULTS

Stained yeast cells

f

A food vacuole forms around yeast cells.

The change in color shows that the vacuole has become acidic, like your stomach; acid helps digest the yeast cells.

Digestion continues.

Waste material is expelled.

As products of digestion move into the cytosol, the pH increases in the vacuole. The dye becomes red again.

Conclusion: Digestion, assisted by low pH, took place in the food vacuole.

27.6 Food Vacuoles Handle Digestion and Excretion

An experiment with *Paramecium* demonstrates the function of food vacuoles. *Paramecium* ingests food by way of the oral groove at the left. The dye Congo red turns green at acidic pH and red at neutral or basic pH.

logeny, and we generally avoid them in this book except as parts of descriptive names such as "brown algae."

Protists have diverse means of locomotion

Although a few protist groups consist entirely of nonmotile organisms, most groups include cells that move, either by amoeboid motion, by ciliary action, or by means of flagella. In amoeboid motion, the cell forms pseudopods ("false feet") that

are extensions of its constantly changing body mass. Cells such as the amoeba on page 476 simply extend a pseudopod and then flow into it. Cilia are tiny, hairlike organelles that beat in a coordinated fashion to move the cell forward or backward (see Figure 4.24). A eukaryotic flagellum moves like a whip; some flagella push the cell forward, others pull the cell forward.

Vesicles perform a variety of functions

Unicellular organisms tend to be of microscopic size. As we noted above, an important reason that cells are small is that they need enough membrane surface area in relation to their volume to support the exchange of materials required for their existence. Many relatively large unicellular protists minimize this problem by having membrane-enclosed vesicles of various types that increase their effective surface area. As we saw in Chapter 5, organisms living in fresh water are hypertonic to their environments. Many freshwater pro-

tists address this problem by means of vesicles that contract to excrete excess water. Members of several protist groups have such contractile vacuoles. Because these organisms have a higher concentration of solutes than their freshwater environment does, they constantly take in water by osmosis. The excess water collects in the contractile vacuole and is then pushed out (Figure 27.5).

It is easy to confirm that bailing out water is the principal function of the contractile vacuole. First, we can observe some protists under a light microscope and note the rate at which the vacuoles are contracting—they look like little eyes winking. Then we can place other protists of the same species in solutions of differing osmotic potential. The less negative the osmotic potential of the surrounding solution, the more hypertonic the cells are, and the faster water rushes into them, causing the contractile vacuoles to pump more rapidly. Conversely, the contractile vacuoles will stop pumping if the solute concentration of the medium is increased so that it is equal to that of the cells.

A second important type of vesicle found in many protists is the food vacuole. Protists such as Paramecium engulf solid food by endocytosis, forming a food vacuole within which the food is digested (Figure 27.6). Smaller vesicles containing digested food pinch away from the food vesicle and enter the cytoplasm. These tiny vesicles provide a large surface area across which the products of digestion may be absorbed by the rest of the cell.

The cell surfaces of protists are diverse

A few protists, such as some amoebas, are surrounded by only a plasma membrane, but most have stiffer surfaces that maintain the structural integrity of the cell. Many protists have cell walls, which are often complex in structure. Other protists that lack cell walls have a variety of ways of strengthening their surfaces. Some have internal "shells," which the organism either produces itself, as foraminiferans do, or makes from bits of sand and thickenings imme-

27.7 Diversity among Protist Cell Surfaces

(a) Foraminiferan shells are made of protein hardened with calcium carbonate. Several species are shown in this photograph.

(b) This amoeba constructed its shell by cementing sand grains together, (c) Spirals of protein make this Paramecium's surface—known as its pellicle—flexible but resilient.

diately beneath the plasma membrane, as some amoebas do (Figure 27.7).

Many protists contain endosymbionts

Endosymbiosis is very common among the protists, and in some instances both the host and the endosymbiont are protists. Many radiolarians, for example, harbor photosynthetic protists (Figure 27.8). As a result, these radiolarians appear greenish or yellowish, depending on the type of endosymbiont they contain. This arrangement is beneficial to the radiolarian, for it can make use of the food produced by its photosynthetic guest. The guest, in turn, may make use of metabolites made by the host, or it may simply receive physical protection. In other cases, the guest may be a victim, exploited for its photosynthetic products while receiving no benefit itself.

27.8 Protists within Protists

Photosynthetic organisms living as endosymbionts within these radiolarians provide food for the radiolarians, as well as part of the pigmentation seen through their glassy skeletons. Both the endosymbionts and the radiolarians are protists.

27.9 Major Protist Groups in an Evolutionary Context

All of these groups except certain green algae appear to be monophyletic lineages. The protists themselves do not constitute a monophyletic lineage. We also show the prokaryotic domains and the plant, fungal, and animal kingdoms to provide context.

"GREEN ALGAE" AND PLANTS

CHOANOFAGELLATA, FUNGI, AND ANIMALS

Other green algae

Both asexual and sexual reproduction occur among the protists

Although most protists practice both asexual and sexual reproduction, some groups lack sexual reproduction. As we will see, some asexually reproducing protists also engage in genetic recombination, even though it does not directly result in reproduction.

Asexual reproductive processes in the protists include binary fission (simple splitting of the cell, with mitosis followed by cytokinesis), multiple fission (splitting into more than two cells), budding (the outgrowth of a new cell from the surface of an

old one), and the formation of spores (cells that are capable of developing into new organisms). Sexual reproduction also takes various forms. In some protists, as in animals, the gametes are the only haploid cells. In some other protists, by contrast, both diploid and haploid cells undergo mitosis, giving rise to alternation of generations, which will be described later in the chapter.

Choanoflagellates

The diversity of form, habitat, metabolism, locomotion, reproduction, and life cycles found among the protists reflects the diversity of avenues pursued during the early evolution of eukaryotes. Many of these avenues led to great success, judging from the abundance and diversity of today's protists and other eukaryotes.

Protist Diversity

As we have seen, the phylogeny of protists is an area of exciting, challenging research. The marvelous diversity of protist body forms and metabolic lifestyles seems reason enough for a fascination with these organisms, but questions about how the multicellular eukaryotic kingdoms originated from the protists stimulate further interest. Fortunately, the tools of molecular biology, such as rRNA sequencing, make it possible to explore evolutionary relationships among the protists in greater detail and with somewhat greater confidence than previously (see Chapters 24 and 26).

We will discuss several apparently monophyletic groups of protists, as well as a few other groups of more uncertain phylogenetic status. Some biologists refer to many of these monophyletic groups as kingdoms; others refer to them as subkingdoms; still others refer to them as phyla. This choice of words is not of immediate concern to us here, so we'll just call them "groups." We'll describe the Euglenozoa, Alveolata, Stramenopila, Rhodophyta, Chlorophyta, and Choanoflagellida (Figure 27.9).

As we shall see, some of the monophyletic protist groups consist of organisms with very diverse body plans. On the other

hand, certain body plans, such as those of amoebas and those of slime molds, have arisen again and again during evolution, in groups only distantly related to one another.

Euglenozoa

The Euglenozoa are a monophyletic group of flagellates: unicellular organisms with flagella. They reproduce asexually by binary fission. There are two subgroups of Euglenozoa: euglenoids and kinetoplastids.

Euglenoids have anterior flagella

The euglenoids possess flagella arising from a pocket at the anterior end of the cell. Euglenoids used to be claimed by the zoologists as animals and by the botanists as plants. They are unicellular flagellates, but many members of the group are photosynthetic.

Figure 27.10 depicts a cell of the genus *Euglena*. Like most other euglenoids, this common freshwater organism has a complex cell structure. It propels itself through the water with one of its two flagella, which may also serve as an anchor to hold the organism in place. The flagellum provides power by means of a wavy motion that spreads from base to tip. The second flagellum is often rudimentary.

Euglena has very flexible nutritional requirements. Many species are always heterotrophic. Other species are fully autotrophic in sunlight, using chloroplasts to synthe-

size organic compounds through photosynthesis. The chloroplasts of euglenas are surrounded by three membranes (unlike plant chloroplasts, which have only two). When kept in the dark, these euglenas lose their photosynthetic pigment and begin to feed exclusively on dead organic material floating in the water around them. Such a "bleached" *Euglena* resynthesizes its photosynthetic pigment when it is returned to the light and becomes autotrophic again. But *Euglena* cells treated with certain antibiotics or mutagens lose their photosynthetic pigment completely; neither they nor their descendants are ever autotrophs again. However, those descendants function well as heterotrophs.

Kinetoplastids have mitochondria that edit their own RNA

The kinetoplastids are unicellular, parasitic flagellates with a single, large mitochondrion. That mitochondrion contains a kinetoplast — a unique structure housing DNA and associated proteins. The kinetoplast DNA is of two types, called minicircles and maxicircles. The maxicircles encode enzymes associated with oxidative metabolism, and the mini-circles encode "guides" that accomplish a remarkable type of RNA editing within the mitochondrion.

Some kinetoplastids are human pathogens. Sleeping sickness, one of the most dreaded diseases of Africa, is caused by the parasitic kinetoplastid *Trypanosoma* (Figure 27.11). The vector (intermediate host) for *Trypanosoma* is an insect, the tsetse fly. Carrying its deadly cargo, the tsetse fly bites livestock, wild animals, and even humans, infecting them with the parasite. *Trypanosoma* then multiplies in the mammalian bloodstream and produces toxins. When these parasites invade the nervous

system, the neurological symptoms of sleeping sickness appear and are followed by death. Other trypanosomes cause leishmaniasis, Chagas' disease, and East Coast fever; all are major diseases in the tropics.

484 CHAPTER TWENTY-SEVEN

Undulating membrane of trypanosome

Trypanosoma gambiense

25 (irn

27.11 A Parasitic Kinetoplastid

Trypanosomes, shown here among human red blood cells, cause sleeping sickness in mammals. A flagellum runs along one edge of the cell as part of a structure called the undulating membrane.

Alveolata

The Alveolata are a monophyletic group of unicellular organisms characterized by the possession of cavities called alveoli just below their plasma membranes. They are diverse in body form. The alveolate groups we'll consider here are the dinoflagellates, apicomplexans, and ciliates.

Dinoflagellates are unicellular marine organisms with two flagella

The dinoflagellates are all unicellular, and most are marine organisms. A distinctive mixture of photo-synthetic and accessory pigments gives their chloroplasts a golden-brown color. The dinoflagellates are of great ecological, evolutionary, and morphological interest. They are among the most important primary photosynthetic producers of organic matter in the oceans.

Many dinoflagellates are endosymbionts, living within the cells of other organisms, including various invertebrates and even other marine protists. Dinoflagellates are particularly common endosymbionts in corals, to whose growth they contribute by photosynthesis. Some dinoflagellates are nonphotosynthetic and live as parasites within other marine organisms.

Dinoflagellates have a distinctive appearance (see Figure 17.1a). They have two flagella, one in an equatorial groove around the cell, the other starting at the same point as the first and passing down a longitudinal groove before extending into the surrounding medium.

Euglenozoa

Stramenopila

Rhodophyta

Chlorophyta

Some dinoflagellates reproduce in enormous numbers in warm and somewhat stagnant waters. The result can be a "red tide," so called because of the reddish color of the sea that results from pigments in the dinoflagellates (Figure 27.12). During a red tide, the concentration of dinoflagellates may reach 60 million cells per liter of ocean water. Certain red tide species produce a potent nerve toxin that can kill tons of fish. The genus *Gonyaulax* produces a toxin that can accumulate in shellfish in amounts that, although not fatal to the shellfish, may kill a person who eats the shellfish.

Many dinoflagellates are bioluminescent. In complete darkness, cultures of these organisms emit a faint glow. If you suddenly stir or bubble air through the culture, the organisms each emit numerous bright flashes. A ship passing through a tropical ocean that contains a rich growth of these species produces a bow wave and wake that glow eerily as billions of these dinoflagellates discharge their light systems.

Apicomplexans are parasites with unusual spores

Exclusively parasitic organisms, the apicomplexans derive their name from the apical complex, a mass of organelles contained within the apical end of their spores. These organelles help the apicomplexan spore invade its host tissue. Unlike many other protists, apicomplexans lack contractile vacuoles.

Apicomplexans generally have an amorphous body form like that of an amoeba. This body form has evolved over and over again in parasitic protists. It appears even among parasitic dinoflagellates, a group of organisms whose nonparasitic relatives

have highly distinctive, complex body forms.

Like many obligate parasites, apicomplexans have elaborate life cycles featuring asexual and sexual reproduction

27.12 A Red Tide of Dinoflagellates

By reproducing in astronomical numbers, the dinoflagellate *Gonyaulax tamarensis* can cause a toxic red tide.

EVENTS IN MOSQUITO

EVENTS IN HUMAN

After a mosquito ingests blood, male and female gametocytes develop into gametes which fuse.

Sporozoites penetrate liver cells and develop into merozoites.

The resulting zygote, the only diploid stage in the life cycle, enters the mosquito's gut wall and forms a cyst.

Within the cyst, the zygote gives rise to sporozoites...

Merozoites can reinfect the liver, producing new generations.

A feeding mosquito ingests the gametocytes and the cycle begins again.

They also invade red blood cells, grow and divide, and lyse the cells.

Eventually, some merozoites develop into male and female gametocytes.

27.13 The Life Cycle of an Apicomplexan

Malaria-causing *Plasmodium* species spend part of their life cycle in humans and part in mosquitoes. Sporozoites and merozoites are spores with apical complexes.

by a series of very dissimilar life stages. Often these stages are associated with two different types of host organism.

The best-known apicomplexans are the malarial parasites of the genus *Plasmodium*, a highly specialized group of organisms

that spend part of the life cycle within human red blood cells (Figure 27.13). Although it has been almost eliminated from the United States, malaria continues to be a major problem in many tropical countries. In terms of the number of people infected, malaria is one of the world's most serious diseases.

Female mosquitoes of the genus *Anopheles* transmit *Plasmodium* to humans. The parasite enters the human circulatory system when an infected *Anopheles* mosquito penetrates the human skin in search of blood. The parasites find their way to cells in the liver and the lymphatic system, change their form, multiply, and reenter the bloodstream, attacking red blood cells. The apical complex enables *Plasmodium* to enter human liver cells and red blood cells.

The parasites multiply inside red blood cells, which then burst, releasing new swarms of parasites. If another *Anopheles* bites the victim, the mosquito takes in some of the parasitic *Plasmodium* cells along with blood. The infecting cells develop into gametes, which unite to form zygotes that lodge in the mosquito's gut, divide several times, and

Q 48-hour cycles of invasion, lysis, and reinvasion cause the characteristic fevers and chills of the host victim.

move into its salivary glands, from which they can be passed on to another human host. Thus, *Plasmodium* is an extracellular parasite in the mosquito vector and an intracellular parasite in the human host.

Malaria kills more than a million people each year, and *Plasmodium* has proved to be a singularly difficult pathogen to attack. The *Plasmodium* life cycle is best broken by the removal of stagnant water, in which mosquitoes breed. The use of insecticides to reduce the *Anopheles* population can be effective, but their benefits must be weighed against the possible ecological, economic, and health risks posed by the insecticides themselves. However, there is now new hope in the form of a genome-sequencing project that targets the common form of *Plasmodium*. Scheduled to be completed by the year 2002, this project may provide the information needed to end the epidemic.

Ciliates have two types of nuclei

The ciliates are so named because they characteristically have hairlike cilia. This group is noteworthy for its diversity and ecological importance (Figure 27.14). Almost all ciliates are heterotrophic (a few contain photosynthetic endosymbionts), and they are much more specialized in body form than are most flagellates and other protists.

The definitive characteristic of ciliates is the possession of two types of nuclei, from one to as many as a thousand large macronuclei and, within the same cell, from one to eighty micronuclei. The micronuclei, which are typical eukaryotic nuclei, are essential for genetic recombination. The

macronuclei are derived from micronuclei. Each macronucleus contains many copies of the genetic information, packaged in units containing very few genes each; the macronuclear DNA is transcribed and translated to regulate the life of the cell. Although we do not know how this system of macro- and micronuclei came into being, we do know something about the behavior of these nuclei, which we will discuss after describing the body plan of one important ciliate, Paramecium.

A closer look at one ciliate. Paramecium, a frequently studied ciliate genus, exemplifies the complex structure and behavior of ciliates (Figure 27.15 a). The slipper-shaped cell is covered by an elaborate pellicle, a structure composed principally of an outer membrane and an inner layer of closely packed, membrane-enclosed sacs (the alveoli) that surround the bases of the cilia. Defensive organelles called trichocysts are also present in the pellicle. In response to a threat, a microscopic explosion expels the trichocysts in a few milliseconds, and they emerge as sharp darts, driven forward at the tip of a long, expanding filament (Figure 27.15b).

The cilia provide a form of locomotion that is generally more precise than locomotion by flagella or pseudopods. A

Figure 27.15 Anatomy of Paramecium

(a) The major structures of a typical Paramecium, (b) A trichocyst discharged from beneath the pellicle of a Paramecium has a sharp point and a straight filament.

Paramecium can direct the beat of its cilia to propel itself either forward or backward in a spiraling manner (Figure 27.16). It can also back off swiftly when it encounters a barrier or a negative stimulus. The coordination of ciliary beating is probably the result of a differential distribution of ion channels in the plasma membrane near the two ends of the cell.

REPRODUCTION WITHOUT SEX, AND SEX WITHOUT REPRODUCTION.

Paramecia reproduce asexually by binary fission. The micro-

nuclei divide mitotically. The macronuclei divide by a still unknown mechanism following a round of DNA replication.

Paramecia also have an elaborate sexual behavior called conjugation. Two paramecia line up tightly against each other and fuse in the oral region of the body. Nuclear material is extensively reorganized and exchanged over the next several hours (Figure 27.17). As a result of this process, each cell ends up with two haploid micronuclei, one from itself and one from the other cell, which fuse to form a new diploid micronucleus. New macronuclei develop from the micronuclei through a series of dramatic chromosomal rearrangements. The exchange of nuclei is fully reciprocal—each of the two paramecia gives and receives an equal amount of DNA. The two organisms then separate and go their own ways, each equipped with new combinations of alleles.

Conjugation in Paramecium is a sexual process of genetic recombination, but it is not a reproductive process. The same two cells that begin the process are there at the end, and no new cells are created. As a rule, each clone of paramecia must periodically conjugate. Experiments have shown that if some species are not permitted to conjugate, the asexual

clones can live through no more than approximately 350 cell divisions before they die out.

Stramenopila

The stramenopiles include three prominent groups, two of which are photosynthetic. The two flagella of a stramenopile cell are typically unequal in length. The longer of the two bears rows of tubular hairs. Some stramenopiles lack flagella, but they are presumed to be descended from ancestors that possessed typical stramenopile flagella. The stramenopiles include the diatoms and the brown algae, which are photosynthetic, and the oomycetes, which are not. Other, smaller stramenopile groups include some that are nonphotosynthetic. Some botanists prefer to call the stramenopiles the "brown plant kingdom."

Diatoms are everywhere in the marine environment

Diatoms (Bacillar Eugknozoa

iophyta) are single-celled organisms, although some species associate in filaments. Many have sufficient carotenoids in their chloroplasts to give them a yellow or brownish color. All make chrysolaminarin (a carbohydrate) and oils as photosynthetic storage products. They lack flagella.

Architectural magnificence on a microscopic scale is the hallmark of the diatoms (Figure 27.18a). Many diatoms deposit silicon in their cell walls. The cell wall of some species

is constructed in two pieces, with the wall of the top overlapping the wall of the bottom like the top and bottom of a petri plate. The silicon-impregnated walls have intricate, unique patterns (Figure 27.18b). Despite their remarkable morphological diversity, however, all diatoms are symmetrical—either bilaterally (with "right" and "left" halves) or radially (with the type of symmetry possessed by a circle).

Diatoms reproduce both sexually and asexually. Asexual reproduction is by cell division and is somewhat constrained by the stiff, silica-containing cell wall. Both the top and the bottom of the "petri plate" become tops of new "plates" without changing

appreciably in size; as a result, the new cells made from former bottoms are smaller than the parent cells (Figure 27.19). If this process continued indefinitely, one cell line would simply vanish, but sexual reproduction largely solves this potential problem. Gametes are formed, shed their cell walls, and fuse. The resulting zygote then increases substantially in size before a new cell wall is laid down.

Diatoms are everywhere in the marine environment and are frequently present in great numbers, making them major photosynthetic producers in coastal waters. Diatoms are also common in fresh water. Because the silicon-containing walls of dead diatom cells resist de-

composition, certain sedimentary rocks are composed al-

■t entirely of diatom skeletons that sank to the seafloor

over time. Diatomaceous earth, which is obtained from

such rocks, has many industrial uses, such as insulation, filtration, and metal polishing. It has also been used as an "Earth-friendly" insecticide that clogs the tracheae (breathing structures) of insects.

The brown algae include the largest protists

All the brown algae (Phaeophyta) are multicellular and composed either of branched filaments (Figure 27.20) or of leaflike growths called thalli (singular thallus) (Figure 27.21f). The brown algae obtain their namesake color from the carotenoid fucoxanthin, which is abundant in their chloro-

fj In asexual reproduction, the two parts of the cell wall separate, each becoming the top of a new "plate."

plasts. The combination of this yellow-orange pigment with the green of chlorophylls a and c yields a brownish tinge.

The brown algae include the largest of the protists. Giant kelps, such as those of the genus *Macrocystis*, may be up to 60 meters long (see Figure 27.1c). The brown algae are almost exclusively marine. Some float in the open ocean; the most famous example is the genus *Sargassum*, which forms dense mats of vegetation in the Sargasso Sea in the mid-Atlantic. Most brown algae, however, are attached to rocks near the shore. A few thrive only where they are regularly exposed to heavy surf; a notable example is the sea palm *Postelsia palmaeformis* of the Pacific coast (Figure 27.21a). All

PROTISTS AND THE DAWN OF THE EUKARYA 489

of the attached forms develop a specialized structure, called a holdfast, that literally glues them to the rocks (Figure 27.21b).

Some brown algae differentiate extensively into stemlike stalks and leaflike blades, and some develop gas-filled cavities or bladders. For biochemical reasons that are only poorly understood, these gas cavities often contain as much as 5 percent carbon monoxide—a concentration high enough to kill a human. In addition to organ differentiation, the larger brown algae also exhibit considerable tissue differentiation. Most of the giant kelps have photosynthetic filaments only in the outermost regions of their stalks and blades. Within the photosynthetic region lie filaments of long cells that closely resemble the food-conducting tissue of plants. Called trumpet cells because they have flaring ends, these tubes rapidly conduct the products of photosynthesis through the body of the organism.

The cell walls of brown algae may contain as much as 25 percent alginic acid, a gummy polymer of sugar acids. Alginic acid cements cells and filaments together and provides good holdfast glue. It is used commercially as an emulsifier in ice cream, cosmetics, and other products.

Many protist and all plant life cycles feature alternation of generations

Brown algae, like many photosynthetic protists and all plants, exhibit a type of life cycle known as alternation of generations, in which a multicellular, diploid, spore-producing organism gives rise to a multicellular, haploid, gamete-producing organism. When two gametes fuse (a process called syngamy), a diploid organism is formed (Figure 27.22). The haploid organism, the diploid organism, or both may also reproduce asexually.

490 CHAPTER TWENTY-SEVEN

Q Spores germinate and divide by mitosis to make a multicellular haploid organism.

27.22 Alternation of Generations

In many multicellular photosynthetic protists and all plants, a diploid generation that produces spores alternates with a haploid generation that produces gametes.

The two generations (spore-producing and gamete-producing) differ genetically (one has haploid cells and the other has diploid cells), but they may or may not differ morphologically. In heteromorphic alternation of generations, the two generations differ morphologically; in isomorphic alternation of generations they do not, despite their genetic difference. We will see examples of both heteromorphic and isomorphic alternation of generations in some representative brown and green algae. In discussing the life cycles of plants and multicellular photosynthetic protists, we will use the terms sporophyte ("spore plant") and gametophyte ("gamete plant") to refer to the multicellular diploid and haploid generations, respectively.

Gametes are not produced by meiosis because the gamete-producing generation is already haploid. Instead, specialized cells of the diploid sporophyte, called sporocytes, divide meiotically to produce four haploid spores. The spores may eventually germinate and divide mitotically to produce multicellular haploid gametophytes, which produce gametes by mitosis and cytokinesis.

Gametes, unlike spores, can produce new organisms only by fusing with other gametes. The fusion of two gametes produces a diploid zygote, which then undergoes mitotic divisions to produce a diploid organism: the sporophyte generation. The sporocytes of the sporophyte generation then undergo meiosis and produce haploid spores, starting the cycle anew.

The brown algae exemplify the extraordinary diversity found among the photosynthetic protists. One genus of simple brown algae is *Ectocarpus* (see Figure 27.20b). Its branched filaments, a few centimeters long, commonly grow on shells and stones. The gametophyte and spore-generations of *Ectocarpus* can be distinguished only by chromosome number or reproductive products (spores or gametes). Thus the generations are isomorphic.

U MAI

Q Gametes (n) are T produced by ^^^ mitosis of — * :::: ^ "1 haploid cells.

Gametes fuse to form a zygote.

The zygote develops into a multicellular i diploid organism.

By contrast, some kelps of the genus *Laminaria* and some other brown algae show a more complex heteromorphic alternation of generations. The larger and more obvious generation of these species is the sporophyte. Meiosis in special fertile regions of the leaflike fronds produces haploid zoospores—motile spores that are propelled by flagella. These germinate to form a tiny, filamentous gametophyte that produces either eggs or sperm. The eggs and sperm of brown algae typically have flagella.

The oomycetes include water molds and their relatives

A nonphotosynthetic stramenopile group called oomycetes consists in large part of the water molds and their terrestrial relatives, such as the downy mildews. Water molds are filamentous and stationary, and they feed by absorption. If you have seen a whitish, cottony mold growing on dead fish or dead insects in water, it was probably a water mold of the common genus *Saprolegnia* (Figure 27.23).

The oomycetes are coenocytes: They have many nuclei enclosed in a single plasma membrane. Their filaments have no cross-walls to separate the many nuclei into discrete cells. Their cytoplasm is continuous throughout the body of the mold, and there is no single structural unit with a single nucleus, except in certain reproductive stages. A distinguishing feature of the oomycetes is their flagellated reproductive cells. Oomycetes are diploid throughout most of their life cycle and have cellulose in their cell walls.

The water molds, such as *Saprolegnia*, are all aquatic and saprobic (they feed on dead organic matter). Some other

Saprolegnia sp.

27.23 An Oomycete

The filaments of a water mold radiate from the carcass of an insect.

oomycetes are terrestrial. Although most terrestrial oomycetes are harmless or helpful decomposers of dead matter, a few are serious plant parasites that attack crops such as avocados, grapes, and potatoes. The mold *Plasmopara infestans*, for example, is the causal agent of late blight of potatoes, which brought about the great Irish potato famine of 1845-1847. *P. infestans* destroyed the entire Irish potato crop in a matter of days in 1846. Among the consequences of the famine were a million deaths from starvation and the emigration of about 2 million people, mostly to the United States.

Rhodophyta

Almost all red algae (Rhodophyta) are multicellular (Figure 27.24). Some botanists now refer to the red algae as the "red plant kingdom." Their characteristic color is a result of the photosynthetic pigment phycoerythrin, which is found in relatively large amounts in the chloroplasts of many species. In addition to phycoerythrin, red algae contain phycocyanin, carotenoids, and chlorophyll.

The red algae include species that grow in the shallowest tide pools, as well as the algae found deepest in the ocean (as deep as 260 meters if nutrient conditions are right and the water is clear enough to permit the penetration of light). Very few red algae inhabit fresh water. Most grow attached to a substrate by a holdfast.

In a sense the red algae, like several other groups of algae, are misnamed. They have the capacity to change the relative amounts of their various photosynthetic pigments depending on the light conditions where they are growing. Thus the leaflike *Chondrus crispus*, a common North Atlantic red alga, may appear bright green when it is growing at or near the surface of the water and deep red when growing at greater depths. The ratio of pigments present

Euglenozoa

Alveolata

Chlorophyta

depends to a remarkable degree on the intensity of the light that reaches the alga. In deep water, where the light is dimmest, the alga accumulates large amounts of phycoerythrin, an accessory photosynthetic pigment (see Figure 8.7). Algae in deep water have as much chlorophyll as the green ones near the surface, but the accumulated phycoerythrin makes them look red.

In addition to being the only photosynthetic protists with phycoerythrin and phycocyanin among their pigments, the red algae have two other unique characteristics: They store the products of photosynthesis in the form of floridean starch, which is composed of very small, branched chains of approximately 15 glucose units. And they produce no motile, flagellated cells at any stage in their life cycle. The male gametes lack cell walls and are slightly amoeboid; the female gametes are completely immobile.

Some red algal species enhance the formation of coral reefs. Like the coral animals, they possess the biochemical machinery for depositing calcium carbonate both in and around their cell walls. After the death of the corals and algae, the calcium carbonate persists, sometimes forming substantial rocky masses.

Some red algae produce large amounts of mucilaginous polysaccharide substances, which contain the sugar galactose with a sulfate group attached. This material readily forms solid gels and is the source of agar, a substance widely used in the

laboratory for making a solid aqueous medium on which tissue cultures and many microorganisms can be grown.

Certain red algae became endosymbionts, long ago, within the cells of other, nonphotosynthetic protists, eventually giving rise to chloroplasts. This was the evolutionary origin of the distinctive chloroplasts of the photosynthetic stramenopiles (the brown algae and the diatoms).

492 CHAPTER TWENTY-SEVEN

Chlorophyta

The "green algae" do not form a monophyletic group, but include at least two lineages. One major lineage constitutes the Chlorophyta, a monophyletic group. A sister lineage to the Chlorophyta consists of other green algal lineages and the plant kingdom. The green algal lineages share characters that distinguish them from other protists: Like the plants, they contain chlorophylls a and b, and their reserve of photosynthetic products is stored as starch in plastids. There are more than 17,000 species of chlorophytes. Most chlorophytes are aquatic—some are marine, but more are freshwater forms—but others are terrestrial, living in moist environments. The chlorophytes range in size from microscopic unicellular forms to multicellular forms many centimeters in length.

Chlorophytes vary in shape and cellular organization

We find in the Chlorophyta an incredible variety in shape and construction of the algal body. *Chlorella* is an example of the simplest type: unicellular and flagellated.

Surprisingly large and well-formed colonies of cells are found in such freshwater groups as the genus *Volvox*. These cells are not differentiated into tissues and organs, as in

Parent Somatic (a) *Volvox* sp. colony cells

Alveolata

Stramenopila

Rhodophyta

Specialized reproductive cells produce and release daughter colonies.

(c) *Micrasterias* sp.

wm

plants and animals, Euglenozoa

but the colonies show vividly how the preliminary step of this great evolutionary development might have been taken. In *Volvox*, the origins of cell specialization can be seen as certain cells within the colony (Figure 27.25a) are specialized for reproduction.

While *Volvox* is colonial and spherical, *Oedogonium* is multicellular and filamentous, and each of its cells has only one nucleus. *Cladophora* is multicellular, but each cell is multinucleate. *Bryopsis* is tubular and coenocytic, forming cross-walls only when reproductive structures form. *Acetabularia* is a single, giant uninucleate cell a few centimeters long that becomes multinucleate only at the end of the reproductive stage. *Ulva lactuca* is a membranous sheet two cells thick; its unusual appearance justifies its common name: sea lettuce (Figure 27.25b).

Chlorophyte life cycles are diverse

The life cycles of chlorophytes show great diversity. Let's examine two chlorophyte life cycles in detail, beginning with that of the sea lettuce *Ulva lactuca* (Figure 27.26). The diploid sporophyte of this common seashore organism is a thin cellular sheet a few centimeters in diameter. Some of its cells (sporocytes) differentiate and undergo meiosis and cytokinesis, producing motile haploid spores (zoospores). These swim away, each propelled by four flagella, and some eventually find a suitable place to settle. The spores then lose their fla-

flagella, undergo mitosis, and produce a new gametophyte directly; in other words, the gametes can also function as zoospores. Few chlorophytes other than *Ulva* have motile gametes that can also function as zoospores.

In contrast to the isomorphic life cycle of *Ulva*, many other chlorophytes have a heteromorphic life cycle: Sporophyte and gametophyte generations differ in structure. In one variation of the heteromorphic life cycle—the haplontic life cycle (Figure 27.27)—a multicellular haploid individual produces gametes that fuse to form a zygote. The zygote functions directly as a sporophyte, undergoing meiosis to produce spores, which in turn produce a new haploid individual. In the entire haplontic life cycle, only one cell—the zygote—is diploid. The filamentous organisms of the genus *Ulothrix* are examples of haplontic chlorophytes.

Other chlorophytes have a diplontic life cycle like that of many animals. In a diplontic life cycle, meiosis of sporocytes

rn

27.26 An Isomorphic Life Cycle

The life cycle of *Ulva lactuca* is an example of isomorphic alternation of generations.

gella and begin to divide mitotically, producing a thin filament that develops into a broad sheet only two cells thick. The gametophyte thus produced looks just like the sporophyte—in other words, *Ulva* has an isomorphic life cycle.

An individual gametophyte can produce only male or female gametes—never both. The gametes arise mitotically within single cells (called gametangia), rather than within a specialized multicellular structure, as in plants. Both types of gametes bear two flagella (in contrast to the four flagella of a haploid spore) and hence are motile.

In most species of *Ulva* the female and male gametes are indistinguishable structurally, making those species isogamous — having gametes of identical appearance. Other chlorophytes, including some other species of *Ulva*, are anisogamous — having female gametes that are distinctly larger than the male gametes.

Female and male gametes come together and unite, losing their flagella as the zygote forms and settles. After resting briefly, the zygote begins mitotic division, producing a multicellular sporophyte. Any gametes that fail to find partners can settle

down on a favorable substrate, lose their

27.27 A Haplontic Life Cycle

In the life cycle of *Ulothrix*, a filamentous, multicellular gametophyte generation alternates with a sporophyte generation consisting of a single cell.

Some cells of a haploid filament divide mitotically to form gametes. Gametes fuse in pairs to form zygotes. Only the zygote is diploid.

494 CHAPTER TWENTY-SEVEN

produces gametes directly; the gametes fuse, and the resulting zygote divides mitotically to form a new multicellular sporophyte. In such organisms, every cell except the gametes is diploid. Between these two extremes are chloro-phytes whose gametophyte and sporophyte generations are both multicellular, but that have one phase (usually the sporophyte) that is much larger and more prominent than the other.

There are green algae other than chlorophytes

As we mentioned above, the Chlorophyta are the largest lineage of green algae, but there are other green algal lineages as well. Those lineages are branches of a lineage that also includes the plant kingdom. The green algal lineage that is sister to the plant kingdom, a group of organisms called charophytes, will be described in the next chapter. But now let's consider a close protist relative of the animals.

Choanoflagellida

One group of protists with flagella, the Choanoflagellida, is thought to comprise the closest relatives of the animals. Members of this group are colonial (Figure 27.28) and are thought to be closely related to the sponges, the most ancient of the surviving phyla of animals. Sponges are also colonial rather than truly multicellular, in that they lack organized tissues and their cells can be separated and recom-bined. Choanoflagellates bear a striking resemblance to the most characteristic type of cell found in the sponges (compare Figures 27.28 and 31.4).

Individual choanoflagellates form colonies that are attached to a single stalk.

Flagellum

27.28 A Link to the Animal Kingdom

This colonial choanoflagellate may be a close relative of the sponges and thus a link between protists and the kingdom Animalia. The connection of unicellular organisms into colonies often leads to the evolution of specialized cells and true multicellularity; another example of a colonial protist was seen earlier in Volvox (Figure 27.25a).

A History of Endosymbiosis

As we have already seen, many protists possess chloroplasts. Groups with chloroplasts appear in several distantly related protist lineages. Some of these groups differ from others in the photosynthetic pigments their chloroplasts contain. And we've seen that not all chloroplasts have a pair of surrounding membranes—in some protists, they

rn ^ 27.29 A Chloroplast Family Tree

One or two primary endosymbioses followed by secondary and tertiary endosymbioses gave rise to all of today's chloroplasts.

have three membranes. We now understand these observations in terms of a remarkable series of endosymbioses.

All chloroplasts trace back to the engulfment of an ancestral cyanobacterium by a larger eukaryotic cell (Figure 27.29). This event constituted primary endosymbiosis. The cyanobacterium had a single membrane—its plasma membrane—and that membrane was surrounded by part of the eukaryote's plasma membrane that wrapped around the bacterium as it was taken up. Thus, the original chloroplasts had two surrounding membranes.

Primary endosymbiosis gave rise to the chloroplasts of the green algae and the red algae. We do not yet know whether both trace back to a single primary endosymbiosis, with later divergence, or whether they resulted from independent occurrences of primary endosymbiosis. In either case, each line participated in further endosymbioses.

The photosynthetic euglenoids derived their chloroplasts from secondary endosymbiosis. Their ancestor took up a unicellular chlorophyte, retaining the endosymbiont's chloroplast and eventually losing the rest of its constituents. This history

accounts for the fact that the photosynthetic euglenoids have the same photosynthetic pigments as the chloro-phytes and plants. It also accounts for the third membrane of the euglenoid chloroplast, which is derived from the eu-glenoid's plasma membrane.

Other photosynthetic protist groups Common derived their chloroplasts by endosym- ancestor biosis with unicellular red algae. Both the green lineage and the red lineage of chloroplasts appear to have given rise to more than one secondary endosymbiosis. At least one secondary endosymbiosis produced a unicellular protist that became, itself, a partner in a tertiary endosymbiosis!

Although euglenoid chloroplasts are descendants of a chlorophyte, and stramenopile chloroplasts are descendants of a red alga, this does not mean that euglenoids themselves are descendants of a chlorophyte, nor are stramenopiles themselves descendants of a red alga. The ancestors that took up green or red algae in secondary endosymbiosis had their own evolutionary histories. It has taken much research to piece together the lineages as we now understand them.

The monophyletic groups of protists that we have discussed are summarized in Table 27.1 and Figure 27.9. Now let's consider two major types of protist body forms—amoebas and other organisms with pseudopods, and slime molds—that are not monophyletic. Rather, they have reappeared in various branches of the eukaryote family tree.

Some Recurrent Body Forms

Amoebas used to be classified together in a single protist group. However, the amoeba body plan has popped up again and again in the course of the evolution of the Eukarya (Figure 27.30). Similarly, three kinds of organisms called slime molds, once classified together, may be quite different phylogenetically

Amoebas form pseudopods

The pseudopods used by amoebas for locomotion are a hallmark of these protists. This body plan has appeared by convergent evolution in various protist groups. The mechanism of amoeboid motion will be discussed in Chapter 47.

Amoebas have often been portrayed in popular writing as blobs—the simplest form of "animal" life imaginable. Superficial examination of a typical amoeba shows how such an impression might have been obtained. An amoeba consists of a single cell. It feeds on small organisms and particles of organic matter by phagocytosis, engulfing them with its pseudopods.

But amoebas are specialized protists. Many are adapted for life on the bottoms of lakes, ponds, and other bodies of water. Their creeping locomotion and their manner of engulfing food particles fit them for life close to a relatively rich supply of sedentary organisms or organic particles. Most amoebas exist as predators, parasites, or scavengers. A few are photosynthetic.

Amoebas of the free-living genus *Naegleria*, some of which can enter humans and cause a fatal disease of the nervous system, have a two-stage life cycle, one stage having amoeboid cells and the other flagellated cells. Some

27.30 Amoebias and Slime Molds

There are several unrelated monophyletic groups of amoebas and slime molds. Body forms featuring amoeboid pseudopods have evolved repeatedly, as have slime molds.

Choano-flagellida

496 CHAPTER TWENTY-SEVEN

amoebas are shelled, living in casings of sand grains glued together (see Figure 27.7b) or in shells secreted by the organism itself.

Actinopods have thin, stiff pseudopods

The actinopods are recognizable by their thin, stiff pseudo-pods, which are reinforced by microtubules. The pseudopods play at least four roles:

- ▶ They greatly increase the surface area of the cell for exchange of materials with the environment.
- ▶ They help the cell float in its marine or freshwater environment.
- ▶ They provide locomotion in some species.
- ▶ They are the cell's feeding organs, trapping smaller organisms and often taking them up by endocytosis.

Radiolarians, actinopods that are exclusively marine, are perhaps the most beautiful of all microorganisms (Figure 27.31a). Almost all radiolarian species secrete glassy endoskeletons (internal skeletons) from which needlelike pseudopods project. Part of the skeleton is a central capsule within the cytoplasm. The skeletons of the different species are as varied as snowflakes, and many have elaborate geometric designs. A few radiolarians are among the largest of the unicellular protists, with skeletons measuring several millimeters across. Innumerable radiolarian skeletons, some as old as 700 million years, form the sediments under some tropical seas.

Heliozoans lack an endoskeleton (Figure 27.31b). Most heliozoans live in fresh water. They roll along the substrate by shortening and elongating their pseudopods.

Foraminiferans have created vast limestone deposits

Foraminiferans are marine protists that secrete shells of calcium carbonate (see Figure 27.7a). Some foraminiferans live as plankton (free-floating microscopic organisms), and many others live at the bottom of the sea. Their long, threadlike, branched pseudopods reach out through numerous microscopic pores in the shell and interconnect to create a sticky net, which the foraminiferan uses to catch smaller plankton.

After foraminiferans reproduce (by mitosis and cytokinesis), the daughter cells abandon the parent shell and make new shells of their own. The discarded skeletons of ancient foraminiferans make up extensive limestone deposits in various parts of the world, forming a layer hundreds to thousands of meters deep over millions of square kilometers of ocean bottom. Foraminiferan skeletons also make up the sand of some beaches. A single gram of such sand may contain as many as 50,000 foraminiferan shells.

The shells of individual foraminiferan species have distinctive shapes and are easily preserved as fossils in marine sediments. Each geological period has distinctive foraminiferan species. For this reason, and because they are so abundant, the remains of foraminiferans are especially valuable as indicators in the classification and dating of sedimentary rocks, as well as in oil prospecting.

Slime molds release spores from erect fruiting bodies

The three groups of slime molds seem so similar at first glance that they were once grouped in a single phylum. However, the slime molds are actually so different that some biologists now classify them in different kingdoms. We will consider two of these groups, called acellular slime molds and cellular slime molds.

The slime molds share only general characteristics. All are motile, all ingest particulate food by endocytosis, and all form spores on erect fruiting bodies. They undergo striking changes in organization during their life cycles, and one stage consists of isolated cells that engage in absorptive nutrition. Some slime molds may cover areas of 1 meter or more in diameter while in their less aggregated stage. Such a large slime mold may weigh more than 50 grams. Slime molds of both types favor cool, moist habitats, primarily in forests. They range from colorless to brilliantly yellow and orange.

ACELLULAR SLIME MOLDS FORM MULTINUCLEATE MASSES. If the

nucleus of an amoeba began rapid mitotic division, accompanied by a tremendous increase in cytoplasm and organelles, the resulting organism might resemble the acel-

ular slime molds (Myxomycota). During its vegetative (feeding) phase, an acellular slime mold is a wall-less mass of cytoplasm with numerous diploid nuclei. This mass streams very slowly over its substrate in a remarkable network of

strands called a plasmodium* (Figure 27.32a). The Plasmodium of an acellular slime mold is an example of a coenocyte, a body in which many nuclei are enclosed in a single plasma membrane. The outer cytoplasm of the plasmodium (closest to the environment) is normally less fluid than the interior cytoplasm and thus provides some structural rigidity.

Acellular slime molds such as *Physarum* (a popular research subject) provide a dramatic example of movement by cytoplasmic streaming. The outer cytoplasmic region becomes more fluid in places, and cytoplasm rushes into those areas, stretching the plasmodium. This streaming somehow reverses its direction every few minutes as cytoplasm rushes into a new area and drains away from an older one, moving the plasmodium over its substrate in search of food. Sometimes an entire wave of plasmodium moves across the substrate, leaving strands behind. Actin filaments and a contractile protein called myxomyosin interact to produce the streaming movement. As it moves, the plasmodium engulfs food particles—predominantly bacteria, yeasts, spores of fungi, and other small organisms, as well as decaying animal and plant remains.

An acellular slime mold can grow almost indefinitely in its plasmodial stage, as long as the food supply is adequate and other conditions, such as moisture and pH, are favorable. However, one of two things can happen if conditions become unfavorable. First, the plasmodium can form an irregular mass of hardened cell-like components called a sclerotium. This resting structure rapidly becomes a plasmodium again when favorable conditions are restored.

Alternatively, the plasmodium can transform itself into

*Do not confuse the plasmodium of an acellular slime mold with the genus *Plasmodium*, the apicomplexan that is the cause of malaria.

spore-bearing fruiting structures (Figure 27.32b). These stalked or branched structures, called sporangiophores, rise from heaped masses of plasmodium. They derive their rigidity from walls that form and thicken between their nuclei. The nuclei of the plasmodium are diploid, and they divide by meiosis as the sporangiophore develops. One or more knobs, called sporangia, develop on the end of the stalk. Within a sporangium, haploid nuclei become surrounded by walls and form spores. Eventually, as the sporangiophore dries, it sheds its spores.

The spores germinate into wall-less, flagellated, haploid cells called swarm cells, which can either divide mitotically to produce more haploid swarm cells or function as gametes. Swarm cells can live as separate individual cells, and can become walled and resistant resting cysts when conditions are unfavorable. When conditions improve again, the cysts release flagellated swarm cells. Two swarm cells can also fuse to form a diploid zygote, which divides by mitosis (but without a wall forming between the nuclei) and thus forms a new, coenocytic plasmodium.

CELLS RETAIN THEIR IDENTITY IN THE CELLULAR SLIME MOLDS.

Whereas the plasmodium is the basic vegetative unit of the acellular slime molds, an amoeboid cell is the vegetative unit of the cellular slime molds. Large numbers of cells called myxamoebas, which have single haploid nuclei, engulf bacteria and other food particles by endocytosis and reproduce by mitosis and fission. This simple life cycle stage, consisting of swarms of independent, isolated cells, can persist indefinitely as long as food and moisture are available.

When conditions become unfavorable, however, the cellular slime molds aggregate and form fruiting structures, as do their acellular counterparts. The apparently independent myxamoebas aggregate into a mass called a slug or pseudoplasmodium (Figure 27.33a). Unlike the true plasmodium of the acellular slime molds (see Figure 27.32rt), this structure is not simply a giant sheet of cytoplasm with many nuclei; the individual myxamoebas retain their plasma membranes and, therefore, their identity.

The chemical signal that causes the myxamoebas of cellular slime molds to aggregate into a slug is 3',5'-cyclic adenosine monophosphate (cAMP), a compound that plays many important roles in chemical signaling in animals (see Chapter 15). A slug may migrate over its substrate for several hours before becoming motionless and reorganizing to construct a delicate, stalked fruiting structure (Figure 27.33b). Cells at the top of the fruiting structure develop into thick-walled spores, which

are eventually released. Later, under favorable conditions, the spores germinate, releasing myxamoebas.

The cycle from myxamoebas through slug and spores to new myxamoebas is asexual. Cellular slime molds also have a sexual cycle, in which two myxamoebas fuse. The product of this fusion develops into a spherical structure that ultimately germinates, releasing new haploid myxamoebas.

In the remaining chapters of Part Four, we will explore the three classic kingdoms of multicellular eukaryotes. Chapters 28 and 29 deal with the kingdom Plantae (which, combined with the Chlorophyta and other green algae, is called by some botanists the "green plant kingdom"). Chapter 30 presents the kingdom Fungi, and Chapters 31-33 describe the kingdom Animalia. These kingdoms all arose from protist ancestors.

Chapter Summary

Protists Defined

► In this book we define the protists simply as all eukaryotes that are not plants, fungi, or animals. The protists are not a monophyletic group.

The Origin of the Eukaryotic Cell

► The modern eukaryotic cell arose from an ancestral prokaryote in several steps. Probable steps included loss of the cell wall and inward folding of the plasma membrane. Review Figure 27.2

► In subsequent steps, an infolded plasma membrane attached to the chromosome may have led to the formation of a nuclear envelope. A primitive cytoskeleton evolved. Review Figure 27.3

► The first truly eukaryotic cell was larger than its prokaryote ancestor, and it may have possessed one or more flagella of the eukaryotic type.

► The incorporation of prokaryotic cells as endosymbionts gave rise to eukaryotic organelles. Peroxisomes, which protected the host cell from an oxygen-rich atmosphere, may have been the first organelles of endosymbiotic origin. Mitochondria evolved from once free-living proteobacteria, and chloroplasts evolved from once free-living cyanobacteria. Cells with nuclei probably appeared before the first cells with mitochondria. Review Figure 27.3

General Biology of the Protists

► Most protists are aquatic; some live within other organisms. The great majority are unicellular and microscopic, but many are multicellular and a few are enormous.

► "Protozoan" is an outdated term sometimes applied to protists, mostly ingestive heterotrophs, that were once classified as animals. "Alga" is an outdated term sometimes applied to photosynthetic protists.

► Protists vary widely in their modes of nutrition, metabolism, and locomotion. Some protist cells contain contractile vacuoles, and some digest their food in food vacuoles. Review Figures 27.5, 27.6

► Protists have a variety of cell surfaces, some of them protective. Review Figure 27.7

► Many protists contain endosymbiotic prokaryotes. Some protists are endosymbionts in other cells, including other protists. Some endosymbiotic protists perform photosynthesis, to the advantage of their hosts.

► Most protists reproduce both asexually and sexually.

Protist Diversity

► Molecular and other techniques are enabling biologists to identify many monophyletic groups of protists. Review Figure 27.9 and Table 27.1

Euglenozoa

► The Euglenozoa are a monophyletic group of unicellular protists with flagella.

► Euglenoids are Euglenozoa, such as *Euglena*, that are often photosynthetic and have anterior flagella.

► Kinetoplastids are Euglenozoa, such as *Trypanosoma*, that have a single, large mitochondrion, in which RNA is edited.

Alveolata

► The Alveolata are a monophyletic group of unicellular organisms with alveoli (cavities) beneath their plasma membranes.

► Dinoflagellates are marine alveolates with a golden-brown color that results from their photosynthetic and accessory

PROTISTS AND THE DAWN OF THE EUKARYA 499

pigments. They are major contributors to world photosynthesis. Many are endosymbionts; in that role they are important contributors to coral reef growth. Dinoflagellates are responsible for toxic "red tides."

► Apicomplexans are parasitic alveolates with an amoebalike body form. Their spores, containing a mass of organelles at the apical end, are adapted to the invasion of host tissue. The apicomplexan *Plasmodium*, which causes malaria, uses two alternate hosts (humans and *Anopheles* mosquitoes). Review Figure 27.13

► Ciliates are alveolates such as *Paramecium* that move rapidly by means of cilia and have two kinds of nuclei. The macronuclei control the cell by means of transcription and translation. The micronuclei are responsible for genetic recombination, accomplished by conjugation, which is sexual but not reproductive. Some ciliates have a remarkably complex internal structure. Review Figures 27.15, 27.16, 27.17

Stramenopila

► Stramenopiles typically have two flagella of unequal length, the longer bearing rows of tubular hairs. Some stramenopile groups are photosynthetic.

► Diatoms are unicellular stramenopiles, many of which have complex, two-part, glassy cell walls. They contribute extensively to world photosynthesis. Review Figure 27.19

► The brown algae are predominantly multicellular, photo-synthetic stramenopiles. They include the largest of all protists, and some show considerable tissue differentiation.

► In many multicellular photosynthetic protists and in all plants, both haploid and diploid cells undergo mitosis, leading to an alternation of generations. The diploid sporophyte generation forms spores by meiosis, and the spores develop into haploid organisms. This haploid gametophyte generation forms gametes by mitosis, and their fusion yields zygotes that develop into the next generation of sporophytes. Review Figure 27.22

► Oomycetes are a group of nonphotosynthetic stramenopiles including water molds and downy mildews. The oomycetes are coenocytic. They are diploid for most of their life cycle.

Rhodophyta

► Red algae (Rhodophyta) are multicellular, photosynthetic protists. They differ from the other photosynthetic protist groups in having a characteristic storage product (floridean starch) and lacking flagellated reproductive cells.

Chlorophyta

► The Chlorophyta, a monophyletic group of green algae, are often multicellular. Like plants, they contain chlorophylls a and b and use starch as a storage product. The chlorophytes have diverse life cycles; among these are the isomorphic alternation of generations of *Ulva* and the haplontic life cycle of *Ulothrix*. Review Figures 27.26, 27.27

► The chlorophytes are sister to a lineage that includes other green algae and the plant kingdom.

Choanoflagellida

► The Choanoflagellida are protists with flagella and a body type similar to the most characteristic type of cell found in sponges. The Choanoflagellida are sister to the animal kingdom.

A History of Endosymbiosis

* ■ Primary endosymbiosis of a cyanobacterium and a eukaryote gave rise to the chloroplasts of green algae, plants, and red algae. Review Figure 27.29

► Secondary endosymbiosis of eukaryotes with unicellular green or red algae gave rise to the chloroplasts of euglenoids, stramenopiles, and other groups. A cell of one of those groups, in tertiary endosymbiosis, has given rise to another type of chloroplast.

Some Recurrent Body Forms

► Some similar body forms are found in several different, unrelated protist groups. Review Figure 27.30

► Amoebas, which appear in many protist groups, move by means of pseudopods.

► Actinopods have thin, stiff pseudopods that serve various functions, including food capture.

► Foraminiferans also use pseudopods for feeding, and secrete shells of calcium carbonate.

► Acellular slime molds and cellular slime molds are superficially very similar, moving as slimy masses and producing stalked fruiting structures. However, they differ at the cellular level. Acellular slime molds are coenocytes with diploid nuclei. Cellular slime molds consist of individual haploid cells that aggregate into masses consisting of distinct cells.

For Discussion

1. For each type of organism below, give a single characteristic that may be used to differentiate it from the other, related organism(s) in parentheses.

a. foraminiferans (radiolarians)

- b. Euglena (Volvox)
 - c. Trypanosoma (Giardia)
 - d. Amoeba (flagellate)
 - e. Physarum (Dictyostelium)
2. For each of the following groups, give at least two characteristics used to distinguish the group from other groups.
 - a. Ciliophora
 - b. Apicomplexa
 - c. Phaeophyta
 - d. Rhodophyta
 3. In what sense are sex and reproduction independent of each other in the ciliates? What does that suggest as to the most important role of sex in biology?
 4. Why are dinoflagellates and apicomplexans placed in one group of protists and brown algae and oomycetes in another?
 5. Giant seaweed (mostly brown algae) have "floats" that aid in keeping their fronds suspended at or near the surface of the water. Why is it important that the fronds be suspended?
 6. Why are algal pigments so much more diverse than those of plants?
 7. For each of the groups Chlorophyta, Euglenozoa, and Rhodophyta, indicate how many membranes surround their chloroplasts, and offer a reasonable explanation in each case. Why do some dinoflagellates have more membranes around their chloroplasts than other dinoflagellates?

Plants without Seeds: From Sea to Land

HOW DO WE RUN OUR ENGINES, HEAT OUR homes, smelt our metals, and generate much of our electricity? We do these things by burning plant-based fuels. The great majority of such fuels—petroleum and natural gas, the so-called fossil fuels—comes from the remains of plants without seeds that grew in great forests hundreds of millions of years ago.

In some parts of the world, people derive the majority of their fuel from peat bogs. They harvest and burn peat, another substance produced largely by a nonseed plant.

Peat consists of partially decomposed plant material. It forms as rapidly growing upper layers of moss, primarily the genus *Sphagnum*, along with some other plants, compress the deeper-lying layers. Peatlands cover an area approximately half as large as the United States—more than 1 percent of Earth's total surface.

Sphagnum is one of the most abundant plants on Earth, yet it and its mossy neighbors at first glance seem to lack adaptations to life on land. Mosses have no internal "plumbing system" to move water and nutrients within their bodies, and their leafy photosynthetic organs are only one cell thick. They require liquid water in order to reproduce, and indeed seem at first glance to be highly dependent on external moisture. They can dry out to the point of becoming brittle, yet they snap back as soon as a bit of water is available. How do they manage to survive on land?

That mosses and their relatives do have effective adaptations for life in terrestrial environments is obvious from their wide distribution. Most live in moist habitats, but a few mosses even live in deserts.

Earth did not take on a green tint until about half a billion years ago, long after the ancestors of today's plants invaded the land sometime during the Paleozoic era (see Table 20.1). The earliest land plants were tiny, but their metabolic activities helped convert native rock into soil that could support the needs of their successors. Larger and larger plants evolved rapidly (in geological terms),

and during the Carboniferous period (354 to 290 million years ago) great forests were widespread. However, few of the trees in those forests were like those we know today. During the tens of millions of years since the Carboniferous, these early trees have been replaced by the modern trees whose adaptations and appearance are familiar to us. In this chapter, we will see how members of the plant kingdom conquered the land and evolved. We will see what made early plants different and made Plantae a unique kingdom, and will survey the diverse products of plant evolution. In the next chapter we will complete our survey of the plant kingdom by considering the seed plants, which dominate the terrestrial scene today.

The Plant Kingdom

As we use the term, a plant is a photosynthetic eukaryote that uses chlorophylls a and b, stores carbohydrates, usually as starch, and develops from an embryo protected by tissues of the parent plant. Most plants have, or had and then lost in the course of evolution, two whiplash flagella at the anterior end of their motile cells. Thus defined, the kingdom Plantae is monophyletic—it forms a single branch of the evolutionary tree. Because of their development from embryos, plants are sometimes referred to as emhryophytes.

r _ • <■

Fuel from Plants

Peat, formed from layers of plant matter including moss of the genus Sphagnum, is the major source of fuel for residents of the Falkland Islands off the coast of Argentina.

Flowering plants Endosperm; carpels; much reduced gametophytes; seeds in fruit

"No extinct groups are included in this classification.

Some botanists refer to a group consisting of the Plantae plus the green algae as the "green plant kingdom," to the Stramenopila as the "brown plant kingdom," and the Rhodophyta as the "red plant kingdom" (see Figure 27.29).

There are twelve surviving phyla of plants

The surviving members of the kingdom Plantae fall naturally into twelve phyla (Table 28.1). All members of nine of the phyla possess well-developed vascular systems that transport materials throughout the plant body. We call these nine phyla, collectively, the tracheophytes because they all possess conducting cells called tracheids.

The remaining three phyla (liverworts, hornworts, and mosses), which lack tracheids, were once considered classes of a single larger phylum, of which the most familiar examples are mosses. Now we use the term nontracheophytes to refer collectively to these three phyla. The nontracheophytes are sometimes collectively called bryophytes, but in this text we reserve that term for the mosses. Collectively, the nontracheophytes are not a monophyletic group.

Life cycles of plants feature alternation of generations

A universal feature of the life cycles of plants is the alternation of generations (see Figure 9.13b). If we begin looking at the plant life cycle at the single-cell stage—the diploid zygote—then the first phase of the cycle features the formation, by mitosis and cytokinesis, of a multicellular embryo and eventually the mature diploid plant (see Figure 27.22).

This multicellular, diploid plant is the sporophyte ("spore plant"). Cells contained in sporangia (singular sporangium, "spore reservoir") on the sporophyte undergo meiosis to produce haploid, unicellular spores. By mitosis and cytokinesis a spore forms a haploid plant. This multicellular, haploid plant is the gametophyte ("gamete plant") and produces haploid gametes. The fusion of two gametes (syngamy, or fertilization) results in the formation of a diploid cell, the zygote, and the cycle repeats.

The sporophyte generation extends from the zygote through the adult, multicellular, diploid plant; the gametophyte generation extends from the spore through the adult, multicellular, haploid plant to the gamete. The transitions between the phases are accomplished by fertilization and meiosis. In all plants, the sporophyte and gametophyte differ genetically: The former has diploid cells, the latter haploid cells.

The Plantae arose from a green algal lineage

Much evidence indicates that the closest living relatives of the plants are a group of green algae called charophytes. The charophytes, along with some other green algae and the plants, are in a lineage that is sister to the Chlorophyta (see Figure 27.9), but we don't yet know which charophyte lineage is the true sister group to the plants. Stoneworts of the genus *Oiara* are charophytes that resemble plants in terms of their rRNA and DNA sequences, peroxisome contents, mechanics of mitosis and cytokinesis, and chloroplast structure (Figure 28.1f). On the other hand, strong evidence from morphology-based cladistic analysis suggests that the

502 CHAPTER TWENTY-EIGHT

(a) *Cham* sp. (stonewort)

28.1 The Closest Relatives of Land Plants

The plant kingdom probably evolved from a common ancestor shared with the charophytes, a green algal group, (a) Molecular evidence seems to favor stoneworts of the genus *Chara*. (b) Evidence from morphology indicates that the group including this coleochaete alga may be the ancestor of land plants.

(b) *Coleochaete* sp.

sister group of the plants is a group of charophytes that includes the genus *Coleochaete* (Figure 28.1b). *Coleochaete*-like algae have features found in plants, such as plasmodesmata and a tendency to protect the young sporophyte.

Whether more similar to stoneworts or to *Coleochaete*, the ancestral green algae lived at the margins of ponds or marshes, ringing them with a green mat. From these margin habitats, which were sometimes wet and sometimes dry, early plants made the move onto land.

The Conquest of the Land

Plants or their immediate ancestors in the green mat pioneered and modified the terrestrial environment. That environment differs dramatically from the aquatic environment. The most obvious difference is the availability of the water that is essential for life: It is everywhere in the aquatic environment, but hard to find and to retain in the terrestrial environment. Water also provides aquatic organisms with support against gravity; a plant on land, however, must either have some other support system or sprawl unsupported on the ground. A land plant must also use different mechanisms for dispersing its gametes and progeny than its aquatic relatives use. How did terrestrial organisms arise from aquatic ancestors to thrive in such a challenging environment?

Adaptations to life on land distinguish plants from green algae

Most of the characteristics that distinguish plants from green algae are evolutionary adaptations to life on land (Figure 28.2). Many of the characteristics that proved adaptive to land plants probably evolved before the appearance of any of the plant groups we will discuss in this chapter. These characteristics include:

- ▶ The cuticle, a waxy covering that retards desiccation (drying).
- ▶ Gametangia, cases that enclose plant gametes and prevent them from drying. Eggs are housed in archegonia, sperm in antheridia.
- ▶ Embryos, which are young sporophytes contained within a protective structure.
- ▶ Certain pigments that afford protection against the mutagenic ultraviolet radiation that bathes the terrestrial environment.
- ▶ Thick spore walls that prevent desiccation and resist decay.

All these characteristics were probably shared by a plant ancestral to today's plants. Further adaptations to the terrestrial environment appeared as plant evolution continued. We will identify the most important ones in this and the next chapter. For now, let's look at one of the key later adaptations: the appearance of vascular tissues.

Most present-day plants have vascular tissue

The first plants were truly nonvascular, lacking both water-conducting and food-conducting cells. Although the term "nonvascular plants" is a time-honored name, it is misleading to apply it to the entire nontracheophyte lineage, because some mosses (unlike liverworts and hornworts) do have a limited amount of vascular-like tissue. Thus the more unwieldy name nontracheophyte is more descriptive. The first true tracheophytes—possessing specialized conducting cells called tracheids—arose later.

The nontracheophytes (the liverworts, hornworts, and mosses) have never been large plants. Except for some of the mosses, they have no water-transporting tissue, yet some are found in dry environments. Many grow in dense masses (see Figure 28.7a), through which water can move by capillary action. Nontracheophytes have leaflike structures that readily catch and hold any water that splashes onto them. These plants are small enough that minerals can be distributed internally by diffusion. They lack the leaves, stems, and roots that characterize tracheophytes, although they have structures analogous to each.

Familiar tracheophytes include the ferns, conifers, and flowering plants. Tracheophytes differ from liverworts, hornworts, and mosses in crucial ways, one of which is the possession of a well-developed vascular system consisting of specialized tissues for the transport of materials from one part of the plant to another. One such tissue, the phloem, conducts the products of photosynthesis from sites where they are produced or released to sites where they are used

28.2 From Green Algae to Plants

Green algae called charophytes are sister to the plants; green algae called chlorophytes are sister to the lineage that includes the charophytes and plants.

or stored. The other vascular tissue, the xylem, conducts water and minerals from the soil to aerial parts of the plant; because some of its cell walls are stiffened by a substance called lignin, xylem also provides support in the terrestrial environment.

Nontracheophyte plants evolved tens of millions of years before the earliest tracheophytes, even though tracheophytes appear earlier in the fossil record. The oldest tracheophyte fossils date back more than 410 million years, whereas the oldest nontracheophyte fossils are only about 350 million years old, dating from a time when tracheophytes were already widely distributed. This simply means that, given their different structures and the chemical makeup of their cell walls, tracheophytes are more likely to form fossils than nontracheophytes are.

We will examine the adaptations of the tracheophytes later in the chapter, concentrating first on the nontracheophytes.

The Nontracheophytes: Liverworts, Horn worts, and Mosses

Most liverworts, hornworts, and mosses grow in dense mats, usually in moist habitats (see Figure 28.7a). The

Club mosses

Horsetails

Whisk ferns

Ferns

largest of these plants are only about 1 meter tall, and most are only a few centimeters tall or long. Why have no large nontracheophytes ever evolved? The probable answer is that they lack an efficient system for conducting water and minerals from the soil to distant parts of the plant body. However, to limit water loss, layers of maternal tissue protect the embryos of all nontracheophytes. All nontracheophyte lineages also have a cuticle, although it is often very thin (or even absent in

some species) and thus not highly effective in retarding water loss.

Most nontracheophytes live on the soil or on other plants, but some grow on bare rock, dead and fallen tree trunks, and even on buildings. Nontracheophytes are widely distributed over six continents and exist very locally on the coast of the seventh (Antarctica). They are very successful plants, well-adapted to their environments. Most are terrestrial. Some live in wetlands. Although a few nontracheophyte species live in fresh water, these aquatic forms are descended from terrestrial ones. There are no marine nontracheophytes.

504 CHAPTER TWENTY-EIGHT

Fertilization in nontracheophytes requires water so that sperm can swim to eggs.

Gametophyte (/ /)

Protonema with bud

The "leafy" plant is the haploid gametophyte.

Germinating spore

The sporophyte is attached to and nutritionally dependent on the gametophyte.

Nontracheophyte sporophytes are dependent on gametophytes

In nontracheophytes, the conspicuous green structure visible to the naked eye is the gametophyte (Figure 28.3). In contrast, the familiar forms of tracheophytes such as ferns and seed plants are sporophytes. The gametophyte of nontracheophytes is photosynthetic and therefore nutritionally independent, whereas the sporophyte may or may not be photosynthetic but is always dependent on the gametophyte and remains permanently attached to it.

A sporophyte produces unicellular, haploid spores as products of meiosis. A spore germinates, giving rise to a multicellular, haploid gametophyte whose cells contain chloroplasts and are thus photosynthetic. Eventually gametes form within specialized sex organs, the gametangia. The archegonium is a multicellular, flask-shaped female sex organ with a long neck and a swollen base (Figure 28.4a). The base contains a single egg. The antheridium is a male sex organ in which sperm, each bearing two flagella, are produced in large numbers (Figure 28.4b).

Figure 28.3 A Nontracheophyte Life Cycle

The life cycle of nontracheophytes, illustrated here by a moss, is dependent on an external source of liquid water. The visible green structure of nontracheophytes is the gametophyte; in nontracheophyte plants, the "leafy" structures are sporophytes.

Once released, the sperm must swim or be splashed by raindrops to a nearby archegonium on the same or a neighboring plant. The sperm are aided in this task by chemical attractants released by the egg or the archegonium. Before sperm can enter the archegonium, certain cells in the neck of the archegonium must break down, leaving a water-filled canal through which the sperm swim to complete their journey. Note that all of these events require liquid water. On arrival at the egg, one of the sperm nuclei fuses with the egg nucleus to form the zygote. Mitotic divisions of the zygote produce a multicellular, diploid sporophyte embryo. The base of the archegonium grows to protect the embryo during its early growth. Eventually the developing sporophyte elongates sufficiently to break out of the archegonium, but it remains connected to the gametophyte by a "foot" that is embedded in the parent tissue and absorbs water and nutrients from it (see Figure 28.3). The sporophyte remains attached to the gametophyte throughout its life. The sporophyte produces a sporangium, or capsule, within which meiotic divisions produce spores and thus the next gametophyte generation.

The structure and pattern of elongation of the sporophyte differ among the three phyla of nontracheophytes— the liverworts (Hepatophyta), hornworts (Anthocero-phyta), and mosses (Bryophyta). The evolutionary relationships of the three phyla and the tracheophytes can be seen in Figure 28.2.

Liverworts are the most ancient surviving plant lineage

The gametophytes of some liverworts (phylum Hepatophyta) are green, leaflike layers that lie flat on the ground (Figure 28.5a). The simplest liverwort gametophytes, however, are flat plates of cells, a centimeter or so long, that produce antheridia or archegonia on their upper surfaces and water-absorbing filaments called rhizoids on the lower. Liverwort sporophytes are shorter than those of mosses and hornworts, rarely exceeding a few millimeters.

The sporophyte has a stalk that connects capsule and foot. The stalk elongates and thus raises the capsule above

(fl)

Archegonia develop at the tip of a gametophyte. In the archegonium the egg will be fertilized and begin development into a sporophyte.

The large egg cell in the center of the archegonium looks like an eye.

Antheridia are also located at the tip of a gametophyte.

These male organs (antheridia) contain a large number of sperm. When released, the sperm must locate an archegonium and swim down its neck to the egg.

PLANTS WITHOUT SEEDS: FROM SEA TO LAND 505

ground level, favoring dispersal of spores when they are released. The capsules of liverworts are simple: a globular capsule wall surrounding a mass of spores. In some species of liverworts, spores are not released by the sporophyte until the surrounding capsule wall rots.

In other liverworts, however, the spores are disseminated by structures called elaters located within the capsule. Elaters are long cells that have a helical thickening of the cell wall. As an elater loses water, the whole cell shrinks to a fraction of its former length, thus compressing the helical thickening like a spring. When the stress becomes sufficient, the compressed "spring" snaps back to its resting position, throwing spores in all directions.

Among the most familiar liverworts are species of the genus *Marchantia* (Figure 28.5a). *Marchantia* is easily recognized by the characteristic structures on which its male and female gametophytes bear their antheridia and archegonia (Figure 28.5b). Like most liverworts, *Marchantia* also reproduces vegetatively by simple fragmentation of the gametophyte. Along with sexual reproduction, *Marchantia* and some other liverworts and mosses also reproduce vegetatively by means of gemmae (singular gemma), which are lens-shaped clumps of cells. In a few liverworts the gemmae are loosely held in structures called gemma cups, which promote dispersal by raindrops (Figure 28.5c).

Hornworts evolved stomata as an adaptation to terrestrial life

The phylum Anthocerotophyta comprises the hornworts, so named because their sporophytes look like little horns (Figure 28.6). Hornworts appear at first glance to be liverworts with very simple gametophytes. These gametophytes consist of flat plates of cells, a few cells thick.

However, the hornworts, along with the mosses and tracheophytes, share an advance over the liverwort lineage in their adaptation to life on land. They have stomata — pores

Anthoceros dieteret

28.6 A Horn wort

The sporophytes of hornworts can resemble little horns.

that, when open, allow the uptake of CO_2 for photosynthesis and the release of O_2 , but that can close to prevent excessive water loss.

Hornworts have two characteristics that distinguish them from both liverworts and mosses. First, the cells of hornworts each contain a single large, platelike chloroplast, whereas the other nontracheophytes contain numerous small, lens-shaped chloroplasts. Second, of all the nontracheophyte sporophytes, those of the hornworts come closest to being capable of indefinite growth (without a set limit).

The stalk of either the liverwort or moss sporophyte stops growing as the capsule matures, so elongation of the sporophyte is strictly limited. In a hornwort such as *Anthoceros*, however, there is no stalk, but a basal region of the capsule remains capable of indefinite cell division, continuously producing new spore-bearing tissue above.

Sporophytes of some hornworts growing in mild and continuously moist conditions can become as tall as 20 centimeters. Eventually the sporophyte's growth is limited by the lack of a transport system. To support their growth, the hornworts need access to nitrogen. Hornworts have internal cavities filled with a mucilage; these cavities are often populated by cyanobacteria that fix atmospheric nitrogen gas into a nutrient form usable by the host plant.

We have presented the hornworts as sister to the lineage consisting of mosses and tracheophytes, but this is only one possible interpretation of the current data. The exact evolutionary status of the hornworts is still in doubt.

Water- and sugar-transport mechanisms emerged in the mosses

The most familiar nontracheophytes are the mosses (phylum Bryophyta). There are more species of mosses than of liverworts and hornworts combined, and these hardy little plants are found in almost every terrestrial environment. They often are found on damp, cool ground, where they form thick mats (Figure 28.7a). The mosses are sister to the tracheophytes (see Figure 28.2).

Many mosses contain a type of cell called a hydroid, which dies and leaves a tiny channel through which water may travel. The hydroid likely is a progenitor of the tracheid, the characteristic water-conducting cell of the tracheophytes, but it lacks lignin (a waterproofing substance) and the wall structure found in tracheids. The possession of hydroids and of a limited system for transport of sucrose by some mosses (via cells called leptoids) shows that the old term "nonvascular plant" is somewhat misleading when applied to mosses.

In contrast to liverworts and hornworts, the sporophytes of mosses and tracheophytes grow by apical cell division. A region at the growing tip provides an organized pattern of cell division, elongation, and differentiation. This allows extensive and sturdy vertical growth of sporophytes.

The moss gametophyte that develops following spore germination is a branched, filamentous structure, or protonema (see Figure 28.3). Although the protonema looks much like a filamentous green alga, it is unique to the mosses. Some of the filaments contain chloroplasts and are photosynthetic; others, called rhizoids, are nonphotosynthetic and anchor the protonema to the substrate. After a period of linear growth, cells close to the tips of the photosynthetic filaments divide

rapidly in three dimensions to form buds. The buds eventually differentiate a distinct tip, or apex, and produce the familiar leafy moss shoot with leaflike structures arranged spirally.

These leafy shoots produce antheridia or archegonia (see Figure 28.4). The antheridia release sperm that travel through liquid water to the archegonia, where they fertilize the eggs. Sporophyte development in most mosses follows a precise pattern, resulting ultimately in the formation of an absorptive foot, a stalk, and, at the tip, a swollen capsule. In contrast to hornworts, which grow from the base, the moss sporophyte stalk grows at its apical end, as tracheophytes do. Cells at the tip of the stalk divide, supporting elongation of the structure and giving rise to the capsule. For a while, archegonial tissue grows rapidly as the stalk elongates, but eventually the archegonium is outgrown and is torn apart by the expanding sporophyte.

The top of the capsule is shed after completing meiosis and spore development. Groups of cells just below the lid form a series of toothlike structures surrounding the opening. Highly responsive to humidity, these structures dig into the mass of spores when the atmosphere is dry; then, when the atmosphere becomes moist, they fling out, scooping out the spores as they go (Figure 28.7b). The spores are thus dispersed when the surrounding air is

28.7 The Mosses

(a) Dense moss forms hummocks in a valley on New Zealand's South Island, (b) The moss capsule, from which spores are dispersed, grows at the tip of the plant.

moist—that is, when conditions favor their subsequent germination.

Only a few mosses depart from this pattern of capsule development. A familiar exception is the genus *Sphagnum*, which we discussed at the beginning of this chapter. Species in this genus have a simple capsule with an air chamber in it. Air pressure builds up in this chamber, eventually causing the capsule lid to pop open, dispersing the spores with an audible explosion.

PLANTS WITHOUT SEEDS: FROM SEA TO LAND 507

With their simple system of internal transport, the mosses are in a sense vascular plants. However, they are not tracheophytes, because they lack true xylem and phloem.

Introducing the Tracheophytes

Although an extraordinarily large and diverse group, the tracheophytes can be said to have been launched by a single evolutionary event. Sometime during the Paleozoic era, probably well before the Silurian period (440 mya), the sporophyte generation of a now long-extinct organism produced a new cell type, the tracheid. The tracheid is the principal water-conducting element of the xylem in all tracheophytes except the angiosperms (flowering plants); and even in angiosperms the tracheid persists alongside a more specialized and efficient system of vessels and fibers derived from tracheids.

The evolutionary appearance of a tissue composed of tracheids had two important consequences. First, it provided a pathway for long-distance transport of water and mineral nutrients from a source of supply to regions of need. Second, it provided something almost completely lacking—and unnecessary—in the largely aquatic green algae: rigid structural support. Support is important in a terrestrial environment because plants tend to grow upward as they compete for sunlight to power

photosynthesis. Thus the tracheid set the stage for the complete and permanent invasion of land by plants.

The tracheophytes feature a further evolutionary novelty: a branching, independent sporophyte. A branching sporophyte can produce more spores than an unbranched body, and it can develop in complex ways. The sporophyte of a tracheophyte is nutritionally independent of the gametophyte.

The present-day evolutionary descendants of the early tracheophytes belong to nine distinct phyla (Figure 28.8). We can sort these phyla into two groups: those that produce seeds and those that do not. The nonseed tracheophytes include ferns, horsetails, club mosses, and whisk ferns. In the nonseed tracheophytes, the haploid and diploid generations are independent at maturity. The sporophyte is the large and obvious plant that one normally notices in nature (in contrast to the nontracheophyte sporophyte, which is attached to, dependent on, and usually much smaller than the gametophyte). Gametophytes of the nonseed tracheophytes are rarely more than 1 or 2 centimeters long and are shortlived, whereas their sporophytes are often highly visible; the sporophyte of a tree fern, for example, may be 15 or 20 meters tall and may live for many years.

The most prominent resting stage in the life cycle of a nonseed tracheophyte is the single-celled spore. This feature makes this life cycle similar to those of the fungi, the green algae, and the nontracheophytes but not, as we will see in the next chapter, to that of the seed plants. Nonseed tracheophytes must have an aqueous environment for at least one stage of their life cycle because fertilization is accomplished by a motile, flagellated sperm.

Seeds appear

28.8 The Evolution of Today's Plants

The nine phyla of existing tracheophytes are divided between those that produce seeds and those that do not.

Flowers, carpels and triploid endosperm appear

H

Y o -a

We now turn to a more detailed account of the evolution of the nonseed tracheophytes.

Tracheophytes have been evolving for almost half a billion years

The plant kingdom successfully invaded the terrestrial environment between 400 and 500 million years ago. The evolution of a water-impermeable cuticle and of protective layers for the gamete-bearing structures (archegonia and antheridia) helped make the invasion successful, as did the initial absence of herbivores (plant-eating animals).

By the late Silurian period, tracheophytes were being preserved as fossils that we can study today. Several remarkable developments arose during the Devonian period, 409 to 354 million years ago. Three groups of nonseed tracheophytes that still exist made their first appearances during that period: the lycopods (club mosses), horsetails, and ferns. Their proliferation made the terrestrial environment more hospitable to animals: Amphibians and insects arrived soon after the plants became established.

Trees of various kinds appeared in the Devonian period, and dominated the landscape of the Carboniferous. Mighty forests of lycopods up to 40 meters tall, horsetails, and tree ferns flourished in the tropical swamps of what would become North

America and Europe (Figure 28.9). In the subsequent Permian period the continents came ponderously together to form a single gigantic land mass, called Pan-gaea. The continental interior became warmer and drier, but late in the period glaciation was extensive. The 200-million-year reign of the lycopod-fern forests came to an

end as they were replaced by forests of seed plants (gym-nosperms) that ruled until other seed plants (angiosperms) became dominant less than 80 million years ago.

The earliest tracheophytes lacked roots and leaves

The first tracheophytes belonged to the now-extinct phylum Rhyniophyta. The rhyniophytes appear to have been the only tracheophytes in the Silurian period. The landscape at that time probably consisted of bare ground, with stands of rhyniophytes in low-lying moist areas. Early versions of the structural features of all the other tracheophyte phyla appeared in the rhyniophytes of that time. These shared features strengthen the case for the origin of all tracheophytes from a common nontracheophyte ancestor.

In 1917, the British paleobotanists Robert Kidston and William H. Lang reported well-preserved fossils of tracheophytes embedded in Devonian rocks near Rhynie, Scotland. The preservation of these plants was remarkable, considering that the rocks were more than 395 million years old. These fossil plants had a simple vascular system of phloem and xylem. Flattened scales on the stems of some of the plants lacked vascular tissue and thus were not comparable with the true leaves of any other tracheophytes.

These plants lacked roots. They were apparently anchored in the soil by horizontal portions of stem, called rhizomes, that bore water-absorbing rhizoids. These rhizomes also bore aerial branches, and sporangia—homologous with the nontracheophyte capsule—were found at

28.9 An Ancient Forest

A little more than 300 million years ago, a forest grew in a setting similar to tropical river delta habitats of today. Most of the plants depicted here were nonseed tracheophytes 10 to 20 m tall. Far in the distance, early seed plants—giants up to 40 m tall—towered over the forest. This artist's impression is based on evidence from fossils.

the tips of these branches. Branching was dichotomous; that is, the shoot apex divided to produce two equivalent new branches, each pair diverging at approximately the same angle from the original stem (Figure 28.10). Scattered fragments of such plants had been found earlier, but never in such profusion or so well preserved as those discovered near Rhynie by Kidston and Lang.

The presence of xylem indicated that these plants, named R_Jn/nia after the site of their discovery, were tracheophytes. But were they sporophytes or gametophytes? Close inspection of thin sections of fossil sporangia revealed that the spores were in groups of four. In almost all living nonseed tracheophytes (with no evidence to the contrary from fossil forms), the four products of a meiotic division and cytokinesis remain attached to one another during their development into spores. The spores separate only when they are mature, and even after separation their walls reveal the exact geometry of how they were attached. Therefore, a group of four closely packed spores is found only immediately after meiosis, and a plant that produces such a group of four must be a diploid sporophyte—and so the Rhynie fossils must have been sporophytes. The gametophytes of the Rhyniophyta also were branched, and depressions at the apices of the branches contained archegonia and antheridia.

Although apparently ancestral to the other tracheophyte phyla, the rhyniophytes themselves are long gone. None of their fossils appear anywhere after the Devonian period.

Dichotomous branching

Sporangia with spores in groups of four determined that fossil structure was sporophyte.

Rhizome

28.70 A Very Ancient Tracheophyte

This extinct plant in the genus *Rhynia* (phylum Rhyniophyta) lacked roots and leaves. The rhizome is a horizontal underground stem, not a root. The aerial shoots were less than 50 cm tall, and some were topped by sporangia.

510 CHAPTER TWENTY-EIGHT

Leaves

The ancestral form lacked roots but had an underground stem (the rhizome) with rhizoids.

A branch penetrated underground; shoot and root systems diverged.

28.11 Is This How Roots Evolved?

According to Lignier's hypothesis, branches from ancestral rootless plants could have penetrated the soil, where they gradually evolved into a root system.

Early tracheophytes added new features

Within a few tens of millions of years, during the Devonian period, three new phyla of tracheophytes—Lycophyta, Sphenophyta, and Pterophyta—appeared on the scene, arising from rhyniophyte-like ancestors. These new groups featured specializations not found in the rhyniophytes, including one or more of the following: true roots, true leaves, and a differentiation between two types of spores.

the origin of roots. Rhynia and its close relatives lacked true roots. They had only rhizoids arising from a rhizome (Figure 28.11, left) with which to gather water and minerals. How, then, did subsequent groups of tracheophytes come to have the complex roots we see today?

In 1903, a French botanist, E. A. O. Lignier, proposed an attractive hypothesis that is still widely accepted today. Lignier argued that the ancestors of the first tracheophytes grew by branching dichotomously. This explanation is supported by the dichotomous branching observed in the rhyniophytes. Lignier suggested that such a branch could bend, penetrate the soil, and branch there (Figure 28.11,

right). The underground portion could anchor the plant firmly, and even in this primitive condition it could absorb water and minerals. The subsequent discovery of fossil plants from the Devonian period, all having horizontal stems (rhizomes) with both underground and aerial branches, supported Lignier's hypothesis.

Underground and aboveground branches, growing in sharply different environments, were subjected to very different selection during the succeeding millions of years. Thus the two parts of the plant axis (the shoot and root systems) diverged in structure and evolved distinct internal and external anatomies. In spite of these differences, scientists believe that the root and shoot systems of tracheophytes are homologous—that they were once part of the same organ.

the origin of true leaves. Thus far we have used the term "leaf" rather loosely. We spoke of "leafy" mosses and commented on the absence of "true leaves" in rhyniophytes. In the strictest sense, a leaf is a flattened photosynthetic structure emerging laterally from a main axis or stem and possessing true vascular tissue. Using this precise definition as we take a closer look at true leaves in the tracheophytes, we see that there are two different types of leaves, very likely of different evolutionary origins.

The first type, the simple leaf, is usually small and only rarely has more than a single vascular strand, at least in plants alive today. Plants in the phylum Lycopphyta (club mosses), of which only a few genera survive, have such leaves. The evolutionary origin of simple leaves is thought by some biologists to be sterile sporangia (Figure 28.12fl). The principal characteristic of this type of leaf is that its vascular strand departs from the vascular system of the stem in such a way that the structure of the stem's vascular system is scarcely disturbed. This was true even in the fossil lycopod trees of the Carboniferous period, many of which had leaves many centimeters long.

28.12 The Evolution of Leaves

{a) Simple leaves are thought to have evolved from sterile sporangia. (5) The complex leaves of ferns and seed plants may have arisen as photosynthetic tissue developed between complex branching patterns.

Q ...becoming progressively reduced...

t

...and flattened.

Q Flat plates of photosynthetic tissue developed between small end branches.

T

The end branches evolved into the veins of leaves.

PLANTS WITHOUT SEEDS: FROM SEA TO LAND 51 1

The other type of leaf is encountered in ferns and seed plants. This larger, more complex leaf is thought to have arisen from the flattening of a dichotomously branching stem system, with the development of extensive photo-synthetic tissue between the branch members (Figure 28.12b). The complex leaf may have evolved several times, in different phyla of tracheophytes.

homospory and heterospory. In the most ancient of the present-day tracheophytes, both the gametophyte and the sporophyte are independent and usually photosynthetic. Spores produced by the sporophytes are of a single type, and they develop into a single type of gametophyte that bears both female and male reproductive organs. Such plants, which bear a single type of spore, are said to be homosporous (Figure 28.13fl). The sex organs on the game-tophytes of homosporous plants are of two types. The female organ is a multicellular archegonium, typically containing a single egg. The male organ is an antheridium, containing many sperm.

A different system, with two distinct types of spores, evolved somewhat later. Plants of this type are said to be heterosporous (Figure 28.13b). One type of spore, the megaspore, develops into a larger, specifically female gametophyte (megagametophyte) that produces only eggs. The other type, the microspore, develops into a smaller, male gametophyte (microgametophyte) that produces only sperm. The sporophyte produces mega-spores in small numbers in megasporangia on the sporophyte, and microspores in large numbers in microsporangia.

The most ancient tracheophytes were all homosporous. Heterospory evidently evolved independently several times in the early evolution of the tracheophytes descended from the rhyniophytes. The fact that heterospory evolved repeatedly suggests that it affords selective advantages. Subsequent evolution in the plant kingdom featured ever greater specialization of the heterosporous condition.

The Surviving Nonseed Tracheophytes

Today ferns are the most abundant and diverse phylum of nonseed tracheophytes, but club mosses and horsetails were once dominant elements of Earth's vegetation. A fourth phylum, the whisk ferns, contains only two genera. In this section we'll look at the characteristics of these four phyla and at some of the evolutionary advances that appeared in them.

The club mosses are sister to the other tracheophytes

The club mosses (lycopods, phylum Lycopphyta) diverged earlier than all other living tracheophytes—that is, the remaining tracheophytes share an ancestor that was not ancestral to the Lycopphyta. There are relatively few surviving species of club mosses. They have roots that branch dichoto-

Hornworts

Mosses

The sporangia in most club mosses are contained within conelike structures called strobili (singular strobilus; Figure 28.14) and are tucked in the upper angle between a specialized leaf and the stem. This placement contrasts with the terminal sporangia of the rhyniophytes (see Figure 28.10). There are both homosporous species and heterosporous species of club mosses. Like all the nonseed tracheophytes, they have a large, independent sporophyte and a small, independent gametophyte.

Although only a

minor element Liverworts

of present-day vegetation, the Lycophyta are one of two phyla that appear to have been the dominant vegetation during the Carboniferous period. One abundant type of coal (Cannel coal) is formed almost entirely from fossilized spores of a tree lycopod named Lepidodendron —which gives us an

idea of the abundance of this genus in the forests of that time. The other major element of the Carboniferous vegetation was the phylum Sphenophyta, the horsetails.

Horsetails grow at the bases of their segments

Like the club mosses, the horsetails (phylum Sphenophyta) are represented by only a few present-day species. They are sometimes called scouring rushes because silica deposits found in the cell walls made them useful for cleaning. They

Ferns

have true roots that branch irregularly, as do the roots of all tracheophytes except the club mosses. Their sporangia curve back toward the stem on the ends of short stalks (sporangiophores) (Figure 28.15a). Horsetails have a large sporophyte and a small gametophyte, both independent.

The leaves of horsetails are simple and form distinct whorls (circles) around the stem (Figure 28.15fr). Growth in horsetails originates to a large extent from discs of dividing cells just above each whorl of leaves, so each segment of the stem grows from its base. Such basal growth is uncommon in plants, although it is found in the grasses, a major group of flowering plants.

Present-day whisk ferns resemble the most ancient tracheophytes

There once was some disagreement about whether rhyniophytes are entirely extinct. The confusion arose because of the existence today of two genera of rootless, spore-bearing plants, Psilotum and Tmesipteris. Psilotum nudum (Figure 28.16) has only minute scales instead of true leaves, but plants of the genus Tmesipteris have flattened photosynthetic organs with

well-developed vascular tissue. Are these two genera the living relics of the rhyniophytes, or do they have more recent origins?

Psilotum and *Tmesipteris* once were thought to be evolutionary ancient descendants of anatomically simple ancestors. That hypothesis was weakened by an enormous hole in the geologic record between the rhyniophytes, which apparently became extinct more than 300 million years ago, and *Psilotum* and *Tmesipteris*, which are modern plants. DNA sequence data finally settled the question in favor

Psilotum malum

28.16 A Whisk Fern

Aerial branches of a whisk fern, a plant once considered by some to be a surviving rhyniophyte and by others to be a fern. It is now included in the phylum Psilotophyta, and is widespread in the tropics and subtropics.

of a more modern origin from fernlike ancestors. Most botanists now treat these two genera as their own phylum, the Psilotophyta (whisk ferns) rather than as relatives of the rhyniophytes.

We now consider the whisk ferns to be highly specialized plants that evolved fairly recently from anatomically more complex ancestors. Whisk fern gametophytes live below the surface of the ground and lack chlorophyll. They depend upon fungal partners for their nutrition.

Ferns evolved large, complex leaves

The sporophytes of the ferns and seed plants have roots, stems, and leaves. Their leaves are typically large and have branching vascular strands. Some species have small leaves as a result of evolutionary reduction, but even the small leaves have more than one vascular strand.

The true ferns constitute the phylum Pterophyta, which first appeared during the Devonian period and today consists of about 12,000 species. The Pterophyta are probably not a monophyletic group. Ferns are characterized by

Whisk ferns

PLANTS WITHOUT SEEDS: FROM SEA TO LAND 513

fronds (large leaves with complex vasculature; Figure 28.17f) and by a requirement for water for the transport of the male gametes to the female gametes. Most ferns inhabit shaded, moist woodlands and swamps. Tree ferns can reach heights of 20 meters. Tree ferns are not as rigid as woody plants, and they have poor root systems. Thus they do not grow in sites exposed directly to

strong winds but rather in ravines or beneath trees in forests. During its development, the fern frond unfurls from a tightly coiled "fiddlehead" (Figure 28.17b). Some fern leaves become climbing organs and may grow to be as much as 30 meters long. The sporangia are found on the undersurfaces of the leaves, sometimes covering the whole undersurface and sometimes only at the edges; in most species the sporangia are clustered in groups called sori (singular, sorus) (Figure 28.18).

The sporophyte generation dominates the fern life cycle

Inside the sporangia, fern cells undergo meiosis to form haploid spores. Once shed, spores travel great distances and eventually germinate to form independent gametophytes. Old World climbing fern, *Lygodium microphyllum*, is currently spreading disastrously through the Florida Everglades, choking off the growth of other plants. This rapid spread is testimony to the effectiveness of wind-borne spores.

28.17 Fern Fronds Take Many Forms

(a) Fronds of maidenhair fern form a pattern in this photograph. (b) The "fiddlehead" (developing frond) of a common

forest fern; this structure will unfurl and expand to give rise to a complex adult frond such as those in (a), (c) The tiny fronds of a water fern.

514 CHAPTER TWENTY-EIGHT

Dryopteris intermedia

28.18 Fern Sori Contain Sporangia

Sori, each with many spore-producing sporangia, form on the underside of a frond of the Midwestern fancy fern.

Fern gametophytes produce antheridia and archegonia, although not necessarily at the same time or on the same gametophyte. Sperm swim through water to archegonia, often on other gametophytes, where they unite with an egg.

The resulting zygote develops into a new sporophyte embryo. The young sporophyte sprouts a root and can thus grow independently of the gametophyte. In the alternating generations of a fern, the gametophyte is small, delicate, and short-lived, but the sporophytes can be very large and can sometimes survive for hundreds of years (Figure 28.19).

Most ferns are homosporous. However, two groups of aquatic ferns, the Marsileales and Salviniaceae, are derived from a common ancestor that evolved heterospory. Mega-spores and microspores of these plants (which germinate to produce female and male gametophytes, respectively) are produced in different sporangia, and the microspores are always much smaller and greater in number than the megaspores.

A few genera of ferns produce a tuberous, fleshy gametophyte instead of the characteristic flattened, photosynthetic structure described earlier. Like the gametophytes of whisk ferns, these tuberous gametophytes depend on a mutualistic fungus for nutrition;* in some genera, even the sporophyte embryo must become associated with the fun-

*In a mutualistic association, both partners—here, the gametophyte and the fungus—profit.

PLANTS WITHOUT SEEDS: FROM SEA TO LAND 515

gus before extensive development can proceed. In Chapter 30 we will see that there are many important plant-fungus mutualisms.

All the tracheophytes we have discussed thus far disperse themselves by spores. In the next chapter we discuss the plants that dominate most of Earth's vegetation today, the seed plants, whose seeds afford new sporophytes protection unavailable to the nonseed tracheophytes.

Chapter Summary

- ▶ Plants are photosynthetic eukaryotes that use chlorophylls a and b, store carbohydrates as starch, and develop from embryos protected by parental tissue.
- ▶ Plant life cycles feature alternation of gametophyte (hap-lloid) and sporophyte (diploid) generations.
- ▶ There are twelve surviving phyla of plants grouped into two main categories, nontracheophytes and tracheophytes. Review Table 28.1
- ▶ Plants arose from a common green algal ancestor, either of the stoneworts or of Coleochaete. Descendants of this ancestral charophyte colonized the land.

The Conquest of the Land

- ▶ Moving toward today's plants, early steps in plant evolution included the acquisition of a cuticle, gametangia, a protected embryo, protective pigments, and thick spore walls.
- ▶ Tracheophytes are characterized by possession of a vascular system, consisting of water- and mineral-conducting xylem and nutrient-conducting phloem. Nontracheophytes lack a vascular system. Review Figure 28.2

Nontracheophytes: Liverworts, Hornworts, and Mosses

- ▶ The nontracheophytes include the liverworts (phylum Hepatophyta), hornworts (phylum Anthocerophyta), and mosses (phylum Bryophyta). Review Table 28.1
- ▶ Nontracheophytes either lack vascular tissues completely or, in the case of certain mosses, have only a rudimentary system of water- and food-conducting cells.
- ▶ The nontracheophyte sporophyte generation is smaller than the gametophyte generation and depends on the gametophyte for water and nutrition. Review Figures 28.3, 28.4
- ▶ Liverwort sporophytes have no specific growing zone. Hornwort sporophytes grow at their basal end, and moss sporophytes grow at their apical end. Review Figure 28.6
- ▶ Beginning with hornworts, all plants have surface pores (stomata) that allow gas exchange and minimize water loss.
- ▶ Beginning with mosses, the sporophytes of all plants grow by apical cell division.
- ▶ The hydroids of mosses, through which water may travel, may have arisen from cells also ancestral to the water-conducting cells of the tracheophytes.

Introducing the Tracheophytes

- ▶ The tracheophytes have vascular tissue with tracheids and other specialized cells designed to conduct water, minerals, and foods.
- ▶ Present-day tracheophytes are grouped into nine phyla that form two major groups: nonseed tracheophytes and seed plants. Review Figure 28.8
- ▶ In tracheophytes the sporophyte generation is larger than the gametophyte and independent of the gametophyte generation.
- ▶ The earliest tracheophytes, known to us only in fossil form, lacked roots and leaves. Roots may have evolved from branches that penetrated the ground. Simple leaves are thought to have evolved from sporangia, and complex leaves may have resulted from the flattening and reduction of a branching stem system. Review Figures 28.10, 28.11, 28.12
- ▶ Heterospory, the production of distinct female megaspores and male microspores, evolved on several occasions from homosporous ancestors. Review Figure 28.13

The Surviving Nonseed Tracheophytes

► Club mosses (phylum Lycophyta) have simple leaves arranged spirally. Horsetails (phylum Sphenophyta) have simple leaves in whorls. Whisk ferns (phylum Psilotophyta) lack roots; one genus has minute scales rather than leaves, and the other has leaves with vascular tissue. Leaves with more complex vasculature are characteristic of all other phyla of tracheophytes. Review Table 28.1

► Ferns (phylum Pterophyta) are probably not a mono-phyletic group. They have complex leaves with branching vascular strands. Review Figure 28.19

For Discussion

1. Mosses and ferns share a common trait that makes water droplets a necessity for sexual reproduction. What is this trait?
2. Are the mosses well adapted to terrestrial life? Justify your answer.
3. Ferns display a dominant sporophyte stage (with large fronds). Describe the major advance in anatomy that enables most ferns to grow much larger than mosses.
4. What features distinguish club mosses from horsetails? What features distinguish these groups from rhyniophytes and psilotophytes? From ferns?
5. Why did some botanists once believe that psilotophytes should be classified together with the rhyniophytes?
6. Contrast simple leaves with complex leaves in terms of structure, evolutionary origin, and occurrence among plants.

The Evolution of Seed Plants

A VIOLENT THUNDERSTORM MOVES through forested hills and valleys where summer rain has been scarce. A jagged fork of lightning strikes a tree and it bursts into flame. Soon the flames reach dead and dry underbrush and fire spreads to surrounding trees. The fire rages rapidly through the forest, leaving a blackened and smoking landscape behind.

Though devastating, such fires are a natural part of the forest ecosystem. Life returns quickly following a fire in a natural grassland or forest, in part because some plants have adaptations that enable them to live with fire. One example, obvious from its common name, is fireweed. The seeds of fireweed not only survive fires, but are encouraged by high temperatures to break their dormancy and sprout. Another example is the lodgepole pine tree, which covers vast fire-prone areas in the Rocky Mountains and elsewhere. Its cones will not release their seeds unless the heat of a fire causes them to open.

Seeds are remarkable structures. They protect the plant embryo within them from environmental extremes through what may be a very long resting period. This and other properties contribute to making seed plants the predominant plants on Earth. All of today's forests are dominated by seed plants.

In this chapter we describe the defining characteristics of the seed plants as a group. We survey the diversity of seed plants and describe the flowers and fruits that are characteristic of the flowering plants. Finally, we consider some of the unsolved problems in seed plant evolution.

General Characteristics of the Seed Plants

The most recent group to appear in the evolution of the tracheophytes is the seed plants: the gymno-sperms (such as pines and cycads) and the angio-sperms (flowering plants). There are four living phyla of gymnosperms and one of angiosperms (Figure 29.1). The phylogenetic relationships among these five lineages have not yet been resolved.

A Forest Ablaze

Fires like this one in a northern Arizona forest can pose dangers to human life and property. But they play an essential role in the life cycles of many fire-adapted seed plants.

In seed plants, the gametophyte generation is reduced even further than it is in the ferns (Figure 29.2). The haploid gametophyte develops partly or entirely while attached to and nutritionally dependent on the diploid sporophyte. Among the seed plants, only the earliest types of gymnosperms and their few survivors had swimming sperm. All other seed plants have evolved other means of bringing female and male gametes together. The culmination of this striking evolutionary trend in plants was independence from the liquid water that earlier plants needed for sexual reproduction.

Seed plants are heterosporous, forming separate mega-sporangia and microsporangia on structures that are grouped on short axes, such as the cones of conifers and the flowers of angiosperms.

As in other plants, the spores of seed plants are produced by meiosis within the sporangia, but in seed plants, the megaspores are not shed. Instead, the female gametophytes develop within the megasporangia and depend on them for food and water. In most species only one of the meiotic products in a megasporangium survives. The surviving haploid nucleus divides mitotically, and the resulting cells divide again to produce a multicellular female gametophyte. In the angiosperms, female gametophytes normally contain eight nuclei. The female gametophyte is retained within the megasporangium, where it matures and

relationship is still uncertain.

houses the early development of the next sporophyte generation following fertilization of the egg. The megasporangium itself is surrounded by sterile sporophyte structures that form a protective integument.

Within the microsporangium, the meiotic products are microspores, which divide within the microspore wall one or a few times to form male gametophytes called pollen grains (Figure 29.3). Distributed by wind, an insect, a bird, or a plant breeder, a pollen grain that reaches the appropriate surface of a sporophyte develops further. It produces a slender pollen tube that elongates and digests its way through the sporophytic tissue toward the female gametophyte.

"O rt>

Sporophyte (2n)

Sporophyte (2n)

The moss gametophyte nourishes the sporophyte.

Gametophyte (n)

When the tip of the pollen tube reaches the female gametophyte, two sperm are released from the tube and fertilization occurs. The resulting diploid zygote divides repeatedly, forming a young sporophyte that develops to an embryonic stage at which growth becomes temporarily suspended (often referred to as a dormant stage). The end product at this stage is a seed.

A seed may contain tissues from three generations. The seed coat and megasporangium develop from tissues of the diploid sporophyte parent (the integument). Within the megasporangium is the haploid female gametophyte tissue from the next generation.

- (This tissue is fairly extensive in most

gymnosperm seeds. In angiosperm seeds its place is taken by a tissue called endosperm, which we will discuss shortly.) In the center of the seed package is the third generation, in the form of the embryo of the new diploid sporophyte.

The multicellular seed of a gymnosperm or an angiosperm is a well-protected resting stage. The seeds of some species may remain viable (capable of growth and development) for many years, germinating when conditions are favorable for the growth of the sporophyte. In contrast, the embryos of nonseed plants develop directly into sporophytes, which either survive or die, depending on environmental conditions; there is no resting stage in the life cycle.

29.2 The Relationship between Sporophyte and Gametophyte Has Evolved

In seed plants, the gametophyte (shown in yellow) is nutritionally dependent on the sporophyte (shown in blue).

wind carries pollen grains from pollen cone...

a cone.

29.3 Pollen Grains

Pollen grains are the male gametophytes of seed plants. Conifers have separate seed cones (which contain the female gametophyte) and pollen cones; their pollen is dispersed by the wind.

During the dormant stage, the seed coat protects the embryo from excessive drying and may also protect against potential predators that would otherwise eat the embryo and its food reserves. Many seeds have structural adaptations that promote dispersal by wind or, more often, by animals. When the young sporophyte resumes growth, it draws on food reserves in the seed. The possession of seeds is a major reason for the enormous evolutionary success of seed plants, which are the dominant life forms of Earth's modern land flora in most areas.

The Gymnosperms: Naked Seeds

The gymnosperms are a group of seed plants that do not form flowers. Although there are probably fewer than 750 species of living gymnosperms, these plants are second only to the angiosperms (flowering plants) in their dominance of the terrestrial environment.

There are four phyla of living gymnosperms today. The cycads (phylum Cycadophyta) are palmlike plants of the tropics, growing as tall as 20 meters (Figure

29.4f). Ginkgos (phylum Ginkgoeae

Ginkgoeae), which were common during the Mesozoic era, are represented today by a single genus and species, *Ginkgo biloba*, the maidenhair tree (Figure 29.4b). There are both microsporangiate and megasporangiate maidenhair trees. The difference is determined by X and Y sex chromo-

somes, as in humans; few other plants have sex chromosomes. The phylum Gnetophyta consists of three very different genera that share certain characteristics with the angiosperms. One of the gnetophytes is *Welwitschia* (Figure 29.4c), a long-lived desert plant with just two straplike leaves that sprawl on the sand and can become as long as 3 meters. Far and away the most abundant of the gymnosperms are the conifers (phylum Coniferophyta), cone-bearing plants such as pines and redwoods (Figure 29.4d).

All living gymnosperms have stems and roots that grow larger in diameter (called secondary growth), and all but the Gnetophyta have only tracheids as water-conducting and support cells in their xylem. Although the gymnosperm water transport and support system may seem less effective than that of the angiosperms, it serves some of the tallest trees known. The coastal redwoods of California are the tallest gymnosperms; the largest are well over 100 m tall. Secondary xylem—wood—produced by gymnosperms is the principal resource of the timber industry.

Before examining the conifer life cycle, we'll take a brief look at the fossil history of gymnosperms.

We know the early gymnosperms only as fossils

The earliest fossil evidence of gymnosperms is found in Devonian rocks. The early gymnosperms combined characteristics of rhyniophytes and heterosporous ferns, but they had tracheids of the same type found in modern gymnosperms. They also differed from the plants around them by their extensively thickened woody stems, which resulted from proliferation of xylem.

By the Carboniferous period, several new lines of gymnosperms had evolved, including various seed ferns that possessed fernlike foliage but had characteristic gymnosperm seeds attached to their leaves. The first true conifers appeared somewhat later. Either they were not dominant trees or they did not grow where conditions were right for fossilization, so we have few

preserved examples. During the Permian period, however, the conifers and cycads flourished. Gymnosperm forests changed with time as the gymnosperm groups evolved, and they dominated the Mesozoic era, in which the continents drifted apart and dinosaurs strode the Earth. Gymnosperms dominated all forests until less than 100 million years ago, and they still dominate some present-day forests.

Conifers have cones but no motile cells

The great Douglas fir and cedar forests of the northwestern United States and the massive boreal forests of pine, fir, and spruce that clothe the northern continental regions and upper slopes of mountain ranges rank among the great vegetation formations of the world. All these trees belong to one phylum of gymnosperms, Coniferophyta—the conifers, or cone-bearers. A cone is an axis bearing a tight cluster of scales or leaves specialized for reproduction. Megaspores and microspores are produced in separate seed and pollen cones. Seed cones are much larger than pollen cones (see Figure 29.3).

(d) *Sequoiadendron giganteum*

We will use the life cycle of a pine to illustrate reproduction in gymnosperms (Figure 29.5). The production of male gametophytes in the form of pollen grains frees the plant completely from its dependence on liquid water for fertilization. Instead of water, wind assists conifer pollen grains in their first stage of travel to the female gametophyte inside the seed cone. The pollen tube provides the means for the last stage of travel by elongating and digesting its way through maternal sporophytic tissue. When it reaches the female gametophyte, it releases two sperm, one of which degenerates after the other unites with the egg.

The megasporangium, which will form the female gametophyte containing eggs within archegonia, is enclosed in a layer of sporophytic tissue—the integument—that will eventually develop into the seed coat. The integument, the megasporangium inside it, and the tissue attaching it to the maternal sporophyte constitute the ovule. The pollen grain enters through a small opening in the integument at the tip of the ovule, the micropyle.

Gymnosperms derive their name (which means "naked-seeded") from the fact that their ovules and seeds are not protected by flower or fruit tissue. Most conifer ovules (which upon fertilization develop into seeds) are borne ex-

The gametophytes are microscopically small and nutritionally dependent on the sporophyte generation.

posed on the upper surfaces of modified branches called cone scales. Their only protection from the environment lies in the fact that the scales are tightly pressed against each other within the cone. As we have seen, some pines, such as

the lodgepole pine, have such tightly closed seed cones that only fire suffices to split them open and release the seeds.

About half of the conifer species have soft, fleshy fruitlike tissues associated with their seeds; examples are the "berries" of juniper and yew. Animals may eat these tissues and then disperse the seeds in their feces, often carrying them considerable distances from the parent plant. These

tissues, however, are not true fruits, which are characteristic of the plant phylum that is dominant today: the angiosperms.

The Angiosperms: Flowering Plants

The phylum Angiospermae consists of the flowering plants, also commonly known as the angiosperms. This highly diverse phylum includes more than 230,000 species. The oldest evidence of angiosperms dates to the late Jurassic period, more than 140 mya. The angiosperms radiated explosively and, over a period of only about 60 million years, became the dominant plant life of the planet. In later chapters, when we mention "plants," we are generally referring to the angiosperms.

The angiosperms represent the current extreme of an evolutionary trend that runs throughout the tracheophytes: The sporophyte generation becomes larger and more independent of the gametophyte, while the gametophyte generation becomes smaller and more dependent on the sporophyte.

Angiosperms differ from other plants in several ways:

- ▶ They have double fertilization.
- ▶ They produce a diploid endosperm.
- ▶ Their ovules and seeds are enclosed in a carpel.
- ▶ They have flowers.
- ▶ They produce fruit.
- ▶ Their xylem contains vessel elements and fibers.
- ▶ Their phloem contains companion cells.

Double fertilization was long considered the single most reliable distinguishing characteristic of the angiosperms. Two male gametes, contained within a single microgametophyte (pollen grain), participate in fertilization events within the megagametophyte of an angiosperm. One sperm combines with the egg to produce a diploid zygote, the first cell of the sporophyte generation. In most angiosperms, the other sperm nucleus combines with two other haploid nuclei of the female gametophyte to form a triploid ($3n$) nucleus. This nucleus, in turn, divides to form a triploid tissue, the endosperm, that nourishes the embryonic sporophyte during its early development.

Double fertilization occurs in all present-day angiosperms. We are not sure when and how it evolved because there is no

fossil evidence on this point. It probably first resulted in two embryos, as it does in the three existing genera of Gnetales: *Ephedra*, *Gnetum*, and *Welwitschia*. Both of the fertilizations in gnetales produce diploid products.

The formation of an extensive triploid endosperm is one of the

The pistil receives pollen, r

most definitive angiosperm traits, although it is not universal.

The name angiosperm ("enclosed seed") is drawn from another diagnostic character: The ovules and seeds of these plants are enclosed in a modified leaf called a carpel. Besides protecting the ovules and seeds, the carpel often interacts with incoming pollen to prevent self-pollination, thus favoring cross-pollination and increasing genetic diversity. Of course, the most evident diagnostic feature of angiosperms is that they have flowers. Production of a fruit is another unique characteristic of the angiosperms.

Angiosperms are also distinguished by the possession of specialized water-transporting cells called vessel elements in their xylem, but these cells are also found, in anatomically different form, in gymnosperms and a few ferns. A second distinctive cell type in angiosperm xylem is the fiber, which plays an important role in supporting the plant body. Angiosperm phloem possesses another unique cell type, called a companion cell.

In the following sections we'll examine the structure and function of flowers, evolutionary trends in flower structure, the functions of pollen and fruits, the angiosperm life cycle, the two major groups of angiosperms, and the origin and evolution of flowering plants.

The sexual structures of angiosperms are flowers

If you examine any familiar flower, you will notice that the outer parts look somewhat like leaves. In fact, all the parts of a flower are modified leaves.

A generalized flower (for which there is no exact counterpart in nature) is shown in Figure 29.6 for the purpose of identifying its parts. The structures bearing microsporangia are called stamens. Each stamen is composed of a filament bearing an anther that contains pollen-producing microsporangia. The structures bearing megasporangia are the carpels. A structure composed of one carpel or two or more fused carpels is called a pistil. The swollen base of the pistil, containing one or more ovules (each containing a

Petal

[m^ 29.6 A Generalized Flower

Not all flowers possess all the structures shown here, but they must possess a stamen (male), pistil (female), or both in order to play their role in reproduction.

Flowers that have both, as this one does, are referred to as perfect.

29.7 Inflorescences

(a) The inflorescence of Queen Anne's lace is an umbel. Each umbel bears flowers on stalks that arise from a common center. (b) Cornflowers are members of the aster family; their inflorescence is a head. In a head, each of the long, petal-like structures is a ray flower; the central portion of the head consists of dozens to hundreds of disc flowers. (c) Grasses such as this fountain grass have inflorescences called spikes.

megasporangium), is called the ovary. The apical stalk of the pistil is the style; and the terminal surface that receives pollen grains is called the stigma.

In addition, a flower often has several specialized sterile (non-spore-bearing) leaves: The inner ones are called petals (collectively, the corolla), and the outer ones sepals (collectively, the calyx). The corolla and calyx, which can be quite showy, often play roles in attracting animal pollinators to the flower. The calyx more commonly protects the immature flower in bud. From base to apex, the sepals, petals, stamens, and carpels (which are referred to as the floral organs; see Figure 15.11) are usually in circular arrangements called whorls and attached to a central stalk called the receptacle.

The generalized flower shown in Figure 29.6 has both megasporangia and microsporangia; such flowers are referred to as perfect. Many angiosperms produce two types of flowers, one with only megasporangia and the other with only microsporangia. Consequently, either the stamens or the carpels are nonfunctional or absent in a given flower, and the flower is referred to as imperfect.

Species such as corn or birch, in which both megasporangiate and microsporangiate flowers occur on the same plant, are said to be monoecious (meaning "one-housed"—but, it must be added, one house with separate rooms). Complete separation is the rule in some other angiosperm species, such as willows and date palms; in these species, a given plant produces either flowers with stamens or flowers with pistils, but never both. Such species are said to be dioecious ("two-housed").

Flowers come in an astonishing variety of forms, as you will realize if you think of some of the flowers you recognize. The generalized flower shown in Figure 29.6 has distinct petals and sepals arranged in distinct whorls. In

(c) *Pennisetum setaceum*

nature, however, petals and sepals sometimes are indistinguishable. Such appendages are called tepals. In other flowers, petals, sepals, or tepals are completely absent.

Flowers may be single, or grouped together to form an inflorescence. Different families of flowering plants have their own, characteristic types of inflorescences, such as the umbels of the carrot family, the heads of the aster family, and the spikes of many grasses (Figure 29.7).

Flower structure has evolved over time

The flowers that are evolutionarily the most ancient have a large and variable number of tepals (or sepals and petals), carpels, and stamens (Figure 29.8a). Evolutionary change within the angiosperms has included some striking modifications from this early condition: reduction in the number of each type of organ to a fixed number; differentiation of petals from sepals; and change in symmetry from radial (as in a lily or magnolia) to bilateral (as in a sweet pea or orchid), often accompanied by an extensive fusion of parts (Figure 29.8b).

According to one theory, the first carpels to evolve were modified simple leaves, folded but incompletely closed, and thus differing from the scales of the gymnosperms. In the groups of angiosperms that evolved later, the carpels fused and became progressively more buried in receptacle tissue (Figure 29.9a). In the flowers of the latest groups to evolve, the other flower parts are attached at the very top of the ovary, rather than at the bottom as in Figure 29.6. The stamens of the most ancient flowers may have appeared leaflike (Figure 29.9b), little resembling those of the generalized flower in Figure 29.6.

Why do so many flowers have pistils with long styles and anthers with long filaments? Natural selection has favored length in both of these structures, probably because length increases the likelihood of successful pollination. Long filaments may bring the anthers into contact with insect bodies, or they may place the anthers in a better position to catch the wind. Similar arguments apply to long styles.

THE EVOLUTION OF SEED PLANTS 523

(a) Carpel evolution

(a)

29.8 Flower Form and Evolution

{a) A magnolia flower shows the major features of early flowers: It is radially symmetrical, and the individual tepals, carpels, and stamens are separate, numerous, and attached at their bases, {b) Orchids have a bilaterally symmetrical structure that evolved much later than the form of the magnolia flower in (a). One of the three petals evolved into the complex lower "lip." Inside, the stamen and pistil are fused, and there is a single anther in this species.

A long style may serve another purpose as well. If several pollen grains land on one stigma, a pollen tube will start growing from each grain toward the ovary. If there are more pollen grains than ovules, there is a "race" to fertilize the ovules. The race down the style can be viewed as "mate selection" by the plant bearing that style.

Angiosperms have coevolved with animals

Pollen has played another crucial role in the evolution of the angiosperms. Whereas many gymnosperms are wind-pollinated, most angiosperms are animal-pollinated. Animals visit flowers to obtain nectar or pollen, and in the process often carry pollen from one flower to another, or from one plant to another. Thus, in its quest for food, the animal contributes to the genetic diversity of the plant population. Insects, especially bees, are among the most important pollinators; birds and some species of bats also play major roles.

For more than 130 million years, angiosperms and their animal pollinators have coevolved in the terrestrial environment. The animals have affected the evolution of the plants, and the plants have affected the evolution of the animals. Flower structure has become incredibly diverse under these selection pressures.

Q According to one theory, the carpel began as a modified leaf with sporangia.

Q In the course of evolution, leaf edges curled inward and finally fused.

DIPLOID (2n)

Megagametophytes develop from megaspores in the ovule, the female flower part.

29.10 The Life Cycle of an Angiosperm

The formation of a triploid endosperm distinguishes the angiosperms from the gymnosperms.

Some of the products of coevolution are highly specific; for example, some yucca species are pollinated by only one species of moth. Pollination by just one or a very few animal species provides a plant species with a reliable mechanism for transferring pollen from one to another of its members.

Most plant-pollinator interactions are much less specific; that is, many different animal species pollinate the same plant species, and the same animal species pollinate many plant species. However, even these less specific interactions have developed some specialization. Bird-pollinated flowers are often red and odorless. Insect-pollinated flowers often have characteristic odors, and bee-pollinated flowers may have conspicuous markings, or nectar guides, that are evident only in the ultraviolet region of the spectrum, where bees have better vision than in the red region. Co-

evolution and other aspects of plant-animal interactions are covered in more detail in Chapter 55.

The angiosperm life cycle features double fertilization

The life cycle of the angiosperms is summarized in Figure 29.10. The angiosperm life cycle will be considered in detail in Chapter 38, but let's look at it briefly here and compare it with the conifer life cycle in Figure 29.5.

Like all seed plants, angiosperms are heterosporous. The female gametophyte is even more reduced than that of the gymnosperms. The ovules are contained within carpels, rather than being exposed on the surfaces of scales, as in most gymnosperms. The male gametophytes are, again, pollen grains.

The ovule develops into a seed containing the products of the double fertilization that characterizes angiosperms. The triploid endosperm serves as storage tissue for starch or lipids, proteins, and other substances that will be needed by the developing embryo.

(«)

29.11 Fleshy Fruits Come in Many Forms and Flavors

(a) A simple fruit (sour cherries), (fc>) An aggregate fruit (raspberries), (c) A multiple fruit (pineapple), (d) An accessory fruit (pear).

The diploid zygote develops into an embryo, consisting of an embryonic axis and one or two cotyledons. Also called seed leaves, the cotyledons have different fates in different plants. In many, they serve as absorptive organs that take up and digest the endosperm. In others, they enlarge and become photosynthetic when the seed germinates. Often they play both roles (see Chapter 37).

Angiosperms produce fruits

The ovary of a flowering plant (together with the seeds it contains) develops into a fruit after fertilization. A fruit may consist only of the mature ovary and its seeds, or it may include other parts of the flower or structures associated with it. A simple fruit, such as a cherry (Figure 29.11rt), is one that develops from a single carpel or several united carpels. A raspberry is an example of an aggregate fruit (Figure 29.11b)—one that develops from several separate carpels of a single flower. Pineapples and figs are examples of multiple fruits (Figure 29.11c), formed from a cluster of flowers (an inflorescence). Fruits derived from parts in addition to the carpel and seeds are called accessory fruits (Figure 29.11d); examples are apples, pears, and strawberries. The development, ripening, and dispersal of fruits will be considered in Chapters 37 and 38.

Determining the oldest living angiosperm lineage

Which angiosperms were the first flowering plants was long a matter of great controversy. Two leading candidates were the magnolia family (see Figure 29.8(7)) and another family, the Chloranthaceae, whose flowers are much simpler than those of the magnolias. At the close of the twentieth century, an impressive convergence of evidence led to the conclusion that the base of the angiosperm phylogenetic tree belongs to neither of those families, but rather to a lineage that today consists of just a single species of the

(b)

genus *Amborella* (Figure 29.12). This woody shrub, with cream-colored flowers, lives only on New Caledonia, an island in the South Pacific. Its 5 to 8 carpels are in a single whorl, and it has 30 to 100 stamens. The xylem of *Amborella* lacks vessel elements, which appeared later in angiosperm evolution. The characteristics of *Amborella* give us a good sense of what the first angiosperms might have been like.

(b)

There are two large monophyletic groups of angiosperms

There are two large lineages that include the great majority of angiosperm species: the monocots and the eudicots. Both are monophyletic groups (Figure 29.13). The monocots are so called because they have a single embryonic cotyledon; the eudicots have two. The cotyledons of some, but not all, eudicots store the reserves originally present in the endosperm. There are several other differences between the two lineages, which we will describe in Chapter 34. Some familiar plants, including magnolias and water lilies, belong to lineages more ancient than either the monocots or the eudicots.

The monocots (Figure 29.14) include grasses, cattails, lilies, orchids, and palm trees. The eudicots (Figure 29.15) include the vast number of familiar seed plants, including most of the herbs, vines, frees,

and shrubs. Among them are oaks, willows, violets, snapdragons, and sunflowers.

The origin of the angiosperms remains a mystery

We have learned a lot about evolution within the angiosperm lineage. The most important unanswered question about the evolution of seed plants is this: How did the angiosperms first arise—to which gymnosperm phylum are they sister? You might think that, given the advances in techniques of molecular genetics and computer technology, as well as new fossil finds,

we would have opened this century with the answer to this question well in hand. A very few years ago, it seemed that we were on the verge of answering it. Although an answer may be agreed upon before the present decade ends, the puzzle is as vexing today as it was before.

Why should this be? Different phylogenetic methods, applied by different investigators, have produced apparently contradictory results. It might seem a simple matter to rectify this situation, but several questions complicate such efforts: What morphological characters should be selected as important, or should they all be treated as equally important? What algorithms should be applied to computerized analysis of data? Are all molecular differences and similarities significant, or are some of them incidental? Which fossils should be chosen for comparisons? What is the likelihood that we can find evidence of double fertilization in ancient fossils?

We are left with the question: Where did the first angiosperm come from? The angiosperms may be most closely related to the gnetophytes, or they may be more closely related to the conifers, or to another gymnosperm phylum. Current progress in methodology gives us reason to hope that our picture of seed plant evolution will be much more complete before this decade ends. We will see in Chapters 31-33 whether our understanding of animal evolution is more complete.

THE EVOLUTION OF SEED PLANTS

29.74 Monocots

(a) Palms are among the few monocot trees. Date palms are a major food source in some areas of the world, (b) Grasses such

as this cultivated wheat and the fountain grass in Figure 29.7c are monocots. (c) Monocots include popular garden flowers such as these daylilies. Orchids (Figure 29.85) are another highly prized monocot flower.

(c) *Hemerocallis* sp.

(c) *Rosa rugosa*

29.15 Eudicots

(a) The cactus family is a large group of eudicots, with about 1,500 species in the Americas. This cactus bears scarlet flowers for a brief period of the year, (b) The flowering dogwood is a small eudicot tree, (c) Climbing Cape Cod roses are members of the eudicot family Rosaceae, as are the familiar roses from your local florist.

528 CHAPTER TWENTY-NINE

Chapter Summary

General Characteristics of the Seed Plants

- The seed plants (gymnosperms and angiosperms) are heterosporous and have greatly reduced gametophytes. Review Figures 29.1, 29.2
- Most modern seed plants have no swimming gametes and do not require liquid water for fertilization. The male gametophyte—the pollen grain—is dispersed by wind or by animals. Review Figure 29.3
- The seed is a well-protected resting stage that often contains food that supports the growth of the embryo.

The Gymnosperms: Naked Seeds

- The gymnosperms, once the dominant vegetation on Earth, still dominate forests in the northern parts of the Northern Hemisphere and at high elevations.
- The four surviving gymnosperm phyla are the Cycadophyta (the most ancient), Ginkgophyta (consisting of a single species, the maidenhair tree), Gnetophyta (which has some characters in common with the angiosperms), and Coniferophyta (the familiar cone-bearing trees).
- Modern gymnosperms all have abundant xylem and extensive secondary growth.
- Conifers have a life cycle in which naked seeds are produced on the scales of female cones. Pollen cones are smaller than seed cones. Pollen is transferred from pollen cones to seed cones by wind. Review Figure 29.5

The Angiosperms: Flowering Plants

- Angiosperms (phylum Angiospermae) are distinguished by double fertilization, which results in a triploid nutritive tissue, the endosperm. Double fertilization is also characteristic of the Gnetophyta. Review Figure 29.10
- The ovules and seeds of angiosperms are enclosed by a carpel. Angiosperms are also characterized by the production of flowers and fruits.
- The vascular tissues of angiosperms contain three characteristic cell types: vessel elements, fibers, and companion cells.
- Flowers are made up of various combinations of carpels, stamens, petals, and sepals. Perfect flowers have both carpels (female parts) and stamens (male parts). Review Figure 29.6
- Monoecious plant species have both female and male flowers on the same plant. Dioecious species have separate female and male plants.

- ▶ Carpels and stamens may have evolved from leaflike structures. Review Figure 29.9
- ▶ Angiosperms and the animals that pollinate them have coevolved.
- ▶ Amborella, a tropical shrub, is the sole living representative of the first angiosperm lineage.
- ▶ There are two major lineages of flowering plants: monocots and eudicots. Review Figure 29.13
- ▶ The evolutionary origin of the angiosperms remains a mystery.

For Discussion

1. In most seed plant species, only one of the products of meiosis in the megasporangium survives. How might this be advantageous?
2. Suggest an explanation for the great success of the angiosperms in occupying terrestrial habitats.
3. In many locales, large gymnosperms predominate over large angiosperms. Under what conditions might gymnosperms have the advantage, and why?
4. Not all flowers possess all of the following parts: sepals, petals, stamens, and carpels. What kind or kinds of flower parts do you think might be found in the flowers that have the smallest number of kinds? Discuss the possibilities, both for a single flower and for a species.
5. The problem of the origin of the angiosperms has long been "an abominable mystery," as Charles Darwin once put it. Scientists still do not know the nearest relatives of the angiosperms. It has often been suggested (correctly or incorrectly) that the gnetophytes are sister to the angiosperms. What pieces of evidence suggested this connection?

Fungi: Recyclers, Killers, and Plant Partners

What are the largest organisms you can think of? Whales? Trees? Some of the largest organisms on Earth are fungi. One such fungus, growing in Michigan, covers an area of 37 acres. Its effect on green plants is evident from the air, but from ground level, it is difficult to realize how large the fungus is. At the surface, you see only seemingly isolated clumps of mushrooms. But the vast body of the fungus *Armillariella*, which weighs approximately the same as a blue whale, grows underground and consists almost entirely of microscopic filaments.

Molecular studies indicate that this giant fungus is or was a single individual that arose from a single spore. It is possible that fragmentation over time may have broken it into a few separate—but still gigantic—individuals. Another, larger fungus of the same genus, growing in the state of Washington, occupies parts of three counties. But not all fungi are huge. Molds and mushrooms are fungi, as are the microscopic, unicellular yeasts.

Every breath we take contains large numbers of fungal spores. Some of those spores can be dangerous, and fungal diseases of humans, some of which are as yet incurable, have become a major global threat. However, other fungi are of immense commercial importance to us. Fungi are essential to plants as well. Fungi interact with roots, greatly enhancing the roots' ability to take up water and mineral nutrients.

Earth would be a messy place without the fungi. They are at work in forests, fields, and garbage dumps, breaking down the remains of dead organisms (and even manufactured substances such as some plastics). For almost a billion years, the ability of fungi to decompose substances has been important for life on Earth, chiefly because by breaking down carbon compounds, they return carbon and other elements to the environment, where they can be used again by other organisms.

In this chapter we will examine the general biology of the kingdom Fungi, which differs in interesting ways from the other kingdoms. We will also explore the diversity of body forms, reproductive structures, and life cycles of the four phyla of fungi, as well as the mutually beneficial associations of certain fungi with other organisms. As we begin

The Tip of the Iceberg

These fungal fruiting bodies of *Armillariella* are only a hint of the presence of a vast underground network of microscopic filaments extending over many acres.

In our study, recall that the fungi and the animals are descended from a common ancestor—we are more closely related to molds and mushrooms than we are to the flowers we admired in the last chapter.

General Biology of the Fungi

The fungi are superbly adapted for absorptive nutrition: They secrete digestive enzymes that break down large food molecules in the environment, then absorb the breakdown products. The kingdom Fungi encompasses heterotrophic

organisms with absorptive nutrition. Many fungi are saprobes that absorb nutrients from dead matter, others are parasites that absorb nutrients from living hosts (Figure 30.1), and still others live in mutually beneficial symbioses with other organisms.

All fungi form spores, but only in one phylum (Chytridiomycota) do spores or gametes possess flagella. Fungi reproduce sexually in a variety of ways. Their cell walls contain at least some chitin, a polysaccharide that is also found in the skeletons of arthropods and in some protists. Most fungi have complex body forms.

These criteria enable us to distinguish between the fungi and some protists that resemble them. The slime molds consist of two protist groups whose members take up food

530 CHAPTER THIRTY

30.1 Parasitic Fungi Attack Other Living Organisms

(a) The gray masses on this ear of corn are the parasitic fungus *Ustilago maydis*, commonly called corn smut.

(b) The tropical fungus whose fruiting body is growing out of the carcass of this ant has developed from a spore ingested by the ant. The spores of this fungus must be ingested by insects before they will germinate and develop. The growing fungus absorbs organic and inorganic nutrients from the ant's body, eventually killing it, after which the fruiting body produces a new crop of spores. (c) An amoeba (below) being parasitized by a fungus (above) of the genus *Amoebophilus* ("amoeba lover").

by phagocytosis rather than by absorption, and a third protist group whose members have cells with flagella. Other funguslike protists (Oomycota) also have flagellated cells; they have cellulose rather than chitin in their cell walls.

The kingdom Fungi consists of four phyla: Chytridiomycota, Zygomycota, Ascomycota, and Basidiomycota (Table 30.1). We distinguish the phyla on the basis of their methods and structures for sexual reproduction and, to a lesser extent, on criteria such as the presence or absence of cross-walls separating their cell-like compartments. This morphologically based phylogeny has proved largely consistent with phylogenies based on DNA sequencing.

Some fungi, called imperfect fungi or deuteromycetes, do not form sexual structures by which they might be easily identified as members of one of the four phyla. However, techniques of molecular taxonomy, such as DNA sequencing, have allowed us to identify many imperfect fungi as asexual zygomycetes, ascomycetes, or basidiomycetes. The deuteromycetes are not considered a phylum, but rather a "holding group" for species whose status is yet to be resolved.

The fungi are an ancient kingdom. Fossil evidence suggests that they have been present since at least 600 million years ago, and perhaps much longer.

In the sections that follow, we'll consider some aspects of the general biology of the fungi, including their body struc-

ture and its intimate relationship with their environment, their nutrition, and some special aspects of their unusual sexual reproductive cycles.

Some fungi are unicellular

Unicellular forms are found in all of the fungal phyla, as well as among the deuteromycete group. Unicellular members of the Zygomycota, Ascomycota, and Basidiomycota are called yeasts. Yeasts may reproduce by budding, by fission, or by sexual means, which help us to place them in their appropriate phyla (Figure 30.2).

30.2 Yeasts Are Microscopic, Unicellular Fungi

Unicellular members of the fungal phyla are known as yeasts. Many yeasts reproduce by budding, as those shown here are

doing.

The body of a fungus is composed of hyphae

Most fungi are not unicellular, but whether they can truly be called multicellular is questionable. The vegetative (feeding) body of a fungus is called a mycelium (plural mycelia). It is composed of rapidly growing individual tubular filaments called hyphae (singular hypha). Within most hyphae, there is no division into separate cells, and organelles (even nuclei) can move around (Figure 30.3). Thus, it may be more appropriate to call these fungi multinucleated than multicellular. Some hyphae are subdivided into cell-like compartments by incomplete cross-walls called septa (singular septum). Other hyphae are coenocytic and have no septa.

(a) Coenocytic hypha

(b) Septate hypha

Both types of hyphae are single cells with multiple nuclei.

Nuclei Cell wall

Pore Septum

Septa are not complete: Pores allow movement of organelles and other materials within the cell.

30.3 Most Hyphae Are Not Divided into Separate Cells

Even when septa are present, they do not block the movement of organelles within the hypha.

FUNGI: RECYCLERS, KILLERS, AND PLANT PARTNERS 531

Certain modified hyphae, the rhizoids, anchor Chytrid-omycota to their substrate (the dead organism or other matter upon which they feed). These rhizoids are not homologous to the rhizoids of plants. Parasitic fungi may have modified hyphae that take up nutrients from their host.

The total hyphal growth of a mycelium (not the growth of an individual hypha) may exceed 1 km per day. The hyphae may be highly dispersed or may clump together in a cottony mass. Sometimes, when sexual spores are produced, the mycelium becomes organized into elaborate fruiting bodies such as mushrooms.

The way in which a parasitic fungus attacks a plant illustrates the roles of some fungal structures (Figure 30.4). The hyphae of a fungus invade a leaf through the stomata, through wounds, or in some cases, by direct penetration of epidermal cells. Once inside the leaf, the hyphae form a mycelium. Some hyphae grow into the living plant cells, absorbing the nutrients within the cells. Fruiting bodies may form, either within the plant body or on its surface.

Fungi are in intimate contact with their environment

The tubular hyphae of a fungus give it a unique relationship with its physical environment. The fungal mycelium has an enormous surface area-to-volume ratio compared with that of most large multicellular organisms. This large ratio of surface area to volume is a marvelous adaptation for absorptive nutrition. Throughout the mycelium (except in fruiting bodies), all the hyphae are very close to their environmental food source.

Another characteristic of some fungi is their tolerance for highly hypertonic environments (those with a solute concentration higher than their own; see Chapter 5). Many fungi are more resistant than bacteria to damage in hypertonic surroundings. Jelly in the refrigerator, for example, will not become a growth medium for bacteria, because it is too hypertonic to the bacteria, but it may eventually harbor mold colonies. The refrigerator itself illustrates another trait of many fungi: tolerance of temperature extremes. Many fungi tolerate temperatures as low as 5-6°C below freezing, and some tolerate temperatures as high as 50°C or more.

Fungi are absorptive heterotrophs

All fungi are heterotrophs that obtain food by direct absorption from their immediate environment. The majority are saprobes, obtaining their energy, carbon, and nitrogen directly from dead organic matter through the action of enzymes they secrete. However, as we've learned already, some are parasites, and still others form mutualistic associations with other organisms.

Saprobic fungi, along with bacteria, are the major decomposers of the biosphere, contributing to decay and thus to the recycling of the elements used by living things. In the forest, for example, the invisible mycelia of fungi absorb nutrients from fallen trees, thus decomposing their wood. Fungi are the principal decomposers of cellulose and lignin,

532 CHAPTER THIRTY

Grass cells

§|Some hyphae penetrate cells within the leaf.

the main components of plant cell walls (most bacteria cannot break down these materials).

Because many saprobic fungi are able to grow on artificial media, we can perform experiments to determine their exact nutritional requirements. Sugars are their favored source of carbon. Most fungi obtain nitrogen from proteins or the products of protein breakdown. Many fungi can use nitrate (NO_3^-) or ammonium (NH_4^+) ions as their sole source of nitrogen. No known fungus can get its nitrogen directly from nitrogen gas, as can some bacteria and plant-bacteria associations (see Chapter 36). Nutritional studies also reveal that most fungi are unable to synthesize their own thiamin (vitamin B₂) or biotin (another B vitamin), and must absorb these vitamins from their environment. On the other hand, fungi can synthesize some vitamins that animals cannot. Like all organisms, fungi also require some mineral elements.

Nutrition in the parasitic fungi is particularly interesting to biologists. Facultative parasites can be grown by themselves on defined artificial media. Obligate parasites cannot be grown on any available medium; they can grow only on their specific living hosts, usually plants. Because their growth is limited to living hosts, they must have unusual nutritional requirements.

Some fungi have adaptations that enable them to function as active predators, trapping nearby microscopic protozoists or animals, from which they obtain nitrogen and energy. The most common strategy is to secrete sticky substances from the hyphae so that passing organisms stick tightly to them. The hyphae then quickly invade the prey, growing and branching within it, spreading through its body, absorbing nutrients, and eventually killing it.

A more dramatic adaptation for predation is the constricting ring formed by some species of *Arthrobotrys*, *Dactylaria*, and *Dactylella* (Figure 30.5). All of these fungi grow in soil. When nematodes (tiny roundworms) are present in the soil, these fungi form three-celled rings with a di-

30.4 A Fungus Attacks a Leaf

The white structures in the micrograph are hyphae of the fungus *Blumeria graminis*, which is growing on the dark surface of the leaf of a grass.

'Fungal hyphae

ameter that just fits a nematode. A nematode crawling through one of these rings stimulates it, causing the cells of the ring to swell and trap the worm. Fungal hyphae quickly invade and digest the unlucky victim.

Certain highly specific associations between fungi and other organisms have nutritional consequences for the fungal partner. Lichens are associations of a fungus with a cyanobacterium, a unicellular photosynthetic eukaryote, or both. Mycorrhizae (singular mycorrhiza) are associations between specific fungi and the roots of plants. In such associations the fungus obtains organic compounds from its photosynthetic partner, but provides it with minerals and water so that the partner's nutrition is also promoted. We will discuss lichens and mycorrhizae more thoroughly later in this chapter.

Most fungi reproduce both asexually and sexually

Both asexual and sexual reproduction are common among the fungi. Asexual reproduction takes several forms:

- The production of (usually) haploid spores within structures called sporangia.

Roundworm

Fungal loop

30.5 Some Fungi Are Predators

A nematode (roundworm) is trapped in sticky loops of the soil-dwelling fungus *Arthrobotrys anthonia*.

- The production of naked spores (not enclosed in sporangia) at the tips of hyphae; such spores are called conidia (from the Greek *kōnis*, "dust").
- Cell division by unicellular fungi—either a relatively equal division or an asymmetrical division in which a tiny bud is produced.
- Simple breakage of the mycelium.

Sexual reproduction in many fungi features an interesting twist. There is often no morphological distinction between female and male structures, or between female and male individuals. Rather, there is a genetically determined distinction between two or more mating types. Individuals of the same mating type cannot mate with one another, but they can mate with individuals of another mating type. This distinction prevents self-fertilization. Individuals of different mating types differ genetically from one another, but are often visually and behaviorally indistinguishable. Many protists also have mating type systems.

In many fungi, the zygote nuclei formed by sexual reproduction are the only diploid nuclei in the life cycle. These nuclei undergo meiosis, producing haploid nuclei that become incorporated into spores. Haploid fungal spores, whether produced sexually in this manner or asexually, germinate, and their nuclei divide mitotically to produce hyphae.

Many fungal life cycles include a dikaryon stage

The hyphae of some Zygomycota, Ascomycota, and Basidiomycota have a nuclear configuration other than the familiar haploid or diploid. In these fungi, sexual reproduction begins in an unusual way: The cytoplasm of two individuals of opposite mating types fuse (plasmogamy) long before their nuclei fuse (karyogamy), so that two genetically different haploid nuclei exist within the same hypha. This hypha is called a dikaryon (having two nuclei). Because the two nuclei differ genetically, the hypha is also called a heterokaryon (having different nuclei).

Eventually, specialized fruiting structures form, within which the pairs of dissimilar nuclei—one from each parent—fuse, giving rise to zygotes long after the original "mating." The zygote nucleus undergoes meiosis, producing four haploid nuclei. The mitotic descendants of those nuclei become the nuclei of the next generation of hyphae.

The reproduction of such fungi displays several unusual features. First, there are no gamete cells, only gamete nuclei. Second, there is never any true diploid tissue, although for a long period the genes of both parents are present in the dikaryon and can be expressed. In effect, these hyphae are neither diploid ($2n$) nor haploid (n); rather, they are dikaryotic ($n + n$). A harmful recessive mutation in one nucleus may be compensated for by a normal allele on the same chromosome in the other nucleus. Dikaryosis is perhaps the most significant of the genetic peculiarities of the fungi.

Finally, although Zygomycota, Ascomycota, and Basidiomycota grow in moist places, their gamete nuclei are not motile and are not released into the environment. Therefore, liquid water is not required for fertilization.

Some fungi are pathogens

Fungal pathogens are a major cause of death among people with compromised immune systems. Most patients with AIDS die

of fungal diseases, such as the pneumonia caused by *Pneumocystis carinii* or the incurable diarrhea caused by some other fungi. *Candida albicans* and certain other yeasts also cause severe diseases in individuals with AIDS and in individuals taking immunosuppressive drugs. Such fungal diseases are a growing international health problem. Our limited understanding of the basic biology of these fungi still hampers our ability to treat the diseases they cause.

Various fungi cause other, less threatening human diseases, such as ringworm and athlete's foot. Still others are responsible for plant diseases that affect human food supplies. These diseases include black stem rust of wheat and other diseases of wheat, corn, and oats. Fungal diseases of plants have cost billions of dollars in crop losses.

Diversity in the Kingdom Fungi

Each of the four phyla of the kingdom Fungi appears to be monophyletic (Figure 30.6). Because the imperfect fungi (deuteromycetes) are polyphyletic, we will not give them phylum status. In this section on fungal diversity, we'll consider the four phyla—Chytridiomycota, Zygomycota, Ascomycota, and Basidiomycota—and we'll discuss the status of the deuteromycetes.

Chytrids probably resemble the ancestral fungi

The earliest-diverging fungal lineage is the chytrids (phylum Chytridiomycota). These aquatic microorganisms have sometimes been classified as protists. We place chytrids among the fungi because their cell walls consist primarily of chitin and because molecular evidence indicates that they and the other fungi form a monophyletic group.

Chytridiomycota were the first to branch away.

Common ancestor

Basidiomycota

Figure 30.6 Phytogeny of the Fungi

Four phyla are recognized among the fungi. In addition, the imperfect fungi, or Deuteromycetes, functions as a "holding group" for fungal species whose status is yet to be determined.

534 CHAPTER THIRTY

Zygomycota

Ascomycota

Basidiomycota

Chytrids are either parasitic (on organisms such as algae, mosses, and nematodes) or saprobic, obtaining nutrients by breaking down dead organic matter. (Chytrids in the compound stomachs of foregut-fermenting animals may be an exception, living in a mutualistic association with their hosts.) Most chytrids live in freshwater habitats or in moist soil, but some are marine. Some chytrids are unicellular; others have mycelia made up of branching chains of cells. Chytrids reproduce both sexually and asexually, but they do not have a dikaryon stage.

Allomyces, a well-studied genus of chytrids, displays alternation of generations. A haploid zoospore (spore with flagella) comes to rest on dead plant or animal material in water and germinates to form a small haploid organism. That produces female and male gametangia (gamete cases) (Figure 30.7). The male gametangia are smaller than the female gametangia and possess a light orange pigment. Mitosis in the gametangia results in the formation of haploid gametes, each with a single nucleus.

Both female and male gametes have flagella. The motile female gamete produces a pheromone, a chemical that attracts the swimming male gamete. The gametes fuse in pairs, and then their nuclei fuse to form a diploid zygote. Mitosis and cytokinesis in the zygote gives rise to a small diploid organism, which produces numerous diploid flagellate zoospores. These diploid zoospores disperse and germinate to form more diploid organisms. Eventually, the diploid organism produces thick-walled resting sporangia that can survive unfavorable conditions such as dry weather or freezing. Nuclei in the resting sporangia

eventually undergo meiosis, giving rise to haploid zoospores that are released into the water and begin the cycle anew.

Chytrids are the only fungi that have flagella at any life cycle stage. We speculate that the protist ancestor of the fungi possessed flagella, because the phylum Chytridiomycota

male gametangia contain male gametes.

Allomyces sp.

30.7 Reproductive Structures of a Chytrid

The haploid gametes produced in these gametangia will fuse with another gamete to form a diploid organism.

cota was the first fungal group to diverge from the others (see Figure 30.6). The same protist ancestor gave rise to the protist group Choanoflagellida and to the animal kingdom. A key event in the evolution of the fungi after the chytrids diverged from the others was the loss of flagella.

Julm Zygomycetes reproduce sexually by fusion Vfljv of two gametangia

Most zygomycetes (phylum Zygomycota) have coenocytic hyphae (hyphae without regularly occurring septa). They produce no motile cells, and only one diploid cell—the zygote—appears in the entire life cycle. The mycelium of a zygomycete spreads over its substrate, growing forward by means of specialized hyphae. Most zygomycetes do not form a fleshy fruiting body; rather, the hyphae spread in an apparently random fashion, with occasional stalked sporangio-phores reaching up into the air (Figure 30.8).

Almost 900 species of zygomycetes have been described. A very important group of zygomycetes serves as the fungal partners in the most common type of mycorrhizal association with plant roots. A zygomycete that you may be more familiar with is Rhizopus stolonifer, the black bread mold. Rhizopus reproduces asexually by producing many stalked sporangiophores, each bearing a single sporangium containing hundreds of minute spores (Figure 30.9f). Other zygomycetes have sporangiophores with many sporangia. As in other filamentous fungi, the spore-forming structure is separated from the rest of the hypha by a wall.

Zygomycetes reproduce sexually when adjacent hyphae of two different mating types release pheromones, which cause them to grow together. These hyphae produce ga-

metangia that fuse to form zygosporangia containing zygospores (Figure 30. 9b). The zygosporangia develop thick, multilayered walls that protect the zygospores. The highly resistant zygospores may remain dormant for months before their nuclei undergo meiosis and a sporangium sprouts. The sporangium contains the products of meiosis: haploid nuclei that are incorporated into spores. These spores disperse and germinate to form a new generation of haploid hyphae.

The sexual reproductive structure of ascomycetes is an ascus

The ascomycetes (phylum Ascomycota) are a large and diverse group of fungi distinguished by the production of sacs called asci (singular ascus) (Figure 30.10). The ascus is the characteristic sexual reproductive structure of the ascomycetes. Ascomycete hyphae are segmented by more or

Ascus

Ascospores

30.10 Asci and Ascospores

The ascomycetes are characterized by the production of ascospores within sacs called asci. Ascospores are the products of meiosis followed by a single mitotic division. Ascospores and asci do not mature all at once, and they may abort, so not every ascus in this micrograph contains eight mature ascospores.

less regularly spaced septa. A pore in each septum permits extensive movement of cytoplasm and organelles (including the nuclei) from one segment to the next.

The approximately 30,000 known species of ascomycetes can be divided into two broad groups, depending on whether the asci are contained within a specialized fruiting structure. Species that have this fruiting structure, the ascocarp, are collectively called euascomycetes ("true ascomycetes"); those without ascocarps are called hemi-ascomycetes ("half ascomycetes").

Chytridiomycota

Zygomycota

Basidiomycota

hemiascomycetes. Most hemiascomycetes are microscopic, and many species are unicellular. Perhaps the best known are the ascomycete yeasts, especially baker's or brewer's yeast (*Saccharomyces cerevisiae*; see Figure 30.2). These yeasts are among the most important domesticated fungi. *S. cerevisiae* metabolizes glucose obtained from its environment to ethanol and carbon dioxide. It forms carbon dioxide bubbles in bread dough and gives baked bread its light texture. Although baked away in bread making, the ethanol and carbon dioxide are both retained in beer. Other yeasts live on fruits such as figs and grapes and play an important role in the making of wine.

Hemiascomycete yeasts reproduce asexually either by fission or by budding (the outgrowth of a new cell from the surface of an old one; see Figure 30.2). Sexual reproduction takes place when two adjacent haploid cells of opposite mating types fuse. (We discussed the genetics of yeast mating types in Chapter 14.) In some species, the resulting zygote buds to form a diploid cell population; in others, the zygote nucleus undergoes meiosis immediately. When these diploid nuclei undergo meiosis, the entire cell becomes an ascus. Depending on whether the products of meiosis then undergo mitosis, a yeast ascus usually has either eight or four ascospores (see Figure

Yeasts, especially *Saccharomyces cerevisiae*, are frequently used in molecular biological research. Just as *E. coli* is the best-studied prokaryote, *S. cerevisiae* is the most completely studied eukaryote.

euscomycetes. The euscomycetes include the filamentous fungi known as molds. Among them are several common molds, including *Neurospora*, the pink molds, one of which Beadle and Tatum used in their pioneering work on biochemical genetics (see Figure 12.1). Many euscomycetes are parasites on higher plants. Chestnut blight and Dutch elm disease are caused by euscomycetes. The powdery mildews are euscomycetes that infect cereal grains, lilacs, and roses, among many other plants. They can be a serious problem to grape growers, and a great deal of research has focused on ways to control these agricultural pests.

The euscomycetes also include the cup fungi (Figure 30.11f and b). In most of these organisms the fruiting structures are cup-shaped and can be as large as several centimeters across. The inner surfaces of the cups are covered with a mixture of both sterile filaments and asci, and they produce huge numbers of spores. Although these fleshy structures appear to be composed of distinct tissue layers, microscopic examination shows that their basic organization is still filamentous—a tightly woven mycelium.

Two particularly delicious cup fungus fruiting structures are morels (Figure 30.11f) and truffles. Truffles grow underground, in a mutualistic association with the roots of some species of oaks. Europeans traditionally used pigs to find truffles because some truffles secrete a substance that has

(b) *Sarcoscypha coccinea*

an odor similar to a pig's sex attractant. Unfortunately, pigs also eat truffles, so dogs are now the usual truffle hunters.

Penicillium is a genus of green molds, of which some species produce the antibiotic penicillin, presumably for defense against competing bacteria. Two species, *P. camemberti* and *P. roquefortii*, are the organisms responsible for the characteristic flavors of Camembert and Roquefort cheeses, respectively.

Brown molds of the genus *Aspergillus* are important in some human diets. *A. tamarii* acts on soybeans in the production of soy sauce, and *A. oryzae* is used in brewing the Japanese alcoholic beverage sake. Some species of *Aspergillus* that grow on nuts such as peanuts and pecans produce extremely carcinogenic (cancer-inducing) compounds called aflatoxins.

The euscomycetes reproduce asexually by means of mating structures called conidia that form at the tips of specialized hyphae (Figure 30.12). Small chains of conidia are

30.72 Conidia

produced by the millions and can survive for weeks in nature. The conidia are what give molds their characteristic colors.

The sexual reproductive cycle of euascomycetes includes the formation of a dikaryon (Figure 30.13). Most euascomycetes form mating structures, some "female" and some "male."

Nuclei from a male structure on one hypha enter a female mating structure on a hypha of a compatible mating type. Dikaryotic ascogenous (ascus-forming) hyphae de-

velop from the now dikaryotic female mating structure. The introduced nuclei divide simultaneously with the host nuclei. Eventually asci form at the tips of the ascogenous hyphae. Only with the formation of asci do the nuclei finally fuse. Both nuclear fusion and the subsequent meiosis of the resulting diploid nucleus take place within individual asci. The meiotic products are incorporated into as-

30.14 Basidiomycete Fruiting Structures

The fruiting structures of the basidiomycetes are probably the most familiar structures produced by fungi, (a) When raindrops hit them, these puffballs will release clouds of spores for dispersal, (b) A member of a highly poisonous mushroom genus, *Amanita*. (c) This edible bracket fungus is parasitizing a tree.

cospores that are ultimately shed by the ascus to begin the new haploid generation.

The sexual reproductive structure of basidiomycetes is a basidium

About 25,000 species of basidiomycetes (phylum Basidiomycota) have been described. Basidiomycetes produce some of the most spectacular fruiting structures found anywhere among the fungi. These fruiting structures include puffballs (which may be more than half a meter in diameter), mushrooms of all kinds, and the giant bracket fungi often encountered on trees and fallen logs in a damp forest (Figure 30.14). There are more than 3,250 species of mushrooms, including the familiar *Agaricus bisporus* you may enjoy on your pizza, as well as poisonous species, such as members of the genus *Amanita*. Bracket fungi do great damage to cut lumber and stands of timber. Some of the most damaging plant pathogens are basidiomycetes, including the smut fungi (see Figure 30.1a) that parasitize cereal grains. In contrast, other basidiomycetes contribute to the well-being of plants as fungal partners in mycorrhizae.

Basidiomycete hyphae characteristically have septa with small, distinctive pores. The basidium (plural basidia), a swollen cell at the tip of a hypha, is the characteristic sexual reproductive structure of the basidiomycetes. It is the site of nuclear fusion and meiosis. Thus, the basidium plays the same role in the basidiomycetes as the ascus does in the ascomycetes and the zygosporangium does in zygomycetes.

The life cycle of the basidiomycetes is shown in Figure 30.15. After nuclei fuse in the basidium, the resulting

Chytridiomycota

(c) *Laetiporus sulphureus*

diploid nucleus undergoes meiosis, and the four resulting haploid nuclei are incorporated into haploid basidiospores, which

form on tiny stalks. These basidiospores typically are forcibly discharged from their basidia and then germinate, giving rise to haploid hyphae. As these hyphae grow, haploid hyphae of different mating types meet and fuse, forming dikaryotic hyphae, each cell of which contains two nuclei, one from each parent hypha. The dikaryotic mycelium grows and eventually produces fruiting structures. The dikaryotic phase may persist for years—some basidiomycetes live for decades or even centuries.

The elaborate fruiting structure of some fleshy basidiomycetes, such as the gill mushroom in Figure 30.15, is topped by a cap, or pileus, which has structures called gills on its underside. Enormous numbers of basidia develop on the surfaces of the gills. The basidia discharge their spores into the air spaces between adjacent gills, and the spores sift down into air currents for dispersal and germination as new haploid mycelia.

Imperfect fungi lack a sexual stage

Mechanisms of sexual reproduction readily distinguish members of the four phyla of fungi from one another. But many fungi, including both saprobes and parasites, lack sexual stages entirely; presumably these stages have been lost during evolution or have not yet been found. Classifying these fungi as belonging to any of the four major phyla was at one time difficult, but biologists now can classify most such fungi on the basis of DNA sequences.

Fungi that have not yet been placed in any of the existing phyla are grouped together as the imperfect fungi, or deuteromycetes. Thus, the deuteromycete group is a holding area for species whose status is yet to be resolved. At present, about 25,000 species are classified as imperfect fungi. Some taxonomists, preferring to emphasize convenience of identification over strict phylogenetic considerations, treat the imperfect fungi as a paraphyletic phylum, Deuteromycota.

If sexual structures are found on a fungus classified as a deuteromycete, the fungus is reassigned to the appropriate phylum. That happened, for example, with a fungus that produces plant growth hormones called gibberellins. Originally classified as the deuteromycete *Fusarium moniliforme*, this fungus was later found to produce asci, whereupon it was renamed *Gibberella fujikuroi* and transferred to the phylum Ascomycota.

Fungal Associations

Earlier in this chapter we mentioned mycorrhizae and lichens, in which fungi live in intimate association with other organisms. Now that we have learned a bit about fungal diversity, let's consider mycorrhizae and lichens in greater detail.

Mycorrhizae are essential to many plants

Almost all tracheophytes enjoy a mutually beneficial symbiotic association with fungi. Unassisted, the root hairs of such plants do not absorb enough water or minerals to sustain maximum growth. However, the roots usually become infected with fungi, forming an association called a mycorrhiza.

540 CHAPTER THIRTY

30.76 Mycorrhizal Associations

(a) Ectomycorrhizal fungi wrap themselves around the plant root, increasing the area available for absorption of water and nutrients, (b) Endomycorrhizae infect the root internally.

Hyphae of the fungus *Pisolithus tinctorius* cover a eucalyptus root.

The shapes filling much of this soybean root cell are sections through the hyphae of the endomycorrhizal fungus *Glomus*

caledonius.

In ectomycorrhizae, the fungus wraps around the root, and its mass is often as great as that of the root itself (Figure 30.16rt). The hyphae of the fungi attached to the root increase the surface area for the absorption of water and minerals, and the mass of the mycorrhiza, like a sponge, holds water efficiently in the neighborhood of the root. Infected roots characteristically branch extensively and become swollen and club-shaped. In endomycorrhizae, the infection is internal to the root, with no hyphae visible on the root surface (Figure 30.16b).

The symbiotic fungus-plant association of a mycorrhiza is important to both partners. The fungus obtains important organic compounds, such as sugars and amino acids, from the plant. In return, the fungus greatly increases the absorption of water and minerals (especially phosphorus) by the plant. The fungus may also provide certain growth hormones, and may protect the plant against attack by microorganisms. Plants that have active mycorrhizae typically are a deeper green and may resist drought and temperature extremes better than plants of the same species that have little mycorrhizal development. Attempts to introduce some plant species to new areas have failed until a bit of soil from the native area (presumably containing the fungus necessary to establish mycorrhizae) was provided.

The partnership between plant and fungus results in a plant better adapted for life on land. It has been suggested that the evolution of this symbiotic association was the single most important step leading to the colonization of the terrestrial environment by living things. Fossils of mycorrhizal structures more than 300 million years old have been found, and some rocks dating back 460 million years contain structures that appear to be fossilized fungal spores.

Some liverworts, which are among the most ancient terrestrial plants (see Chapter 28), form mycorrhizae. Certain plants that live in nitrogen-poor habitats, such as cranberry bushes and orchids, invariably have mycorrhizae. Orchid seeds will not germinate in nature unless they are already infected by the fungus that will form their mycorrhizae. Plants that lack chlorophyll always have mycorrhizae,

which they often share with the roots of green, photosynthetic plants.

Lichens grow where no eukaryote has succeeded

A lichen is not a single organism, but rather a meshwork of two radically different organisms: a fungus and a photo-synthetic microorganism. Together the organisms constituting a lichen can survive some of the harshest environments on Earth. The flora of Antarctica, for example, features more than 100 times as many species of lichens as of plants.

In spite of this hardiness, lichens are very sensitive to air pollution because they are unable to excrete toxic substances that they absorb. Hence they are not common in industrialized cities. Because of their sensitivity, lichens are good biological indicators of air pollution.

The fungal components of most lichens are ascomycetes, but some are basidiomycetes or imperfect fungi (only one zygomycete serving as the fungal component of a lichen has been reported). The photosynthetic component may be either a cyanobacterium or a unicellular green alga. Relatively little experimental work has focused on lichens, perhaps because they grow so slowly—typically less than 1 centimeter per year.

There are about 13,500 "species" of lichens; their fungal components may constitute as many as 20 percent of all fungal species. Lichens are found in all sorts of exposed habitats: on tree bark, open soil, or bare rock. Reindeer "moss" (actually not a moss at all, but the lichen *Cladonia subtenuis*) covers vast areas in arctic, subarctic, and boreal regions, where it is an important part of the diets of reindeer and other large mammals. Lichens come in various forms and colors. Crustose (crustlike) lichens look like colored powder dusted over their substrate (Figure 30.17a); foliose (leafy) and fruticose (shrubby) lichens may have complex forms (Figure 30.17b).

The most widely held interpretation of the lichen relationship is that it is a type of mutually beneficial symbiosis. The hyphae of the fungal mycelium are tightly pressed against the photosynthetic cells of the alga or cyanobacterium and sometimes even invade them. The bacterial or

30.7 7 Lichen Body Forms

Lichens fall into three principal classes based on their body form. (a) Foliose and crustose lichens grow on otherwise bare rock, (b) A miniature jungle of fruticose lichens.

algal cells not only survive these indignities, but continue their growth and photosynthesis. In fact, algal cells in a lichen "leak" photosynthetic products at a greater rate than do similar cells growing on their own. On the other hand, photosynthetic cells from lichens grow more rapidly on their own than when combined with a fungus. On this basis, we could consider lichen fungi as parasitic on their photosynthetic partners.

Lichens can reproduce simply by fragmentation of the vegetative body, which is called the thallus, or by means of

specialized structures called soredia (singular soredium). Soredia consist of one or a few photosynthetic cells surrounded by fungal hyphae (Figure 30.1877). The soredia become detached, are dispersed by air currents, and upon arriving at a favorable location, develop into a new lichen. Alternatively, if the fungal partner is an ascomycete or a basidiomycete, it may go through its sexual cycle, producing either ascospores or basidiospores. When these spores are discharged, however, they disperse alone, unaccompanied by the photosynthetic partner, and thus may not be capable of reestablishing the lichen association. Nevertheless, many lichens produce characteristic fruiting structures containing asci or basidia.

Visible in a cross section of a typical foliose lichen are a tight upper region of fungal hyphae, a layer of cyanobacte-

L&3&SI

ria or algae, a looser hyphal layer, and finally hyphal rhizoids that attach the whole structure to its substrate (Figure 30.15). The meshwork of fungal hyphae takes up some nutrients needed by the photosynthetic cells and provides a suitably moist environment for them by holding water tenaciously. The fungi derive fixed carbon from the photosynthesis of the algal or cyanobacterial cells.

Lichens are often the first colonists on new areas of bare rock. They satisfy most of their needs from the air and from rainwater, augmented by minerals absorbed from dust. A lichen begins to grow shortly after a rain, as it begins to dry. As it grows the lichen acidifies its environment slightly, and this acid contributes to the slow breakdown of rocks, an early step in soil formation. After further drying, the lichen's photosynthesis ceases. The water content of the lichen may drop to less than 10 percent of its dry weight, at which point it becomes highly insensitive to extremes of temperature.

Whether living on their own or in symbiotic associations, fungi have spread successfully over much of Earth since their origin from a protist ancestor. That ancestor also gave rise to the choanoflagellates and the animal kingdom, the group we'll consider in the next three chapters.

Chapter Summary

- Fungi are the principal degraders of dead organic matter in the biosphere. Fungi are nutritional partners of almost all eukaryotic plants. Some fungi are serious pathogens of plants and animals, including humans.

General Biology of the Fungi

- Fungi are heterotrophic eukaryotes with absorptive nutrition. They may be saprobes, parasites, or mutualists. Review Figure 30.4
- The yeasts are unicellular.
- The bodies of other fungi are composed of chitinous-walled, multinucleate hyphae, often massed to form a mycelium. The filamentous hyphae give fungi a large surface area-to-volume ratio, enhancing their ability to absorb nutrients. The hyphae usually have incomplete partitions (septa) that do not divide them into separate cells. Review Figure 30.5
- Fungi reproduce asexually by means of spores formed within sporangia, by conidia formed at the tips of hyphae, by budding, or by fragmentation.
- Fungi reproduce sexually when hyphae or motile cells of different mating types meet and fuse.
- In addition to the haploid and diploid states, many fungi demonstrate a third nuclear condition: the dikaryotic, or

Stable Review Figure 30.13

Diversity in the Kingdom Fungi

- The kingdom Fungi consists of four phyla: Chytridiomycota, Zygomycota, Ascomycota, and Basidiomycota. These phyla differ in their reproductive structures, mechanisms of reproduction, and less importantly, the presence and form of their hyphae. Review Figure 30.6, Table 30.1
- Chytrids, with their flagellated zoospores and gametes, probably resemble the ancestral fungi.
- Zygomycetes reproduce sexually by fusion of gametangia. Review Figure 30.9
- The sexual reproductive structure of ascomycetes is an ascus containing ascospores. The ascomycetes are divided into two groups, euascomycetes and hemiascomycetes, on the basis of whether they have an ascocarp, or fruiting structure. Review Figure 30.13
- The sexual reproductive structure of basidiomycetes is a basidium, a swollen cell bearing basidiospores. Review Figure 30.15
- Imperfect fungi (deuteromycetes) lack sexual structures, but DNA sequencing can sometimes identify the phylum to which they belong.

Fungal Associations

- Mycorrhizae, associations of fungi with plant roots, enhance the ability of the roots to absorb water and nutrients.
- Lichens, mutualistic combinations of a fungus with a cyanobacterium or a green alga, are found in some of the most inhospitable environments on the planet. Review Figure 30.18

For Discussion

1. You are shown an object that looks superficially like a pale green mushroom. Describe at least three criteria (including anatomical and chemical traits) that would enable you to tell whether the object is a piece of a plant or a piece of a fungus.
2. Differentiate among the members of the following pairs of related terms:
 - a. hypha/mycelium
 - b. euascomycete/hemiascomycete
 - c. ascus/basidium
 - d. ectomycorrhiza/endomycorrhiza
3. For each type of organism listed below, give a single characteristic that may be used to differentiate it from the other, related organism(s) in parentheses.
 - a. Zygomycota (Ascomycota)
 - b. Basidiomycota (deuteromycetes)
 - c. Ascomycota (Basidiomycota)
 - d. baker's yeast {*Neurospora crassa*}
4. Many fungi are dikaryotic during part of their life cycle. Why are dikaryons described as $n + n$ instead of $2n$?
5. If all the fungi on Earth were suddenly to die, how would the surviving organisms be affected? Be thorough and specific in your answer.
6. How might the first mycorrhizae have arisen?
7. What might account for the ability of lichens to withstand the intensely cold environment of Antarctica? Be specific in your answer.

31

Animal Origins and Lophotrochozoans

In 1822, NEARLY 40 YEARS BEFORE DARWIN wrote *The Origin of Species*, French naturalist E. Geoffroy Saint-Hilaire was examining a lobster. He noticed that when he viewed the lobster with its ventral surface up, its central nervous system was located above its digestive tract, which in turn was located above its heart—the same relative positions these systems have in mammals viewed dorsally. His observation led Saint-Hilaire to conclude that the differences between arthropods and vertebrates could be explained if the embryos of one of those groups had been inverted during development.

Saint-Hilaire's suggestion was regarded as totally preposterous at the time and was largely dismissed until recently. However, the discovery of two genes that influence a system of extracellular signals involved in development has lent new support to Saint-Hilaire's seemingly outrageous hypothesis.

A vertebrate gene called *chordin* helps establish cells on one side of the embryo as dorsal, the other as ventral. A probably homologous gene in fruit flies,* called *sog*, acts in a similar manner, but has the opposite effect. Fly cells where *sog* is active become ventral, whereas vertebrate cells expressing *chordin* become dorsal (see Figure 16.19). However, when *sog* mRNA is injected into the frog *Xenopus*, a vertebrate, it causes dorsal development. *Chordin* mRNA injected into flies promotes ventral development. In both cases, injection of the mRNA promotes the development of the portion of the embryo that contains the central nervous system!

Chordin and *sog* are among the many genes that appear to regulate similar functions in very different organisms. There

"Insects (such as fruit flies) are arthropods and belong to the same evolutionary lineage as crustaceans (such as the lobster), as we will discuss in Chapter 32.

Genes that Control Development

The human and the lobster carry similar genes that control the development of the body axis. A lobster's nervous system runs up its ventral (belly) surface, while its circulatory system is dorsal (down its back). In vertebrates such as humans, similar genes position these two systems inversely to those of the lobster.

are several almost universal animal genes that help transform a single-celled egg into a multicellular adult. Such genes are providing evolutionary biologists with information that can help them understand relationships among animal lineages that separated from one another in ancient times. As we saw in Chapter 23 new knowledge about gene functions and gene sequences provides some of the most powerful data being used in modern phylogenetic investigations to infer evolutionary relationships among organisms.

In this chapter we will first discuss how biologists infer evolutionary relationships among animals and review the defining characteristics of the animal way of life. Then we will describe several lineages of simple animals. Finally, we will describe the lophotrochozoans, one of the three great evolutionary lineages of animals. The next two chapters will discuss the other two great animal lineages: the ecdysozoans and the deuterostomes.

Descendants of a Common Ancestor

Biologists have long debated whether animals arose once or several times from protist ancestors, but enough molecular and morphological evidence has now been assembled to indicate that, with the possible exception of sponges (Porifera), the kingdom Animalia is a monophyletic group—that is, all animals are descendants of a single ancestral lineage.

544 CHAPTER THIRTY-ONE

This conclusion is supported by the fact that all animals share a set of derived traits:

- ▶ Similarities in their 5S and 18S ribosomal RNAs
- ▶ Special types of cell-cell junctions: tight junctions, desmosomes, and gap junctions (see Figure 5.6)
- ▶ A common set of extracellular matrix molecules, including collagen (see Figure 4.28)

Animals evolved from ancestral colonial flagellated protists as a result of division of labor among their aggregated cells. Within these ancestral colonies of cells—perhaps analogous to those still existing in the chlorophyte *Volvox* or some colonial choanoflagellates (see Figures 27.25a and 27.28)—some cells became specialized for movement, others for nutrition, and still others differentiated into gametes. Once the division of labor had begun, these units continued to differentiate while improving their coordination with other working groups of cells. Such coordinated groups of cells evolved into the larger and more complex organisms that we now call animals.

The Animal Way of Life

What traits characterize the organisms we call animals? Animals are multicellular organisms that must take in preformed organic molecules because they cannot synthesize them from inorganic chemicals. They acquire these organic molecules by ingesting other organisms, either living or dead, and digesting them inside their bodies. To acquire these organic molecules, animals must expend energy to move themselves through the environment to find food, to position themselves where food will pass by them, or to move the environment and the food it contains to them.

The foods animals eat include most other members of the animal kingdom, as well as members of all other evolutionary lineages. Much of the diversity of animal sizes and shapes evolved as animals acquired the ability to capture and eat many different kinds of foods, and to avoid becoming food for other animals.

The need to move in search for food has favored sensory structures that provide animals with detailed information about their environment, and nervous systems able to receive and coordinate this information. Consequently, most animals are behaviorally much more complex than plants. Because animals ingest chemically complex foods, they expend considerable energy to maintain relatively constant internal conditions while taking in foods that vary chemically.

A real appreciation of animal structure and functioning is best achieved through firsthand experience in the field and laboratory. The accounts in this chapter and the following two serve as an orientation to the major groups of animals, their similarities and differences, and the evolutionary pathways that resulted in the current richness of animal evolutionary lineages and species. But how do biologists infer evolutionary relationships among animals?

Clues to Evolutionary Relationships among Animals

Biologists use a variety of traits to infer animal phylogenies. As we discussed in Chapters 23 and 24, clues to these relationships are found in the fossil record, in patterns of embryonic development, in the comparative morphology and physiology of living and fossil animals, and in the structure of their molecules.

Patterns of early development evolved very slowly in some animal lineages. For this reason, biologists have traditionally based their classifications of the major lineages of animals on developmental patterns. More recently, comparative molecular data from small subunit rRNA and mitochondrial genes also have been used. These two types of evidence suggest similar animal phylogenies.

31.1 Animal Body Cavities

The three major types of animal body cavities, (a) Acoelomates do not have enclosed body cavities, (b) Pseudocoelomates have only one layer of muscle, lying outside the body cavity, (c) Coelomates have a peritoneum surrounding the internal organs; the body cavities of some, such as this earthworm, are segmented.

(c) Coelomate

Roundworm

Earthworm

Gut (endoderm)

Internal organ

Peritoneum (mesoderm)

Coelom

Muscle (mesoderm)

Ectoderm

Acoelomates do not have enclosed body cavities.

Pseudocoelomates have a cavity lined with muscle (mesoderm) on the outer side, but no mesoderm surrounds the internal organs.

Coelomates possess body cavities with mesoderm on both the outer side and surrounding internal organs.

Using this wide variety of comparative data, zoologists have concluded that the sponges, cnidarians, and ctenophores separated from the remaining animal lineages early in evolutionary history. They have divided the remaining animals into two major lineages: the protostomes and the deuterostomes.

In the common ancestor of the protostomes and the deuterostomes, the pattern of early cell division in the fertilized egg—called cleavage—was radial. During radial cleavage, cells divide along a plane either parallel to or at right angles to the long axis of the fertilized egg. This pattern persisted during the evolution of deuterostomes and in many protostome lineages, but spiral cleavage evolved in one major protostome lineage. In spiral cleavage, the plane of cell division is oblique to the long axis of the egg, causing the cells to be arranged in a spiral pattern.

Other developmental patterns typically differ between protostomes and deuterostomes. Cleavage of the fertilized egg in protostomes is determinate; that is, if the egg is allowed to divide a few times and the cells are then separated, each cell develops into only a partial embryo. In contrast, cleavage in deuterostomes typically is indeterminate; cells separated after several cell divisions can still develop into complete embryos. We see this phenomenon in humans in identical twins. Among deuterostomes, the mouth of the embryo originates some distance away from the embryonic structure called the blastopore, which becomes the anus. Among protostomes, the mouth arises from or near the blastopore.

During development from a single-celled zygote to a multicellular adult, animals form layers of cells. The embryos of diploblastic animals have only two cell layers: an outer ectoderm and an inner endoderm. The embryos of triploblastic animals have a third layer, the mesoderm, which lies between the ectoderm and the endoderm.

Fluid-filled spaces, called body cavities, lie between the cell layers of the bodies of many kinds of animals. The type of body cavity an animal has strongly influences how it can move.

Common ancestor of all animals

Animals that lack an enclosed body cavity are called acoelomates. In these animals, the space between the gut and the body wall is filled with masses of cells called mesenchyme (Figure 31.1a). Another group of animals, the pseudocoelomates, have a body cavity called the pseudocoel. The pseudocoel is a liquid-filled space in which many of the body organs

37.2 A Probable Phylogeny of Animals

The evolutionary tree that we will use in this chapter and the following two postulates that animals are monophyletic. The traits highlighted by red circles on the tree will be explained as we discuss the different phyla.

Indeterminate cleavage, blind gut, two cell layers

are suspended, but control over body shape is crude because a pseudocoel has muscles only on the outside (Figure 31.1b). ► Coelomate animals have a coelom, a body cavity that develops within the embryonic mesoderm. It is lined with a special structure called the peritoneum, and has muscles both inside and outside. The internal organs of coelomates are slung in pouches of peritoneum rather than being suspended within the body cavity (Figure 31.1c).

An animal with a coelom has better control over the movement of the fluids it contains, but control is limited if the animal has only a single, large body cavity. Control is improved if the coelom is separated into compartments or segments so that circular and longitudinal muscles in each individual segment can change its shape independently of the other segments. Segmentation of the coelom evolved several different times among both protostomes and deuterostomes.

The phylogeny of animals we adopt in this book is based on analyses of many developmental, structural (from both living and fossil animals), and molecular traits. Figure 31.2 shows the postulated order of splitting of the major lineages in animal evolution. New information continues to modify and refine our understanding of the details of phylogenetic relationships among animals. Nonetheless, the division of the animals into the lineages shown here is supported by many types of data.

Body Plans Are Basic Structural Designs

The entire structure of an animal, its organ systems, and the integrated functioning of its parts are known as its body plan. Animals in many (but not all) lineages have evolved greater body complexity over time.

A fundamental aspect of an animal's body plan is its overall shape, described as its symmetry. A symmetrical animal can be divided along at least one plane into similar halves. Animals that have no plane of symmetry are said to

37.3 Body Symmetry

Most animals are either biradially or bilaterally symmetrical. Biradially symmetrical animals appear similar to radially symmetrical ones.

Two planes, at right angles to each other, divide the animal into similar halves.

The fish, a vertebrate, has bilateral symmetry.

Dorsal

Vent

be asymmetrical. Many sponges are asymmetrical, but most animals have some kind of symmetry.

The simplest form of symmetry is spherical symmetry, in which body parts radiate out from a central point. An infinite number of planes passing through the central point can divide a spherically symmetrical organism into similar halves. Spherical symmetry is widespread among protists, but most animals possess other forms of symmetry.

An organism with radial symmetry has one main axis around which its body parts are arranged. A perfectly radially symmetrical animal can be divided into similar halves by any plane that contains the main axis. Some simple sponges and a few other animals, such as some sea anemones, have true radial symmetry.

Most radially symmetrical animals are modified such that only two planes, at right angles to each other, can divide them into similar halves. These animals are said to have biradial symmetry (Figure 31.3a). Three animal phyla—Cnidaria, Ctenophora, and Echinodermata—are composed primarily of radially or biradially symmetrical animals. These animals move slowly or not at all.

Bilateral symmetry is a common characteristic of animals that move freely through their environments. A bilaterally symmetrical animal can be divided into mirror images (left and right sides) by only a single plane that passes through the midline of its body from the front (anterior) to the back (posterior) end (Figure 31.3b). A plane at right angles to the first divides the body into two dissimilar sides; the side of a bilaterally symmetrical animal without a mouth is its dorsal (back) surface; the side with a mouth is its ventral (belly) surface.

Bilateral symmetry is strongly correlated with cephalization: the presence of a head, bearing sensory organs and central nervous tissues, at the anterior end of the animal. Cephalization may have been evolutionary advantageous because the anterior end of a freely moving animal typically encounters new environments first.

Speed is often advantageous for both prey and the predators that pursue them. Fast-moving prey and predators had evolved by the early Cambrian period. To move rapidly, an animal needs some type of skeleton that supports its body and allows body parts to be moved relative to one another. A skeleton may be internal or external, rigid or flexible, and be composed of one, two, or more elements.

The fluid-filled body cavities of early animals functioned as hydrostatic skeletons. Because fluids are relatively incompressible, they move to another part of the cavity when muscles surrounding them contract. If the body tissues around the cavity are flexible, fluids moving from one region cause some other region to expand. Moving fluids can thus move specific body parts, or even the whole animal, provided that temporary attachments can be made to the substrate.

Other forms of skeletons developed in many animal lineages, either as substitutes for, or in combination with, hydrostatic skeletons. Some of these skeletons consist of a single element (snail shells); some have two elements (clam shells); others have many elements (centipedes). Some are internal (vertebrate bones); others are external (crab shells). The form of the body cavity also changed in many animal lineages. Many became divided into compartments. The form of its skeleton and body cavities strongly influences the degree to which an animal can control and change its shape, and thus the complexity of the movements it can perform. What type of body plan and symmetry did the common ancestors of all animals possess? We are not certain, but because evidence suggests that animals evolved from colonies of flagellated cells, they may have been similar in structure to living flagellates.

Sponges: Loosely Organized Animals

The difference between protist colonies and simple multicellular animals is that the cells of animals are differentiated and their activities are coordinated. The lineage leading to modern sponges separated from the lineage leading to all other animals early during animal evolution. Some living

The flow of water through the sponge is shown by blue arrows. The body wall is studded with choanocytes, a type of specialized feeding cell that may be a link between animals and protists (see Figure 27.28).

sponges are still very similar to the probable ancestral colonial protists. Sponges are loosely organized. Even if a sponge is completely disassociated by being strained through a filter, its cells can reassociate into a new sponge.

length—is an aggregation of cells built around a water canal system. A sponge feeds by drawing water into itself and filtering out the small organisms and nutrient particles that flow past the walls of its inner cavity.

Feeding cells with a collar and a flagellum, called choanocytes, line the inside of the water canals. By beating their flagella, the choanocytes cause water to flow into the animal, either by way of small pores that perforate special epidermal cells (in simple sponges) or through intercellular pores (in complex sponges). Water passes into small chambers within the body where food particles are captured by the choanocytes. Water then exits through one or more larger openings called oscula (Figure 31.4).

Between the thin epidermis and the choanocytes is a layer of cells, some of which are similar to amoebas and move about within the body. A supporting skeleton is also present, either in the form of simple or branching spines called spicules or as an elastic, often complex, network of fibers.

Most of the 10,000 species of sponges are marine animals; only about 50 species live in fresh water. Sponges come in a wide variety of sizes and shapes that are adapted to different patterns of water movement (Figure 31.5). Sponges living in intertidal or shallow subtidal environ-

merits, where they are subjected to strong wave action, hug the substrate. Many sponges that live in calm waters are simple, with a single large opening on top of the body. Most sponges that live in flowing water are flattened and are oriented at right angles to the direction of current flow; they intercept water and the prey it contains as it flows past them.

Sponges reproduce both sexually and asexually. In most species, a single individual produces both eggs

and sperm. Water currents carry sperm from one individual to another. Asexual reproduction is by budding and fragmentation.

Cnidarians: Cell Layers and Blind Guts

Animals in all phyla other than the Porifera have distinct cell layers and symmetrical bodies. The next lineage to split off from the main line of animal evolution after the sponges resulted in a phylum of animals—the cnidarians (phylum Cnidaria) — having only two cell layers (diploblastic) and a blind gut (with only one entrance). Within the constraints of this simple body organization, cnidarians evolved a wide variety of ways of making a living.

Cnidarians are simple but specialized carnivores

Cnidarians (phylum Cnidaria) appeared early in evolutionary history and radiated in the late Precambrian. About 10,000 cnidarian species—jelly fishes, sea anemones, corals, and hydrozoans—are living today (Figure 31.6). All but a few are marine. The smallest cnidarians can hardly be seen without a microscope; the largest known jellyfish is 2.5 meters in diameter. These animals are simple but specialized carnivores. The cnidarian body plan combines a low metabolic rate with the ability to capture large prey. These traits allow cnidarians to survive in environments where prey are scarce.

A key feature of cnidarians is tentacles that bear cnidocytes, specialized cells that contain stinging structures called nematocysts that can discharge toxins into their prey (Figure

Porifera

Ctenophora

Lophotrochozoans

PROTOSTOMES

Ecdysozoans

DEUTEROSTOMES

31.7). Cnidocytes allow cnidarians to capture prey larger and more complex than themselves. Nematocysts are responsible for the sting that some jellyfishes and other cnidarians can inflict on human swimmers.

The mouth of a cnidarian is connected to a blind sac called the gastrovascular cavity, which functions in digestion, circulation, and gas exchange. The single opening serves as both mouth and anus. Cnidarians also have epithelial cells with muscle fibers whose contractions enable the animals to move, as well as nerve nets that integrate their body activities.

Cnidarian life cycles

The generalized cnidarian life cycle has two distinct stages, the polyp and the medusa (Figure 31.8), although many species lack one of the stages.

► The sessile polyp stage has a cylindrical stalk attached to the substrate, with tentacles surrounding a mouth located at the opposite end from the site of attachment. This stage is usually asexual, but individual polyps may reproduce by budding, thereby forming a colony.

► The medusa is a free-swimming, sexual stage shaped like a bell or an umbrella. It typically floats with its mouth and tentacles facing downward. Medusae produce eggs and sperm and release them into the water. When an egg is fertilized, it develops into a free-swimming, ciliated larva called a planula that eventually settles to the bottom and transforms into a polyp.

Although the polyp and medusa stages appear very different, they share a similar body plan. A medusa is essentially a polyp without a stalk. Most of the outward differences between polyps and medusae are due to the mesoglea, a mass of jellylike material that lies between the two cell layers. The mesoglea contains few cells and has a low metabolic rate. In polyps, the mesoglea is usually thin; in medusae it is very thick, constituting the bulk of the animal.

During the life cycle of many cnidarians, the usually sessile, asexual polyp alternates with the free-swimming, sexual medusa.

The mesoglea is a jellylike layer with few cells.

As the positions of the mouth and tentacles indicate, the medusa is "upside down" from the polyp—or vice versa.

hydrozoans. Life cycles are diverse among the hydrozoans (class Hydrozoa), a group containing the only freshwater cnidarians. The polyp commonly dominates the life cycle, but some species have only medusae and others only polyps. A few species have solitary polyps, but most hydrozoans are colonial. A single planula eventually gives rise to a colony of many polyps, all interconnected and sharing a continuous gastrovascular cavity (Figure 31.9). Within such a colony, some polyps have tentacles with many nematocysts; they capture prey for the colony. Others lack ten-

31.8 A Generalized Cnidarian Life Cycle

Cnidarians typically have two body forms, one asexual (the polyp) and the other sexual (the medusa).

tacles and are unable to feed, but are specialized for the production of medusae. Still others are fingerlike and defend the colony.

scyphozoans. The several hundred species of the class Scyphozoa are all marine. The mesoglea of their medusae is very thick and firm, giving rise to their common name, jelly fishes. The medusa typically has the form of an inverted cup, and the tentacles with nematocysts extend downward from the margin of the cup.

The medusa, rather than the polyp, dominates the life cycle of scyphozoans. An individual medusa is male or female, releasing eggs or sperm into the open sea. The fertilized egg develops into a small planula that quickly settles on a substrate and changes into a small polyp. This polyp feeds and grows and may produce additional polyps by budding. After a period of growth, the polyp begins to bud off small medusae (Figure 31.10). These small medusae feed, grow, and transform themselves into adult medusae, which are commonly seen during summer in harbors and bays. Thus a polyp that grows from a single fertilized egg is capable of producing many genetically identical medusae that will eventually reproduce sexually.

anthozoans. The roughly 6,000 species of sea anemones and corals that constitute the anthozoans (class Anthozoa) are all marine. Unlike other cnidarians, anthozoans entirely lack the medusa stage of the life cycle. The polyp produces eggs and sperm, and the fertilized egg develops into a planula that develops directly into another polyp. Many species can also reproduce asexually by budding or fission.

Sea anemones (see Figure 31.6c) are solitary. They are widespread in both warm and cold ocean waters. Many sea anemones are able to crawl slowly on the discs with which they attach themselves to the substrate. A few species can swim; some can burrow.

Corals, by contrast, are usually sessile and colonial. The polyps of most corals secrete a matrix of organic molecules upon which calcium carbonate—the eventual skeleton of the coral colony—is deposited. The forms of

31.11 Corals

(a) Many different species of corals and sponges grow together on this reef in the Bahama Islands. (fc>) The green plates of cabbage coral (*Turbinaria* sp.) and the branching staghorn coral (*Acrophora* sp.) are oriented to intercept sunlight in this Papua New Guinea reef.

coral skeletons are species-specific and highly diverse (Figure 31.11a). The common names of coral groups—horn corals, brain corals, staghorn corals, organ pipe corals, sea fans, and sea whips, among others—describe their appearance.

As a coral colony grows, old polyps die, but their calcareous skeletons remain. The living members form a layer on top of a growing reef of skeletal remains, eventually forming chains of islands and reefs. Corals are especially abundant in the Indo-

Pacific region. The Great Barrier Reef along the northeastern coast of Australia is a system of coral formations more than 2,000 km long and as wide as 150 km. A continuous coral reef hundreds of kilometers long in the Red Sea has been calculated to contain more material than all the buildings in the major cities of North America combined.

Corals flourish in nutrient-poor, clear, tropical waters. For a long time scientists wondered how corals obtain enough nutrients to grow rapidly. The answer is that photo-synthetic dinoflagellates live symbiotically within a coral's cells. They provide the corals with products of photosynthesis and contribute to calcium deposition. In turn, the corals protect the dinoflagellates from predators. This symbiotic relationship explains why reef-forming corals are restricted to clear surface waters, where light levels are high enough to allow photosynthesis (Figure 31.11).

Coral reefs throughout the world are being threatened by both global warming, which is raising the temperatures of tropical shallow ocean waters, and nutrient runoff from developments on adjacent shorelines. An overabundance of

(b)

nitrogen gives an advantage to algae, which overgrow the corals and smother them.

Ctenophores: Complete Guts and Tentacles

Ctenophores (phylum Ctenophora) were the next lineage to separate from the lineage leading to all other animals. Ctenophores, also known as comb jellies, have body plans that are superficially similar to those of cnidarians. Both have two cell layers separated by a thick, gelatinous meso-glea, and both have radial symmetry and feeding tentacles. Like cnidarians, ctenophores have low metabolic rates because they are composed primarily of inert mesoglea. Unlike cnidarians, however, ctenophores have a complete gut. Food enters through a mouth and wastes are voided through two anal pores.

Ctenophores have eight comblike rows of fused plates of cilia, called combs. They move by beating these Cnidaria

cilia rather than by use of muscular contractions. Ctenophoran Lophotrochozoans , . , PROTOSTOMES

tentacles do not have nematocysts

nematocysts; rather, they are covered with sticky filaments to which prey adhere (Figure 31.12). After capturing its prey, a ctenophore retracts its tentacles to bring the food to its mouth. In some species, the entire surface of the body is coated with a sticky mucus that captures prey. All of the 100 known species of ctenophores are marine carnivores. They are common in open seas, where prey are often scarce. Most ctenophores cannot capture large prey.

Ctenophore life cycles are simple. Gametes from gonads located on the walls of the gastrovascular cavity are released into the cavity and then discharged through the

mouth or through pores. Fertilization takes place in the open seawater. In nearly all species, the fertilized egg develops directly into a miniature ctenophore that gradually grows into an adult.

The Evolution of Bilaterally Symmetrical Animals

The phylogenetic tree in Figure 31.2 postulates a common ancestor of all bilaterally symmetrical animals, but it does not tell us what that common ancestor looked like. Evolutionary biologists have attempted to infer the nature of those ancestral animals, which they call urbilateria, using evidence from the genes, development, and structure of existing animals.

One clue is provided by the fact that all living bilaterally symmetrical animals have an array of intercellular signaling systems and many homeobox gene families (see Chapter 16). The simplest bilaterally symmetrical animals have only a few homeobox genes, but some of them are shared with more complex animals. The mechanisms that regulate embryonic development in the protostomes and deuterostomes are governed by homologous homeobox genes. Such regulatory genes with similar functions are unlikely to have evolved independently in several different animal lineages.

Some evidence that urbilaterians may have been relatively complex is provided by fossilized traces of their movements. Fossilized trails from late Precambrian times exhibit complex search patterns, transverse furrows, and longitudinal ridges (Figure 31.13). They were made by organisms that were at least several centimeters long. The complexity of the movements recorded by the tracks suggests that urbilaterians had circulatory systems, systems of antagonistic muscles, and a tissue or fluid-filled body cavity. Some of their descendants subsequently lost some of those traits, but they retain signatures of their past in their genes.

Protostomes and

Deuterostomes:

An Early Lineage Split

The next major lineage split in the evolution of animals separated two groups that have been evolving separately ever since the Cambrian period. These two major lineages—the protostomes and deuterostomes—dominate today's biota. Members of both lineages are bilaterally symmetrical and have definite heads (cephalization). Because their skeletons and body cavities are more complex than those of the animals we have discussed so far, they are capable of more elaborate movements.

The most important shared, derived traits that unite the protostomes are a

37.74 A Phylogeny of Lophotrochozoans

Three major lineages, including the lophophorate and spiralian phyla, dominate the tree. Some small phyla are not included in this diagram.

Three cell layers

Lopho-trochozoan ■ (ancestor

Most of the world's living animal species are protostomes. The diversity of protostome body plans and lifestyles has posed many challenges to zoologists attempting to infer the evolutionary relationships among these animals. Developmental, structural, and molecular data all suggest that protostomes split into two major lineages that have been evolving independently since ancient times: the lophotrochozoans and the ecdysozoans.

Lophotrochozoans, the animals we will discuss in the remainder of this chapter, grow by adding to the size of their skeletal elements. They use cilia for locomotion, and many lineages have a type of free-living larva known as a trochophore. The phylogeny of lophotrochozoans we will use in this chapter is shown in Figure 31.14. In contrast, ecdysozoans, the animals we will discuss in the next chapter, increase in size by molting their external skeletons. They move by mechanisms other than ciliary action, and they share a common set of homeobox genes.

Simple Lophotrochozoans

Flatworms move by beating cilia

Members of the phylum Platyhelminthes, or flatworms, are the simplest lopho-

trochozoans (Figure 31.15). They are bilaterally symmetrical animals that have no enclosed body cavity. They lack organs for transporting oxygen to internal tissues, and they have only simple organs for excreting metabolic wastes. This body plan dictates that each cell must be near a body surface, a requirement met by the flattened body form.

Mollusca

The digestive tract of a flatworm consists of a mouth opening into a blind sac. However, the sac is often highly branched, forming intricate patterns that increase the surface area available for absorption of nutrients. All living flatworms feed on animal tissues—living or dead. Motile flatworms glide over surfaces, powered by broad bands of cilia. This form of movement is very slow, but it is sufficient

37.75 Flatworms Live Freely and Parasitically

(a) Some flatworm species are free-living, like this marine flatworm of the South Pacific, (b) The flatworm diagrammed here lives parasitically in the gut of sea urchins. It is representative of parasitic flukes. Because their hosts provide all the nutrition they need, intestinal parasites do not require elaborate feeding or digestive organs.

for small, scavenging animals. Parasitic species that absorb digested food from their hosts do not have a digestive tract.

The flatworms probably most similar to the ancestral forms are the turbellarians (class Turbellaria), which are small, free-living marine and freshwater animals (a few live in moist terrestrial habitats). Freshwater turbellarians of the genus *Dugesia*, better known as planarians, are the most familiar species of flatworms. At one end they have a head with chemoreceptor organs, two simple eyes, and a tiny brain composed of anterior thickenings of the longitudinal nerve cords.

Although the earliest flatworms were free-living (Figure 31.15f), many species evolved a parasitic existence. A likely evolutionary transition was from feeding on dead organisms, to feeding on the body surfaces of dying hosts, to invading and consuming parts of living, healthy hosts. Most of the 25,000 species of living flatworms—including the tapeworms (class Cestoda) and flukes (class Trematoda; Figure 31.15b)—are parasitic. These worms inhabit the bodies of many other species, including vertebrates; some cause serious human diseases. Monogeneans (class Mono-

37.76 Reaching a Host by a Complex Route

The broad fish tapeworm *Diphyllobothrium latum* must pass through the bodies of a copepod (a type of crustacean) and a fish before it can reinfect its primary host, a mammal. Such complex life cycles assist the flatworm's recolonization of hosts, but they also offer opportunities for humans to break the cycle with hygienic measures.

genea) are external parasites of fishes and other aquatic vertebrates.

Parasitic flatworms live in nutrient-rich environments in which food is delivered to them, but they face other challenges. To complete their life cycle, parasites must overcome the defenses of their host. And because they die when their host dies, their offspring must disperse to new hosts. The eggs of some parasitic flatworms are voided with the host's feces and later ingested directly by other host individuals. However, most parasitic species have complex life cycles involving two or more hosts and several larval stages (Figure 31.16).

Rotifers are small but structurally complex

Rotifers (phylum Rotifera) are bilaterally symmetrical, pseudocoelomate, unsegmented animals that have three cell

layers. Most rotifers are tiny (50-500 μm long)—smaller than some ciliate protists—but they have highly developed internal organs (Figure 31.17). A complete gut passes from an anterior mouth to a posterior anus; the pseudocoel functions as a hydrostatic skeleton. Most rotifers propel themselves through the water by means of rapidly beating cilia rather than by muscular contraction. This type of movement is effective because rotifers are so small.

The most distinctive organs of rotifers are those used to collect and process food. A conspicuous ciliated organ called the corona surmounts the head of many species. Coordinated beating of the cilia provides the force for locomotion and also sweeps particles of organic matter from the water into the mouth and down to a complex structure (the mastax) where the food is ground. By contracting the muscles that surround the pseudocoel, a few rotifer species that prey on protists and small animals can protrude the mastax through the mouth and seize small objects with it.

Mollusca

Some rotifers are marine, but most of the 1,800 known species live in fresh water. Members of a few species rest on the surface of mosses and lichens in a desiccated, inactive state until it rains. When rain falls, they absorb water and become motile, feeding in the films of water that temporarily cover the plants. Most rotifers live no longer than 1 or 2 weeks.

Lophophorates: An Ancient Body Plan

After the platyhelminthes and rotifers diverged from it, the lophotrochozoan lineage divided into two branches. The descendants of these branches became the lophophorates—the subject of this section—and the spiralian, which we will describe in the following section.

Four phyla of lophophorate animals survive today: Phoronida, Brachiopoda, Ecto-procta, and Pterobranchia. Nearly all members of these phyla are marine; only a few species live in fresh water. About 4,500 living species are known, but many times that number existed during the Paleozoic and Mesozoic eras. These animals all have a body divided into three parts: prosome (anterior), mesosome (middle), and metasome (posterior). In most species, each region has a separate coelomic compartment: the protoel, mesocoel, and metacoel, respectively.

Lophophorate animals obtain food by filtering it from ocean waters, a trait that they shared with many other protostomes.

The most conspicuous feature of these animals, the lo-phophore, is a circular or U-shaped ridge around the mouth that bears one or two rows of ciliated, hollow tentacles (Figure 31.18). This large and complex structure is an organ for both food collection and gas exchange. All adult lophophorate animals are sessile; they use the tentacles and cilia of the lophophore to capture plankton. Lophophorates also have a U-shaped gut; the anus is located close to the mouth, but outside the tentacles.

The 20 known species of phoronids (phylum Phoronida) are sedentary worms that live in muddy or sandy sediments or attached to a rocky substrate. Phoronids are found in waters ranging from intertidal zones to about 400 meters deep. They range in size from 5 to 25 cm in length, and they secrete chitinous tubes in which they live. The lophophore is the most conspicuous external feature of

phoronids (see Figure 31.18). Cilia drive water into the top of the lophophore. Water exits through the narrow spaces between the tentacles. Suspended food particles are caught and transported by ciliary action to the food groove and into the mouth.

There are only 10 living species of pterobranchs (phylum Pterobranchia). Pterobranchs are sedentary animals up to 12 mm in length that live in tubes secreted by a proboscis, which is homologous to the prosome of phoronids. Some species are solitary; others form colonies of individuals joined together (Figure 31.19). Behind the proboscis is a collar with 1-9 pairs of arms bearing long tentacles that capture prey and permit gas exchange.

(a) *Iodyticium* sp.

(b)

31.19 Pterobranchs May Be Colonial or Solitary

This drawing of *Rhabdopleura* depicts two members of a colony.

Bryozoans Are Colonial Lophophorates

Bryozoans (phylum Ectoprocta) are colonial lophophorates that live in a "house" secreted by the body wall. A colony consists of many small individuals connected by strands of tissue along which materials can be moved (Figure 31.20f). Most bryozoans are marine, but a few live in fresh water. They are able to completely retract the lophophore, which they can also rock and rotate to increase contact with prey (Figure 31.20b).

A colony of bryozoans is created by the asexual reproduction of its founding members. One colony may contain as many as 2 million individuals. In some species, individual colony members are specialized for feeding, reproduction, defense, or support. Bryozoans reproduce sexually by releasing sperm into the water, where they are collected by other individuals. Eggs are fertilized internally, and devel-

Brachiopods Superficially Resemble Bivalve Mollusks

Brachiopods (phylum Brachiopoda) are solitary, marine lophophorate animals that superficially resemble bivalve mollusks (Figure 31.21). Most brachiopods are between 4 and 6 cm long, but some are as long as 9 cm. Brachiopods have a shell divided into two parts connected by a ligament. The two halves can be pulled shut to protect the soft body. The shell differs from that of mollusks in that the two halves are dorsal and ventral rather than lateral. The two-armed lophophore of a brachiopod is located within the shell. The beating of cilia on the lophophore draws water into the slightly opened shell. Food is trapped in the lophophore and directed to a ridge along which it is transferred to the mouth.

Brachiopods are either attached to a solid substrate or embedded in soft sediments. Most species are attached by means of a short, flexible stalk that holds the animal above the substrate. Gases are exchanged across body surfaces, especially the tentacles of the lophophore. Most brachiopods release their gametes into the water, where they are fertilized. The larvae remain in the plankton for only a few days before they settle and change into adults.

Brachiopods reached their peak abundance and diversity in Paleozoic and Mesozoic times. More than 26,000 fossil species have been described. Only about 350 species survive, but they are common in some marine environments.

cles to move on the surface of sediments or to burrow. Movement by both of these methods is slow.

Within the body of almost all 900 species of ribbon worms is a fluid-filled cavity called the rhynchocoel, within which floats a hollow, muscular proboscis. The proboscis, which is the feeding organ, may extend much of the length of the worm. Contraction of the muscles surrounding the rhynchocoel causes the proboscis to be everted explosively through an anterior opening (Figure 31.22) without moving

Spiralians: Wormlike Body Plans

The spiralian lineage gave rise to many phyla. Members of more than a dozen of these phyla are wormlike; that is, they are bilaterally symmetrical, legless, soft-bodied, and at least several times longer than they are wide. This body form enables animals to move efficiently through muddy and sandy marine sediments. Most of these phyla have no more than several hundred species, even though the lineages have been evolving independently since early animal evolution.

The carnivorous ribbon worms (phylum Nemertea) are dorsoventrally flattened and have nervous and excretory systems similar to those of flatworms but, unlike flatworms, they have a complete digestive tract with a mouth at one end and an anus at the other. Food moves in one direction through the digestive tract of a ribbon worm and is acted on by a series of digestive enzymes. Small ribbon worms move by beating their cilia. Larger ones employ waves of contraction of body mus

the rest of the animal. The proboscis of most ribbon worms is armed with a sharp stylet that pierces the prey. Paralysis-causing toxins produced by the proboscis are discharged into the wound made by the stylet.

Segmented Bodies: Improved Locomotion

A body cavity divided into segments allows an animal to alter the shape of its body in complex ways and to control its movements precisely. Fossils of segmented worms are known from the middle Cambrian; the earliest forms are thought to have been burrowing marine animals. Segmentation evolved several times among spiralian.

Annelids have many-segmented bodies

The annelids (phylum Annelida) are a diverse group of segmented worms (Figure 31.23). The approximately 15,000 known annelid species live in marine, freshwater, and terrestrial environments. A separate nerve center called a ganglion controls each segment, but the ganglia are connected by nerve cords that coordinate their functioning. The coelom in each segment is isolated from those in other segments. Most annelids lack a rigid, external protective covering. The thin body wall serves as a surface for gas exchange in most species, but this thin, permeable body surface restricts annelids to moist environments; they lose body water rapidly in dry air.

polychaetes. More than half of all annelid species are members of the class Polychaeta. Nearly all polychaetes are marine animals. Most have one or more pairs of eyes and one or more pairs of tentacles at the anterior end of the body. The body wall in most segments extends laterally as

a series of thin outgrowths, called parapodia, that contain many blood vessels. The parapodia function in gas exchange, and some species use them to move. Stiff bristles called setae protrude from each parapodium, forming temporary attachments to the substrate and preventing the animal from slipping backward when its muscles contract.

Many polychaete species live in burrows in soft sediments and filter prey from the surrounding water with elaborate feathery tentacles (Figure 31.24/?). Typically, males and females release gametes into the water, where the eggs are fertilized and develop into a trochophore larva. As the larva develops, it forms body segments at its posterior end, eventually changing into a small adult worm.

OLIGOCHAETES. More than 90 percent of the approximately 3,000 described species of oligochaetes (class Oligochaeta) live in freshwater or terrestrial habitats. Oligochaetes have no parapodia, eyes, or anterior tentacles, and they have relatively few setae. Earthworms—the most familiar oligochaetes— are scavengers and ingesters of soil, from which they extract food particles.

Unlike polychaetes, all oligochaetes are hermaphroditic: Each individual is both male and female. Sperm are exchanged simultaneously between two copulating individuals (Figure 31.24b). Eggs are laid in a cocoon outside the adult's body. The cocoon is shed, and when development is complete, miniature worms emerge and begin independent life.

leeches. Leeches (class Hirudinea) probably evolved from oligochaete ancestors. Most species live in freshwater or terrestrial habitats and, like oligochaetes, lack parapodia and tentacles. Like oligochaetes, leeches are hermaphroditic. The coelom of leeches is not divided into compartments, and the coelomic space is largely filled with mesenchyme tissue. Groups of segments at each end of a leech are modified to form suckers, which serve as temporary anchors that aid in movement (Figure 31.24c). With its posterior sucker attached to a substrate, the leech extends its body by contracting its circular muscles. The anterior sucker is

(d) Vestimentiferans live around thermal vents deep in the ocean. Their skin secretes chitin and other substances, forming tubes from which they extend feeding tentacles.

then attached, the posterior one detached, and the leech shortens itself by contracting its longitudinal muscles.

Many leeches are external parasites of other animals, although some species eat snails and other invertebrates. A parasitic leech makes an incision in its host to expose its blood. It can ingest so much blood in a single feeding that its body may enlarge several times. A substance called hirudin secreted by the leech into the wound keeps the host's blood flowing (and gives this class its name; see the opening page of Chapter 6). For hundreds of years leeches were widely employed in medicine for bloodletting. Even today leeches are used to reduce fluid pressure and prevent blood clotting in damaged tissues and to eliminate pools of coagulated blood.

vestimentiferans. Members of one lineage of annelids, the vestimentiferans, evolved into burrowing forms with a crown of tentacles through which gases are exchanged, and entirely lost their digestive systems (Figure 31.24d). The coel-

om of a vestimentiferan consists of an anterior compartment, into which the tentacles can be withdrawn, and a long, subdivided cavity that extends much of the length of its body. Experiments using radioactively labeled molecules have shown that vestimentiferans take up dissolved organic matter at high rates v from either the sediments

k*^'^ in which they live or the

surrounding water.

Vestimentiferans were not discovered until the twentieth century, when deep-ocean exploration revealed them living many thousands of meters below the surface. In these deep oceanic sediments they are abundant, reaching densities of many thousands per square meter. About 145 species have been described. The largest and most remarkable vestimentiferans, which grow to 2 meters in length, live near deep-ocean hydrothermal vents—openings in the seafloor through which hot, sulfide-rich water pours. The tissues of these species harbor endosymbiotic prokaryotes that fix carbon using energy obtained from the oxidation of hydrogen sulfide (H_2S).

Mollusks lost segmentation but evolved shells

Mollusks (phylum Mollusca) range in size from snails only a millimeter high to giant squids more than 18 meters long—the largest known pro-tostomes. Beginning with a segmented common ancestor, mollusks underwent one of the most

dramatic of animal evolutionary radiations, based on a body plan with three major structural components: a foot, a mantle, and a visceral mass. Animals that appear very different, such as snails, clams, and squids, are all built from these three components (Figure 31.25).

► The molluscan foot is a large, muscular structure that originally was both an organ of locomotion and a support for the internal organs.

In the lineage leading to squids and octopuses, the foot was modified to form arms and tentacles borne on a head with complex sensory organs. In other groups, such as clams, the foot was transformed into a burrowing organ. In some lineages the foot is greatly reduced.

► The mantle is a fold of tissue that covers the visceral mass of internal organs. In many mollusks, the mantle extends beyond the visceral mass to form a mantle cavity.

The gills, which are used for gas exchange and, in some species, for feeding, lie in the mantle cavity. When the cilia on the gills beat, they create a flow of oxygenated water over the gills.

The coelom of mollusks is much reduced, but the open circulatory system has large fluid-filled cavities that are major components of a hydraulic skeleton.

The mollusks also developed a rasping feeding structure known as the radula. The radula was originally an organ for scraping algae from rocks, a function it retains in many living mollusks. However, in some mollusks, it has been modified into a drill or a poison dart. In others, such as clams, it is absent.

Although individual components have been lost in some lineages, these three unique shared derived characteristics are why zoologists believe that all 100,000 species of mollusks share a common ancestor. A small sample of these species is shown in Figure 31.26.

monoplacophorans. Monoplacophorans (class Mono-placophora) were the most abundant mollusks during the Cambrian period, but today there only a few surviving species. Unlike all other living mollusks, the surviving monoplacophorans have multiple gills, muscles, and excretory structures that are repeated over the length of the body. The gills are located in a large cavity under the shell, through which oxygen-bearing water circulates.

CHITONS. Chitons (class Polyplacophora) have multiple gills and segmented shells, but their other body parts are not segmented (Figure 31.26<?). The chiton body is bilaterally symmetrical, and its internal organs, particularly the digestive and nervous systems, are relatively simple. The

31.25 Molluscan Body Plans

(c) Slugs are terrestrial and marine gastropods that have lost their shells; this shell-less sea slug is very conspicuously colored, (d) Land snails are shelled, terrestrial gastropods, (e) Cephalopods such as the octopus are active predators. (o) The boundaries of its chambers are clearly visible on the outer surface of this shelled Nautilus, another cephalopod.

(/) *Nautilus belavensis*

562 CHAPTER THIRTY-ONE

trochophore Larvae of chitons are almost indistinguishable from those of annelids. Most chitons are marine herbivores that scrape algae from rocks with their sharp radulae. An adult chiton spends most of its life glued tightly to rock surfaces by its large, muscular, mucus-covered foot. It moves slowly by means of rippling waves of muscular contraction in the foot

bivalves. One lineage of early mollusks developed a hinged, two-part shell that extended over the sides of the body as well as the top, giving rise to the bivalves (class Bivalvia), which include the familiar clams, oysters, scallops, and mussels (Figure 31.26b). Bivalves are largely sedentary and have greatly reduced heads. The foot is compressed and, in many clams, is used for burrowing into mud and sand. Bivalves feed by bringing water in through an opening called a siphon and extracting food from the water using their large gills, which are also the main sites of gas exchange. Water exits through another siphon.

gastropods. Another lineage of early mollusks gave rise to the gastropods (class Gastropoda), which includes the snails. Most gastropods are motile, using the large foot to move slowly across the substrate or to burrow through it. Gastropods are the most species-rich and widely distributed of the molluscan classes (Figure 31.26c,d). Some species, such as snails, whelks, limpets, slugs, abalones, and the often brilliantly ornamented nudibranchs, can crawl. Others—the sea butterflies and heteropods—have a modified foot that functions as a swimming organ with which they move through open ocean waters. The only mollusks that live in terrestrial environments—land snails and slugs—are gastropods. In these terrestrial species the mantle cavity is modified into a highly vascularized lung.

cephalopods. In one lineage of mollusks, the cephalopods (class Cephalopoda), the exit siphon, which initially may have simply improved the flow of water over the gills, became modified to allow the early cephalopods to control the water content of the mantle cavity. The modification of the mantle into a device for forcibly ejecting water from the cavity enabled cephalopods to move rapidly through the water. Furthermore, as fluid moves out of a chamber, gases diffuse into it, changing the buoyancy of the animal. Thus, by pumping out water, the animals could also control their buoyancy. Together, these adaptations allowed cephalopods to live in open water.

With their greatly enhanced mobility, some cephalopods, such as squids and octopuses, became the major predators in open ocean waters (Figure 31.26e). They are still important marine predators today. Cephalopods capture and subdue their prey with their tentacles; octopuses use theirs to move over the substrate. As is typical of active predators, cephalopods have complex sensory organs, most notably eyes that are comparable to those of vertebrates in their ability to resolve images. The cephalopod head is closely associ-

ated with a large, branched foot that bears tentacles and a siphon. The large, muscular mantle is a solid external supporting structure. The gills hang within the mantle cavity.

Cephalopods appeared about 600 million years ago, near the beginning of the Cambrian period, and by the Ordovician period a wide variety of types were present. They were the first large, shelled animals able to move vertically in the ocean. The earliest cephalopod shells were divided by partitions penetrated by tubes through which liquids could be moved. Nautiloids (genus *Nautilus*) are the only cephalopods with external chambered shells that survive today (Figure 31.26f). Increases in size and reductions in external hard parts characterize the subsequent evolution of many lineages.

ro

Chapter Summary

Descendants of a Common Ancestor

- ▶ All members of the kingdom Animalia are believed to have a common flagellated protist ancestor.
- ▶ The specialization of cells by function made possible the complex, multicellular body plan of animals.

The Animal Way of Life

- ▶ Animals obtain their food—complex organic molecules— by active expenditure of energy.

Clues to Evolutionary Relationships among Animals

- ▶ Morphological, developmental, and molecular data support similar animal phylogenies.
- ▶ The body cavity of an animal is strongly correlated with its ability to move. On the basis of their body cavities, animals are classified as acoelomates, pseudocoelomates, or coelomates. Review Figure 31.1
- ▶ The two major animal lineages—protostomes and deuterostomes—are believed to have separated early in animal evolution; they differ in several components of their early embryological development. Review Figure 31.2

Body Plans Are Basic Structural Designs

- ▶ Most animals have either radial or bilateral symmetry. Radially symmetrical animals move slowly or not at all. Bilateral symmetry is strongly correlated with more rapid movement and the development of sensory organs at the anterior end of the animal. Review Figure 31.3

Sponges: Loosely Organized Animals

- ▶ Sponges (phylum Porifera) are simple animals that lack cell layers and body symmetry, but have several different cell types.
- ▶ Sponges feed via choanocytes, feeding cells that draw water through the sponge body and filter out small organisms and nutrient particles. Review Figure 31.4

Cnidarians: Cell Layers and Blind Guts

- ▶ Cnidarians (phylum Cnidaria) are radially symmetrical and have only two cell layers, but with their nematocyst-studded tentacles they can capture prey larger and more complex than themselves. Review Figure 31.7

ANIMAL ORIGINS AND LOPHOTROCHOZOANS 563

- ▶ Most cnidarian life cycles have a sessile polyp and a free-swimming, sexual medusa stage, but some species lack one of the stages. Review Figures 31.8, 31.9, 31.10

Ctenophores: Complete Guts and Tentacles

- ▶ Ctenophores (phylum Ctenophora), descendants of the first split in the lineage of bilaterally symmetrical animals, are marine carnivores that have simple life cycles. Review Figure 31.12

The Evolution of Bilaterally Symmetrical Animals

- ▶ The common ancestors of bilateral animals, called urbilaterians, were probably simple, bilaterally symmetrical animals composed of flattened masses of cells.

Protostomes and Deuterostomes: An Early Lineage Split

► Protostomes and deuterostomes are monophyletic lineages that have been evolving separately since the Cambrian period. Their members are structurally more complex than cnidarians and ctenophores. Protostomes have a ventral nervous system, paired nerve cords, and larvae with compound cilia. Deuterostomes have a dorsal nervous system and larvae with single cilia.

► Protostomes split into two major clades—lophotrochozoans and ecdysozoans. Review Figure 31.14

Simple Lophotrochozoans

► Flatworms (phylum Platyhelminthes) have no body cavity, lack organs for oxygen transport, have only one entrance to the gut, and move by beating their cilia. Many species are parasitic. Review Figures 31.15, 31.16

► Although no larger than many ciliated protists, rotifers (phylum Rotifera) have highly developed internal organs. Review Figure 31.17

Lophophorates: An Ancient Body Plan

► The lophotrochozoan lineage split into two branches whose descendants became the lophophorates and the spiralian.

► The lophophore dominates the anatomy of many lophophorate animals. Review Figure 31.18

► Bryozoans are colonial lophophorates that can move their lophophores. Review Figure 31.20

► Brachiopods, which superficially resemble bivalve mollusks, were much more abundant in the past than they are today.

Spiralians: Wormlike Body Plans

► The spiralian lineage gave rise to many phyla, most of whose members have wormlike body forms.

► Ribbon worms (phylum Nemertea) have a complete digestive tract and capture prey with an eversible proboscis. Review Figure 31.22

Segmented Bodies: Improved Locomotion

► Annelids (phylum Annelida) are a diverse group of segmented worms that live in marine, freshwater, and terrestrial environments. Review Figure 31.23

► Mollusks (phylum Mollusca) evolved from segmented ancestors but subsequently became unsegmented. The molluscan body plan has three basic components: foot, mantle, and visceral mass. Review Figure 31.25

► The molluscan body plan has been modified to yield a diverse array of animals that superficially appear very different from one another.

For Discussion

1. Differentiate among the members of each of the following sets of related terms:

a. radial symmetry/bilateral symmetry

b. protostome/deuterostome

c. indeterminate cleavage/determinate cleavage

d. spiral cleavage/radial cleavage

e. coelomate/pseudocoelomate/acoelomate

2. For each of the types of organisms listed below, give a single trait that may be used to distinguish them from the organisms in parentheses:

a. cnidarians (sponges)

b. gastropods (all other mollusks)

c. polychaetes (other annelids)

3. In this chapter we listed some of the traits shared by all animals that convince most biologists that all animals are descendants of a single common ancestral lineage. In your opinion, which of these traits provides the most compelling evidence that animals are monophyletic?

4. Describe some features that allow animals to capture prey that are larger and more complex than they themselves are.

5. Animals in many phyla have wormlike, or vermiform, shapes. Why has this body form met the needs of species in so many different lineages of animals? In what types of environments does the worm shape function well? Why?

6. Having a complete digestive tract in which materials enter at an anterior mouth and move in one direction until they exit from a posterior opening would appear to be a very efficient way to digest food and rid the body of the indigestible residues. Nonetheless, several successful phyla of animals with a blind gut must void their digestive wastes via the same opening through which food entered. Why has this type of digestive system persisted? What limitations does it impose on the types of food animals can eat and the way in which the food is treated?

32

Ecdysozoans: The Molting Animals

A FIRM, NONLIVING COVERING THAT IS DIFFICULT to penetrate—an exoskeleton —provides an animal with both protection and support. Its very attributes, however, pose a huge problem: An exoskeleton cannot grow as the animal body inside it grows. Ancestors of today's ecdysozoan animals evolved a solution. They shed, or molt, the outgrown exoskeleton and expand and harden a new, larger one.

The new exoskeleton is already in place, growing underneath the old one. Directly after molting, the animal is very vulnerable. With its soft, new armor it can move only very slowly for a while. Despite this constraint, the lineages of Ecdysozoa—the molting animals—have more species than all other animal lineages combined.

An increasingly rich array of molecular and genetic evidence, including a common set of homeobox genes, suggests that molting may have evolved only once during animal evolution. The exoskeletons of ecdysozoan animals range from thin and flexible to thick, hard, and rigid.

The presence of an exoskeleton presented new problems and opportunities in other areas of the body plan besides growth. Unlike the lophotrochozoans, ecdysozoans cannot use cilia for locomotion; new forms of locomotion evolved in these lineages. And because hard exoskeletons impede the passage of oxygen into the animal, new mechanisms for respiration evolved.

In this chapter we will review the characteristics of animals in the various ecdysozoan phyla and show how developing an exoskeleton has influenced the evolution of these animals. The phylogeny we follow here is presented in Figure 32.1. The latter half of the chapter details the characteristics of several ecdysozoan lineages that have traditionally been classified in the phylum Arthropoda—the arthropods.

Collectively, arthropods (which include the terrestrial insects and the marine crustaceans) are the dominant animals on Earth, both in number of species (some 1.5 million) and number of individuals (estimated at some 10¹⁸ individuals, or a billion billion). The highly successful arthropod body plan is based on three elements: the rigid exoskeleton that marks them as ecdysozoans; segmenta-

Molting the Exoskeleton

This green darner dragonfly (genus *Anax*) has just emerged from its larval exoskeleton and is pumping fluids into its expanding wings. At this stage the insect can move only very slowly.

tion; and jointed appendages, which immensely enhance their powers of locomotion, and which we will encounter again in Chapter 33 when we cover another major lineage, the vertebrates.

We close the chapter with an overview of evolutionary themes found in the evolution of the protostomate phyla, including both the lophotrochozoan and ecdysozoan lineages.

Cuticles: Flexible, Unsegmented Exoskeletons

Some ecdysozoans have wormlike bodies covered by exoskeletons that are relatively thin and flexible. These exoskeletons, called cuticles, protect the animal, but do not provide support for the bodies. The action of circular and longitudinal muscles on fluid in the body cavity provides a hydrostatic skeleton for many of these animals, which can

Cuticle

Ecdysozoan ancestor

Jointed appendages

Chitin in exoskeleton;

appendages for locomotion

32.1 A Probable Phylogeny of Ecdysozoans

This approach is in line with current molecular evidence. The bottom four phyla—those with jointed appendages—were traditionally classified as the phylum Arthropoda, and many classifications retain this distinction.

move only slowly. A thin cuticle allows the exchange of gases, minerals, and water across the body surface, but restricts the animal to moist habitats.

Some marine phyla have few species

Several phyla of marine wormlike animals (that is, they are long and slender, without appendages) branched off early within the ecdysozoan lineage. These phyla contain only a few species. They have relatively thin cuticles that are molted periodically as they grow to full size. Their bodies are supported primarily by their hydrostatic skeletons, not by the cuticle.

priapulids and kinorhynchs. The 16 species of priapulids (phylum Priapulida) are cylindrical, unsegmented, wormlike animals that range in size from half a millimeter to 20 centimeters in length. They burrow in fine marine sediments.

About 150 species of kinorhynchs (phylum Kinorhyncha) have been described. They are all less than 1 millimeter in length and live in marine sands or muds. Their bodies are divided into 13 segments by a series of cuticular plates that are periodically molted during growth (Figure 32.2). Kinorhynchs feed by ingesting the substratum and digesting the organic material found within it, which may include living algae as well as dead matter.

arrow worms. Arrow worms (phylum Chaetognatha)

have three-part, streamlined bodies. Their body plan is based on a coelom that is divided into head, trunk, and tail compartments. Most of them swim in the open sea, but a few live on the seafloor. Their abundance as fossils indicates that they were already common more than 500 million years ago. The 100 or so living species of arrow worms are so small—less than 12 centimeters long—that their gas exchange and excretion requirements can be met by diffusion through the body surface. Arrow worms lack a circulatory system. Wastes and nutrients are moved around the body in the coelomic fluid, which is propelled by cilia that line the coelom. Arrow

worms are stabilized in the water by means of one or two pairs of lateral fins and a "tail" fin (Figure 32.3). There is no distinct

larval stage; miniature adults hatch directly from eggs that are released into the water.

Arrow worms are major predators of small organisms in the open oceans. Their prey range from small protists to young fish as large as an arrow worm. An arrow worm typically lies motionless in the water until movement of the water signals the approach of prey. The arrow worm then darts forward and grasps the prey with the stiff spines adjacent to its mouth.

Tough cuticles evolved in some unsegmented worms ^^

Tough external cuticles evolved in some members of an ecdysozoan lineage whose descendants have colonized freshwater

and terrestrial environments

Two extant phyla represent this lineage.

Chelicerata HORSEHAIR WORMS. About 230 species

of horsehair worms (phylum Nematomorpha) have been described. As their name

implies, they are extremely thin and range in length from a

few millimeters to up to a meter (Figure 32.4). Most adult horsehair worms live in fresh water among litter and algal mats

near the edges of streams and ponds. The larvae of horsehair worms are all internal parasites of terrestrial and aquatic

insects and crabs. The much reduced gut has no mouth opening and is probably nonfunctional. Horsehair worms may feed

only as larvae, absorbing nutrients from their hosts across their body wall, but many continue to grow after they have left their hosts, suggesting that adults may also absorb nutrients from their environment.

Roundworms. Roundworms (phylum Nematoda) have a thick, multilayered cuticle secreted by the underlying epidermis that gives their body its shape (Figure 32.5). As a roundworm grows, it sheds and re-secretes its cuticle four times. The largest known roundworm, which reaches a length of 9 meters, is a parasite in the placentas of female sperm whales. About 20,000 species of roundworms have been described, but the actual number of living species may be more than a million.

Roundworms exchange oxygen and nutrients with their environment through both the cuticle and the intestine, which is only one cell layer thick. Materials are moved through the gut by rhythmic contraction of a highly muscular organ, the pharynx, at the worm's anterior end. Roundworms move by contracting their longitudinal muscles.

Roundworms are one of the most abundant and universally distributed of all animal groups. Countless roundworms live as scavengers in the upper layers of the soil, on the bottoms of lakes and streams, and as parasites in the bodies of most kinds of plants and animals. The flesh of a single rotting apple found on the ground in an orchard contained 90,000 roundworms, and 1 square meter of mud off the coast of the Netherlands yielded 4,420,000 individuals. The topsoil of rich farmland has up to 3 billion nematodes per acre.

(b)

32.5 Nematodes

{a,b) *Trichinella* is an example of a parasitic roundworm that infects mammals, including humans, (c) Free-living roundworms have a body plan similar to the adult parasite's.

The diets of roundworms are as varied as their habitats. Many are predators, preying on protists and other small animals (including other roundworms). Many roundworms live parasitically within their hosts. The roundworms that are parasites of humans (causing diseases such as trichinosis, filariasis, and elephantiasis), domestic animals, and economically important plants have been studied intensively in an effort to find ways of controlling them. One soil-inhabiting nematode species, *Caenorhabditis elegans*, has been intensely studied in the laboratory by geneticists and developmental biologists.

The structure of parasitic roundworms is similar to that of free-living species, but the life cycles of many parasitic species have special stages that facilitate their transfer among hosts. *Trichinella spiralis*, the species that causes the human disease trichinosis, has a relatively simple life cycle. A person may become infected by eating the flesh of an animal (usually a pig) containing larvae of *Trichinella* encysted in its muscles.

The larvae are activated in the mammalian digestive tract, leave their cysts, and attach to the person's intestinal wall, where they feed. Later they bore through the intestinal wall and are carried in the bloodstream to the muscles, where they form cysts (Figure 32.5b). If present in great numbers, these cysts can cause severe pain or even death.

Trichinella can infect a number of mammal species; there is no special stage in the life cycle that lives in a particular alternate host. Other roundworm life cycles are more complex, involving one or more alternate hosts.

(c)

Arthropods and Their Relatives: Segmented External Skeletons

In Precambrian times, the body coverings of some wormlike ecdysozoan lineages became thickened by the incorporation of layers of protein and a strong, flexible, waterproof polysaccharide called chitin. After this change, which initially probably had a protective function, the rigid body covering acquired both support and locomotory functions.

A rigid body covering precludes wormlike movement. To move, these animals require appendages that can be manipulated by muscles. Such appendages evolved several times in late Precambrian times, leading to the phyla collectively called arthropods. The divisions among arthropod lineages are so ancient that we divide them into a number of phyla. However, as indicated at the opening of this chapter, many zoologists treat these groups as members of a single phylum, Arthropoda.

The bodies of arthropods are divided into segments. Their muscles attach to the inside of the skeleton, and each segment has muscles that operate that particular segment and the appendages attached to it (Figure 32.6). The appendages of most present-day arthropods have joints, although those of some lineages do not. Arthropod appendages serve many functions, including walking and swimming, food capture and manipulation, copulation, and sensory perception.

The sturdy exoskeleton had a profound influence on arthropod evolution. Encasement within armor provides support for walking on dry land, and, with special waterproofing, it keeps the animal from dehydrating in dry air. Aquatic arthropods were, in short, excellent candidates to invade the terrestrial environment, and as we will see, they did so several times.

segmented annelid worms, the molecular evidence links the 80 species of onychophorans (phylum Onychophora) to the arthropod lineages. Onychophorans have soft bodies that are covered by a thin, flexible cuticle that contains chitin. Onychophorans use their body cavities as hydrostatic skeletons. Their soft, fleshy, unjointed, claw-bearing legs are formed by outgrowths of the body (Figure 32.7a). They are probably similar in appearance to ancestral arthropods.

Like the onychophorans, water bears (phylum Tardigrada) have fleshy, unjointed legs and use their fluid-filled body cavities as hydrostatic skeletons (Figure 32.7b). Unlike onychophorans, water bears are all extremely small (0.1-0.5 mm in length), and they lack circulatory systems and gas exchange organs. The 600 extant species of water bears live in marine sands and on temporary water films on plants. When these films dry out, the water bears also lose water and shrink to small, barrel-shaped objects that can survive for at least a decade in a dehydrated resting state. They may occur at densities as high as 2,000,000 per square meter of moss.

Jointed legs appeared in the trilobites

Once the dominant line of arthropods, the trilobites (phylum Trilobita) flourished in Cambrian and Ordovician seas but were extinct by the close of the Paleozoic era. Trilobites were heavily armored, and their body segmentation and appendages followed a relatively simple, repetitive plan. But their appendages were jointed, giving them led flexibility, and the beginnings of specialization— ig different appendages for different functions—can be discerned.

32.7 Arthropod Relatives with Unjointed Appendages

(a) Onychophorans have unjointed legs and use the body cavity as a hydrostatic skeleton, (b) The appendages and general anatomy of a water bear (phylum Tardigrada) superficially resemble those of onychophorans.

Why trilobites declined in abundance and eventually became extinct is unknown. However, because their heavy external skeletons provided ideal material for fossilization, they left behind a vivid record of their presence (Figure

32.8).

Chelicerates Invaded the Land

The bodies of all chelicerates (phylum Chelicerata) are divided into two major regions. The anterior region bears two pairs of appendages, modified to form mouthparts, and four pairs of walking legs. The 63,000 described species are usually placed in three classes: Pycnogonida, Arachnida, and Merostomata. Only the class Arachnida contains many species.

The pycnogonids (class Pycnogonida), or sea spiders, are a small group of marine species that are seldom seen except by marine biologists (Figure 32.9a). The class Merostomata contains a single order, the Xiphosura, or horseshoe crabs. These marine animals, which have changed very little during their long fossil history, have a large horseshoe-shaped covering over most of the body. They are common in shallow waters along the eastern coasts of North America and Southeast Asia, where they scavenge and prey on bottom-dwelling invertebrates. Periodically they crawl into the intertidal zone to mate and lay eggs (Figure 32.9b).

Arachnids (class Arachnida) are abundant in terrestrial environments. Most arachnids have a simple life cycle in which miniature adults hatch from eggs and begin independent lives almost immediately. Some arachnids retain their eggs during development and give birth to live young. The most species-rich and abundant arachnids are the scorpions, harvestmen, spiders, mites, and ticks (Figure 32.10).

Spiders are important terrestrial predators. Some have excellent vision that enables them to chase and seize their prey. Others spin elaborate webs made of protein threads to

Kinorhyncha Priapulida Chaetognatha Nematomorpha Nematoda Onychophora Tardigrada Trilobita

Chelicerata

Crustacea Uniramia

snare prey. The webs of different groups of spiders are strikingly varied and enable spiders to position their snares in many different environments. Spiders also use protein threads to construct safety lines during climbing and as homes, mating structures, protection for developing young, and means of dispersal. The threads are produced by modified abdominal appendages that are connected to internal glands that secrete the proteins of which the threads are constructed.

Crustaceans: Diverse and Abundant

Crustaceans (phylum Crustacea) are the dominant marine arthropods. The most familiar crustaceans are decapods (shrimps, lobsters, crayfishes, and crabs; Figure 32.11f); isopods (sow bugs; Figure 32.11b); and amphipods (sand fleas; see Figure 1.11). Also included among the crustaceans are a wide variety of other small species, many of which superficially resemble shrimps (Figure 32.11c). The individuals of one group alone, the copepods (class Cope-poda), are so numerous that they may be the most abundant of all animals.

Barnacles (class Cirripedia) are unusual crustaceans that are sessile as adults (Figure 32.1d). With their calcareous shells, they superficially resemble mollusks, but, as the zoologist Louis Agassiz remarked more than a century ago, a barnacle is "nothing more than a little shrimp-like animal, standing on its head in a limestone house and kicking food into its mouth."

32.12 Crustacean Structure

(a) The bodies of most crustaceans are divided into three regions, each segment of which bears appendages, (b) A nauplius larva has one simple eye and three pairs of appendages.

Myriapods have many legs

Centipedes, millipedes, and the two other groups of animals in the subphylum Myriapoda have two body regions: a head and a trunk. Centipedes and millipedes have a well-formed head and a long, flexible, segmented trunk that bears many pairs of legs (Figure 32.13). Centipedes prey on insects and other small animals. Millipedes scavenge and eat plants. More than 3,000 species of centipedes and 10,000 species of millipedes have been described; many more species probably remain unknown. Although most myriapods are less than a few centimeters long, some tropical species are ten times that size.

Insects are the dominant uniramians

The 1.5 million species of insects (subphylum Insecta) that have been described are believed to be only a small fraction of the total number living on Earth today. Insects are found in nearly all terrestrial and freshwater habitats, and they utilize as food nearly all species of plants and many species of animals. Some are internal parasites of plants and animals; others suck their host's blood or consume its surface

Kinorhyncha Priapulida Chaetognatha ematomorpha toda Onychophora Tardigrada TriJobita Chelicerata Crustacea

Most of the 40,000 described species of crustaceans have a body that is divided into three regions: head, thorax, and abdomen. The segments of the head are fused together, and the head bears five pairs of appendages. Each of the multiple thoracic and abdominal segments usually bears one pair of appendages. In many species, a fold of the exoskeleton, the carapace, extends dorsally and laterally back from the head to cover and protect some of the other segments (Figure 32.12a).

The fertilized eggs of most crustacean species are attached to the outside of the female's body, where they remain during their early development. At hatching, the young of some species are released as larvae; those of other species are released as juveniles that are similar in form to the adults. Still other species release fertilized eggs into the water or attach them to an object in the environment. The typical crustacean larva, called a nauplius, has three pairs of appendages and one simple eye (Figure 32.12b). In many crustaceans, the nauplius larva develops within the egg before it hatches.

Uniramians are Primarily Terrestrial

The body of a uniramian (phylum Uniramia) is divided into either two or three regions (in myriapods and insects, respectively). The anterior regions have few segments, but the posterior region—the abdomen—has many segments. Uniramians are primarily terrestrial animals; most have elaborate systems of channels that bring oxygen to the cells of their internal organs.

32.14 Structure of an Insect

The body plan of an insect differs in many details from that of other arthropods, but the basic theme of a segmented body with modified jointed appendages is shared with most arthropod lineages.

body tissues. Insects transmit many viral, bacterial, and protist diseases among plants and animals. Very few insect species are oceanic. In freshwater environments, on the other hand, they are sometimes the dominant animals, burrowing through the muddy substrate, extracting suspended prey from the water, or actively pursuing other animals.

Insects, like the crustaceans, have three basic body parts: head, thorax, and abdomen. They have a single pair of antennae on the head, and three pairs of legs attached to the thorax (Figure 32.14). An insect exchanges gases by means of air sacs and tubular channels called tracheae (singular trachea) that extend from external openings inward to tissues throughout the body. The adults of most flying insects have two pairs of stiff, membranous wings attached to the thorax. The exceptions are flies, which have only one pair of wings, and beetles, in which the forewings form heavy, hardened wing covers.

Wingless insects (class Apterygota) include firebrats and collembolans (Figure 32.15a). Of the modern insects, they are probably the most similar in form to insect ancestors. Apterygote insects have a simple life cycle, hatching from their eggs looking like small adults.

Development in the winged insects (class Pterygota) is more complex. The hatchlings are not similar to adults, and they undergo substantial changes at each molt in the process of growing larger. The immature stages of insects between molts are called instars. A substantial change that occurs between one developmental stage and another is called metamorphosis. When the change from one instar to the next is gradual, an insect is said to undergo incomplete metamorphosis.

In some insect genera, the larvae and adult forms can appear to be completely different animals. The most familiar example of such complete metamorphosis occurs in members of the order Lepidoptera, when the larval caterpillar trans-

forms itself into the adult butterfly (see Figure 1.6). During complete metamorphosis, the wormlike larva transforms itself during a specialized phase, called the pupa, in which many larval tissues are broken down and the adult form develops.

Entomologists divide the winged insects into about 28 different orders. We can make sense out of this bewildering variety by recognizing three major lineages:

- ▶ Winged insects that cannot fold their wings back against the body.
- ▶ Winged insects that can fold their wings and that undergo incomplete metamorphosis.
- ▶ Winged insects that can fold their wings and that undergo complete metamorphosis.

Because they can fold their wings over their backs, flying insects belonging to the second and third lineages are able to tuck their wings out of the way upon landing and crawl into crevices and other tight places.

The only surviving groups of the first lineage are the orders Odonata (dragonflies and damselflies; Figure 32.15b) and Ephemeroptera (mayflies). All members of these two orders have aquatic larvae that metamorphose into flying adults after they crawl out of the water. Although many of these insects are excellent flyers, they require a great deal of open space in which to maneuver. Dragonflies and damselflies are active predators as adults, but adult mayflies lack functional digestive tracts and do not eat, living only long enough to mate and lay eggs.

The second lineage includes the orders Orthoptera (grasshoppers, crickets, roaches, mantids, and walking sticks; Figure 32.15c), Isoptera (termites), Plecoptera (stone flies), Dermaptera (earwigs), Thysanoptera (thrips), Hemiptera (true bugs; Figure 32.15d), and Homoptera (aphids, cicadas, and leafhoppers). Hatchlings are sufficiently similar in form to adults to be recognizable. They acquire adult organ systems, such as wings and compound eyes, gradually through several juvenile instars.

Insects belonging to the third lineage have different life stages specialized for living in different environments and using different food sources. In many species the larvae are adapted for feeding and growing, and the adults are specialized for reproduction and dispersal. The adults of some species do not feed at all, living only long enough to mate, disperse, and lay eggs. In many species whose adults do feed, adults and larvae use different food resources. About 85 percent of all species of winged insects belong to this lineage. Familiar examples are the orders Neuroptera (lacewings

32.15 Diversity among the Insects \

(a) This silverfish is a typical member of the apterygote order Thysanura. (b) Unlike most insects, this adult dragonfly (order Odonata) cannot fold its wings over its back. Representatives of some of the largest insect orders are (c) a broad-winged katydid (Orthoptera), (d) harlequin bugs (Hemiptera), (e) a predaceous diving beetle (order Coleoptera), (f) a Great Mormon butterfly (Lepidoptera), (g) a hoverfly (Diptera), and (h) a honeybee (Hymenoptera).

574 CHAPTER THIRTY-TWO

"All have bilateral symmetry.

and their relatives), Coleoptera (beetles; Figure 32.15e), Tri-choptera (caddisflies), Lepidoptera (butterflies and moths; Figure 32.15f), Diptera (flies; Figure 32.15g), and Hymenoptera (sawflies, bees, wasps, and ants; Figure 32.15h).

There are also several orders of pterygote insects, including the Phthiraptera (lice) and Siphonaptera (fleas) that are parasitic. Although descended from flying ancestors, these insects have lost the ability to fly.

Why have the insects undergone such incredible evolutionary diversification? Insects may have originated from a centipede-like ancestor as far back as the Devonian period. The terrestrial environments penetrated by the arthropods were like a new planet, an ecological world with more complexity than the seas they came from, but one containing relatively few species other than the insects. The evolution of the ability to fly allowed the insects to escape from potential predators and to traverse boundaries that might otherwise have been insurmountable—both very highly adaptive features. The numbers and diversity of insect species attest to the supreme success of this highly visible and dominant animal group.

Themes in Protostome Evolution

Most of protostome evolution took place in the oceans. As we have seen, early animals used fluids within their body cavities as the basis for support and movement. Subdivisions of the body cavity allowed better control of movement and permitted different parts of the body to be moved independently of one another. Thus some protostome lineages gradually evolved the ability to change their shape in complex

ways and to move with greater speed on and through sediments or in the water.

During much of animal evolution, the only food available in the water consisted of dissolved organic matter and very small organisms. Consequently, many different lineages of animals evolved feeding structures designed to extract small prey from water, as well as structures for moving water through or over their prey-collecting devices. Animals that feed in this manner are abundant and widespread in marine waters today.

Because water flows readily, bringing food with it, sessile lifestyles evolved repeatedly during lophotrochozoan and ecdysozoan evolution. Most protostome phyla today have at least some sessile members. Sessile lifestyles have both advantages and disadvantages. A sessile animal gains access to local resources, but forfeits access to more distant resources. Sessile animals cannot come together to mate; instead, they must rely on the fertilization of gametes that they have ejected into the water. Some species eject both eggs and sperm into the water; others retain their eggs within their bodies and extrude only their sperm, which are carried by the water to other individuals. Species whose adults are sessile often have motile larvae, many of which have complicated mechanisms for locating suitable sites on which to settle. Many colonial sessile protostomes are able to grow in the direction of better resources or into sites offering better protection.

A frequent consequence of a sessile existence is competition for space. Such competition is intense among plants in most terrestrial environments. In the sea, especially in shallow waters, animals also compete directly for space. They

ECDYSOZOANS:THE MOLTING ANIMALS 575

have evolved mechanisms for overgrowing one another and for engaging in toxic warfare where they come into contact.

Individual members of sessile colonies, if they are directly connected, can share resources. The ability to share resources enables some individuals to specialize for particular functions, such as reproduction, defense, or feeding. The nonfeeding individuals derive their nutrition from their feeding associates.

Predation may have been the major selective pressure behind the development of external body coverings. Such coverings evolved independently in many lophotrochozoan and ecdysozoan lineages. In addition to providing protection, they became key elements in the development of new systems of locomotion. Locomotory abilities permitted prey to escape more readily from predators, but also allowed predators to pursue their prey more effectively. Thus, the evolution of animals has been, and continues to be, a complex arms race among predators and prey.

Although we have concentrated on the evolution of greater complexity in animal lineages, many lineages that remained simple have been very successful. Cnidarians are common in the oceans; roundworms abound in most aquatic and terrestrial environments. Parasites lost complex body plans but evolved complex life cycles.

The characteristics of the major existing phyla of proto-stomate animals are summarized in Table 32.1. All the phyla had evolved by the Cambrian period, but extinction and diversification within these lineages continue.

Many of the evolutionary trends demonstrated by proto-stomes also dominated the evolution of deuterostomes, the lineage that includes the chordates, the group to which humans belong. Hard external body coverings evolved and were later abandoned by many lineages. We will consider the evolution of the deuterostomes in the next chapter.

\ra

Chapter Summary

- ▶ A major innovation during animal evolution was the development of a sturdy, nonliving external cover—an exoskeleton. An animal with an exoskeleton grows by periodically molting its exoskeleton and replacing it with a larger one.
- ▶ The presence of an exoskeleton opened avenues for the evolution of new body plans in the ecdysozoan lineage. Review Figure 32.1

Animals with Flexible Exoskeletons

- ▶ Tough cuticles are found in members of two phyla that live in freshwater, marine, and terrestrial environments.
- ▶ Roundworms (phylum Nematoda) are one of the most abundant and universally distributed of all animal groups. Many are parasites. Review Figure 32.5

Arthropods and Their Relatives: Segmented External Skeletons

- ▶ The body coverings of one ecdysozoan lineage, the arthropods, became thickened and made rigid by the incorporation of layers of protein and the polysaccharide chitin.
- ▶ Animals with rigid exoskeletons cannot move in a wormlike fashion. To move, they have appendages that can be

manipulated by muscles. Review Figure 32.6

- ▶ Onychophorans have soft, fleshy, unjointed legs. They are probably similar to ancestral arthropods.
- ▶ The tiny and abundant water bears (phylum Tardigrada) also have unjointed legs.
- ▶ Jointed legs with specialized functions appeared among the trilobites (phylum Trilobita). Trilobites flourished in Cambrian and Ordovician seas, but became extinct by the close of the Paleozoic era.

Chelicerates: Invasion of the Land

- ▶ The bodies of all chelicerates (phylum Chelicerata) are divided into two major regions, the anterior of which bears four pairs of jointed legs.
- ▶ Arachnids—scorpions, harvestmen, spiders, mites, and ticks—are abundant in terrestrial environments.

Crustaceans: Diverse and Abundant

- ▶ Most of the 40,000 described species of crustaceans (phylum Crustacea) have a body that is divided into three regions: head, thorax, and abdomen. Review Figure 32.12
- ▶ The most familiar crustaceans are shrimps, lobsters, crayfishes, crabs, sow bugs, and sand fleas.

Uniramians are Primarily Terrestrial

- ▶ The body of a uniramian (phylum Uniramia) is divided into two or three regions; the posterior region has paired legs.
- ▶ Myriapods (centipedes and millipedes) have many segments and many pairs of legs.
- ▶ About 1.5 million species of insects (subphylum Insecta) have been described, but that is probably only a small fraction of the total number of species living on Earth today.
- ▶ Insects have three body regions (head, thorax, abdomen), a single pair of antennae on the head, and three pairs of legs attached to the thorax. Review Figure 32.14
- ▶ Wingless insects (class Apterygota) look like little adults when they hatch from their eggs. Hatchlings of many winged insects (class Pterygota) do not resemble adults and undergo substantial changes at each molt.
- ▶ Entomologists divide the winged insects into three major subgroups and about 28 different orders. Members of one subgroup cannot fold their wings back against the body; members of the other two groups can.

Themes in Protostome Evolution

- ▶ Most evolution of protostomes took place in the oceans.
- ▶ Early animals used fluid-filled spaces as hydrostatic skeletons. Subdivision of the body cavity allowed better control of movement and permitted different parts of the body to be moved independently of one another.
- ▶ Predation may have been the major selective pressure for the development of hard, external body coverings.
- ▶ Early in animal evolution, the only food in the water consisted of dissolved organic matter and very small organisms.
- ▶ Flowing water brings food with it, so many animals are sessile.
- ▶ All the phyla of protostomate animals had evolved by the Cambrian period.

576 CHAPTER THIRTY-TWO

For Discussion

1. Segmentation has arisen several times during animal evolution. What advantages does segmentation provide? Given these advantages, why do so many unsegmented animals survive?
2. Many animals extract food from the surrounding medium. What phyla contain animals that extract suspended food from the water column? What structures do these animals use to capture prey?
3. An animal that sheds its external skeleton in order to grow in size is virtually helpless during the time that its new, larger exoskeleton is hardening. Give some examples of how predators take advantage of this vulnerable stage of their prey. Include at least one example of predation by humans.
4. The British biologist J. B. S. Haldane is reputed to have quipped that "God was unusually fond of beetles." Beetles are, indeed, the most species-rich lineage of organisms. What features of beetles have contributed to the generation and survival of so many species? In Part Three we pointed out that major structural novelties have arisen infrequently during the course of evolution. Which of the features of

protostomes do you think are major evolutionary novelties? What criteria do you use to judge whether a feature is a major as opposed to a minor novelty?

A frequent consequence of sessile existence is competition for space. How do plants and animals differ in the ways in which they compete for space?

There are more described and named species of insects than of all other animals lineages combined. However, only a very few species of insects live in marine environments, and those species are restricted to the intertidal zone or the ocean surface. What factors may have contributed to the inability of insects to be successful in the oceans?

33

^/^/ Deuterostome Animals

^ There are about 25,000 species of ray-finned fishes—more species than exist in all other vertebrate groups combined. Ray-finned fishes include almost all fish species with bony skeletons (as opposed to the sharks, whose skeletons are made of cartilage). Most ray-finned fishes have excellent color vision, and they use their brightly colored bodies to advertise their presence, species identity, and sex. Some go through dramatic color changes at different stages of their lives, and some are even able to change colors quickly when they are ready to mate, fight, or flee.

Part of the reason for the richness of ray-finned species may be that fishes are an ancient lineage that has had many millions of years in which to radiate in Earth's oceans and fresh waters. But part of the reason may be genetic. Most vertebrates have only four clusters of homeobox genes, but some ray-finned fishes have seven. The entire genome of these fishes was apparently duplicated about 300 million years ago, providing new opportunities for genetic variability that may have helped drive their explosive evolutionary radiation.

There are fewer major lineages and many fewer species among deuterostomes than among protostomes (Table 33.1), but we have a special interest in deuterostomes because we are members of that lineage. In this chapter, we first discuss some evolutionary themes shared by protostomes and deuterostomes, then describe and discuss the deuterostome phyla Echinodermata, Hemichordata, and Chordata, with special attention to the primate lineage of Chordata that gave rise to our own species.

Deuterostomes and Protostomes: Shared Evolutionary Themes

Deuterostome evolution paralleled protostome evolution in several important ways. Both lineages exploited the abundant food supplies buried in soft marine sediments, attached to rocks, or suspended in water. Because of the ease with which water can be moved, many groups in both lineages developed elaborate structures for moving water and extracting prey from it.

Two Colors, One Fish

The spotted puffer fish, *Arothron meleagris*, changes color during the course of its life cycle. The individuals shown here are in two different color phases of the cycle.

In lineages of both groups, the body became divided into compartments that allowed better control of shape and movement. Some members of both groups evolved mechanisms for controlling their buoyancy in water, using gas-filled internal spaces. Planktonic larval stages evolved in marine members of many protostome and deuterostome phyla; these all fed on tiny planktonic organisms while floating freely in the open water.

The ancestral traits shared by all members of the deuterostome lineage include indeterminate cleavage in the early embryo, a blastopore that becomes the anus, three body layers (they are triploblastic), formation of the mesoderm from an outpocketing of the embryonic gut, and a well-developed coelom (see Chapter 31). No fossils of ancestral deuterostomes that lived before the lineage split into two major lineages (echinoderms and chordates; Figure 33.1) have been found, so we can only deduce what they must have been like from these shared traits.

Both protostomes and deuterostomes colonized the land—the former via beaches, the latter via fresh water— but the consequences of these colonizations were very different. The jointed external skeletons of arthropods, although they provide excellent support and protection in air, cannot support large animals. The internal skeletons developed by deuterostomes are capable of supporting large bodies. The largest terrestrial deuterostomes to ever live were some of the dinosaurs; elephants are the largest living terrestrial animals.

Terrestrial deuterostomes recolonized aquatic environments a number of times. Suspension feeding re-evolved in several of these lineages. The largest living animals, the baleen (toothless) whales, feed on relatively small prey that they extract from the water with large straining structures in their mouths.

33.1 A Probable Deuterostomate Phylogeny

There are fewer major lineages and many fewer species of deuterostomes than of protostomes.

Echinoderms: Complex Biradial Symmetry

The ancestors of one deuterostome lineage, the echinoderms (phylum Echinodermata), were probably sluggish animals. They evolved into more aggressive and active forms as a result of two major structural features. One is a system of calcified internal plates covered by thin layers of skin and some muscles. The calcified plates of early echinoderm ancestors became enlarged and thickened until they fused inside the entire body, giving rise to an internal skeleton.

Hemichordata

Urochordata (tunicates)

Cephalochordata

Vertebrata

The other major innovation was the evolution of a water vascular system, a network of calcified hydraulic canals leading to extensions called tube feet. The water vascular system functions in gas exchange, locomotion, and feeding (Figure 33.2a). Seawater enters the water vascular system through a perforated sieve plate. A calcified canal leads from the sieve plate to another canal that rings the esophagus. Other canals radiate from this ring canal extending through the arms (in species that have arms) and connecting with the tube feet. The development of these two structural innovations—calcified internal skeleton and water vascular system—resulted in one of the most striking of evolutionary radiations.

Echinoderms have an extensive fossil record. About 23 classes have been described, of which only 6 survive today. About 7,000 species of echinoderms exist today, but 13,000 species—probably only a small fraction of those that actually lived—have been described from their fossil remains. Nearly all living species have a bilaterally symmetrical, ciliated larva that feeds for some time as a planktonic organism before settling and transforming into a biradially symmetrical adult (Figure 33.2b).

The living echinoderms are divided into two lineages: Pelmatozoa and Eleutherozoa. The two lineages differ in the number of arms they have and the form of their water vascular systems. Pelmatozoa consists only of the crinoids, whereas several groups are included in the Eleutherozoa.

(a) The flexible arms of the golden feather star are clearly visible.

(b) Purple sea urchins are important grazers of algae in the inter-tidal zone of the Pacific Coast of North America, (c) This sea cucumber lives on rocky substrates in seas around Papua New Guinea, (d) The blood sea star is typical of many sea stars; some species, however, have more than five arms, (e) This brittle star is resting on a sponge.

Pelmatozoans have jointed arms

Sea lilies and feather stars (class Crinoidea) are the only surviving pelmatozoans. Sea lilies were abundant 300-500 mya, but only about 80 species survive today. Most sea lilies attach to a substratum by means of a flexible stalk consisting of a stack of calcareous discs. The main body of the animal is a cup-shaped structure that contains a tubular digestive system. Five to several hundred arms, usually in multiples of five, extend outward from the cup. The jointed calcareous plates of the arms enable them to bend. A groove runs down the center of each arm to the mouth. On both sides of the groove are tube feet covered with mucus-secreting glands.

A sea lily feeds by orienting its arms in passing water currents. Food particles strike and stick to the tube feet, which transfer the particles to the grooves in the arms, where the action of cilia carries the food to the mouth. The tube feet of sea lilies are also used for gas exchange and elimination of nitrogenous wastes.

Feather stars are similar to sea lilies, but they have flexible appendages with which they grasp the substratum while they are feeding and resting (Figure 33.3a). Feather

DEUTEROSTOMATE ANIMALS 581

stars feed in much the same manner as sea lilies. They can walk on the tips of their arms or swim by rhythmically beating their arms. About 600 living species of feather stars have been described.

Eleutherozoans are the dominant echinoderms

Most surviving echinoderms are members of the eleuthero-zoan lineage. Biochemical data suggest that the ancestors of sea urchins and sand dollars (class Echinoidea) were the first to split off from the lineage leading to the other eleutherozoans. Sea urchins and sand dollars lack arms, but they share a five-part body plan with all other echinoderms. Sea urchins are hemispherical animals that are covered with spines attached to the underlying skeleton via ball-and-socket joints (Figure 33.3b). The spines of sea urchins come in varied sizes and shapes; a few produce highly toxic substances. Many sea urchins consume algae, which they scrape from the rocks with a complex rasping structure. Others feed on small organic debris that they collect with their tube feet or spines. Sand dollars, which are flattened and disc-shaped, feed on algae and fragments of organic matter on the seafloor.

The tube feet of sea cucumbers (class Holothuroidea; Figure 33.3c) are used primarily for attaching to the substratum rather than for moving. The anterior tube feet are modified into large, feathery, sticky tentacles that can be protruded around the mouth. Periodically, a sea cucumber withdraws the tentacles into its mouth, wipes off the material that has adhered to them, and digests it.

Sea daisies (class Concentricycloidea) were not discovered until 1986. Little is known about them. They have tiny disc-shaped bodies with a ring of marginal spines, and two ring canals, but no arms. Sea daisies are found on rotting wood in ocean waters. They apparently feed on prokaryotes, which they digest outside their bodies and absorb either through a membrane that covers the oral surface or via a shallow saclike stomach.

The most familiar echinoderms are the sea stars (class Asteroidea; Figure 33.3d; see also Figure 33.2). Their tube feet serve as organs of locomotion and, because their walls are thin, they are important sites for gas exchange. Each tube foot of a sea star is also an adhesive organ, consisting of an internal bulb connected by a muscular tube to an external sucker. A tube foot is moved by expansion and contraction of the circular and longitudinal muscles of the tube. It can adhere to a surface by secreting a sticky substance around the sucker.

Many sea stars prey on polychaetes, gastropods, bivalves, and fishes. They are important predators in many marine environments, such as coral reefs and rocky inter-tidal zones. With hundreds of tube feet acting simultaneously, a sea star can exert an enormous and continuous force. It can grasp a clam in its arms, anchor the arms with its tube feet, and, by steady contraction of the muscles in the arms, gradually exhaust the muscles with which the clam keeps its shell closed. Sea stars that feed on bivalves are able to push the stomach out through the mouth and

then through the narrow space between the two halves of the shell. The stomach secretes digestive enzymes into the soft parts of the bivalve, digesting it.

Brittle stars (class Ophiuroidea) are similar in structure to sea stars, but their flexible arms are composed of jointed hard plates (Figure 33.3e). Brittle stars generally have five arms, but each arm may divide a number of times. Most of the 2,000 species of brittle stars ingest particles from the surfaces of sediments and assimilate the organic material from them, but some species remove suspended food particles from the water; others capture small animals. They eject the indigestible particles through their mouths because, unlike most other echinoderms, brittle stars have only one opening to their digestive tract.

Chordates: New Ways of Feeding

The second major lineage of deuterostomes, the phylum Chordata, evolved several different modifications of the coelomic cavity that provided new ways of capturing and handling food. Some living representatives of one early lineage—acorn worms—live buried in marine sand or mud, under rocks, or attached to algae. They may be similar to the ancestors of the chordate lineage, but are currently classed in their own lineage as hemichordates ("half-chor-dates"). Animals in the chordate lineage evolved a strikingly different body plan from the acorn worms, characterized by an internal dorsal supporting structure, which in the vertebrates evolved into the spinal column.

Acorn worms capture prey with a proboscis

The acorn worms (phylum Hemichordata) have a three-part body consisting

of a proboscis, collar, and trunk (Figure 33.4). The 70 species of acorn worms live in burrows in muddy and sandy sediments.

The large proboscis of acorn vertebrata

worms is a digging organ. It is coated with a sticky mucus that traps prey items in the sediment. The mucus and its attached prey are conveyed by cilia to the mouth. In the esophagus, the food-laden mucus is compacted into a ropelike mass that is moved through the digestive tract by ciliary action. Behind the mouth is a pharynx that opens to the outside through a number of pharyngeal slits through which water can exit. Highly vascularized tissue surrounding the pharyngeal slits serves as a gas exchange apparatus. An acorn worm breathes by pumping water into its mouth and out through its pharyngeal slits.

The pharynx becomes a feeding device

The same property required for effective gas exchange— a large surface area—also serves well for capturing prey. The pharyngeal slits, which originally functioned as sites for

gas exchange and eliminating water, as they do in modern acorn worms, were enlarged in a sister lineage. This enlargement of the pharyngeal slits eventually led to the remarkable evolutionary developments that gave rise to the chordates.

Chordates (phylum Chordata) are bilaterally symmetrical animals whose body plans are characterized by several shared features:

- ▶ Pharyngeal slits (at some stage of their development).
- ▶ A dorsal, hollow nerve cord.
- ▶ A ventral heart.
- ▶ A tail that extends beyond the anus.
- ▶ A dorsal supporting rod, the notochord.

The notochord is the most important derived trait of the Chordata and is unique to that phylum. In some species, such as tunicates, the notochord is lost during metamorphosis to the adult stage. In the vertebrates, it is replaced by skeletal structures that provide support for the body.

A notochord appears in tunicates and lancelets

The tunicates (sub-phylum Urochordata) may be similar to the ancestors of all chordates. All 2,500 species of tunicates are marine animals, most of which are sessile as adults. It is their swimming, tadpolelike larvae that reveal the close evolutionary relationships between tunicates and other chordates.

A tunicate larva has pharyngeal slits, a dorsal, hollow nerve cord, and a notochord. Muscles are attached to the notochord, providing the body with relatively rigid support. After a short time floating in the water, the larva settles on the seafloor and becomes a sessile adult. The nerve cord and notochord disappear in the adult animal, which

Echinodermata

Vertebra ta

feeds by extracting plankton from the water. An adult's pharynx is enlarged into a pharyngeal basket lined with cilia, whose beating moves water through the animal.

More than 90 percent of known species of tunicates are sea squirts (class Ascidiacea). Some sea squirts are solitary,

but others produce colonies by asexual budding from a single founder. Individual sea squirts range in size from less than 1 mm to 60 cm in length, but colonies may measure several meters across. The baglike body of an adult is surrounded by a tough tunic, composed of protein and a complex polysaccharide, which is secreted by the epidermal cells. Much of the body is occupied by the large pharyngeal basket (Figure 33.5).

The 25 species of lancelets (subphylum Cephalochordata) are small animals that rarely exceed 5 cm in length. Their notochord extends the entire length of the body throughout their lives, and they resemble small fishes. Lancelets live partly buried in soft marine sediments. They extract small prey from the water with their pharyngeal baskets (Figure 33.6).

Origin of the Vertebrates

In one chordate lineage, the pharyngeal basket became enlarged. With its many exit openings, an enlarged basket was effective in extracting prey from mud, which contains many inedible particles along with food. This lineage gave rise to the vertebrates (subphylum Vertebrata). In the late Cambrian period, these early vertebrates evolved improved structures for extracting food from mud and sand and for moving over the surface of the substratum.

Vertebrates take their name from a jointed, dorsal vertebral column, which replaced the notochord as their primary support. The vertebrate body plan (Figure 33.7) can be characterized as follows:

- ▶ With the vertebral column as its anchor, a rigid internal skeleton provides support and mobility.
- ▶ Two pairs of appendages are attached to the vertebral column.
- ▶ The faster locomotion made possible by appendages favored the evolution of an anterior skull with a large brain and highly developed sensory receptors.
- ▶ The internal organs are suspended in a large coelom.
- ▶ A well-developed circulatory system, driven by contractions of a ventral heart, delivers oxygen to internal organs.

The filter-feeding ancestral vertebrates lacked jaws. They probably swam over the sediments, sucking up mud and extracting microscopic food from it. These animals gave rise to the fishes. The lineage leading to modern hagfishes probably separated first from

33.7 The Vertebrate Body Plan

A bony fish is used here to illustrate the structural elements common to all vertebrates.

the other groups (Figure 33.8). One early group of jawless fishes, called ostracoderms, meaning "shell-skinned," evolved a bony external armor that protected them from predators. With their heavy armor, these small fishes could swim only slowly, but they could safely swim above the substratum, which was easier than having to burrow through it, as all previous sediment feeders had done.

The new mobility of jawless fishes enabled them to exploit their environments in new ways. They could attach to dead organisms and use the pharynx to create suction to pull fluids and partly decomposed tissues into the mouth. Hag-fishes and lampreys, the only jawless fishes to survive beyond the Devonian period, feed on both dead and living organisms in this way (Figure 33.9). These fishes have tough, scaly skins instead of external armor. The round mouth is a sucking organ with which the animals attach to their prey and rasp at the flesh. Lampreys live in both fresh and salt water; many species move between the two environments, laying their eggs in rivers and maturing in the sea.

Hagfishes have become entirely marine...

33.8 A Probable Vertebrate Phylogeny

This phylogeny incorporates the view that vertebrates evolved in estuaries, where their ability to handle varying salinities allowed them to exploit habitats not available to marine animals.

Jaws improve nutrition

During the Devonian period, many new kinds of fishes evolved in the seas, estuaries, and fresh waters. Although most of these were jawless, members of one lineage evolved jaws from some of the skeletal arches that supported the gill region (Figure 33.10). A jaw allows a fish to grasp and subdue relatively large, living prey. Further development of jaws and teeth among fishes led to the ability to chew both soft and hard body parts of prey. Chewing aided chemical digestion and improved the ability of fishes to obtain nutrients from prey.

350

Present

Petromyzon marinus

33.9 A Modern Jawless Fish

A lamprey uses its large, jawless mouth to suck blood and flesh from other fishes.

The dominant early jawed fishes were the heavily armored placoderms (class Placodermi). Some of these fishes evolved elaborate appendages and relatively sleek body forms that improved their ability to maneuver in open water. A few became huge (10 meters long) and, together with squids (cephalopod mollusks), were probably the major predators in the Devonian oceans. Despite their early abundance, however, most placoderms disappeared by the end of the Devonian period; none survived to the end of the Paleozoic era.

Fins improve mobility

Two other groups of fishes—the bony fishes and the cartilaginous fishes, both ^^^^^^^^^^^^^^^^^

have a skeleton composed entirely ^^

of a firm but pliable material called Tetrapods

cartilage. Their skin is flexible and leathery, sometimes bearing bristly projections that give it the consistency of sandpaper. The loss of external armor increased their mobility and ability to escape from predators.

In the cartilaginous fishes and their descendants, swimming is controlled by pairs of unjointed appendages called fins: a pair of pectoral fins just behind the gill slits and a pair of pelvic fins just in front of the anal region. A dorsal median fin stabilizes the fish as it moves. Sharks move forward by means of their tail and pelvic fins. Skates and rays propel themselves by means of the undulating movements of their greatly enlarged pectoral fins.

Cartilaginous fishes

Living forms

Additional gill arches were incorporated to form heavier, more efficient jaws.

33.10 Jaws from Gill Arches

This illustrates one probable scenario for the evolution of jaws from the anterior gill arches of fishes.

(a) *Triaenodon obesus*

Most sharks are predators, but some feed by filtering plankton from the water. The world's largest fish, the whale shark (*Rhincodon typhus*), is a filter feeder. It may grow to more than 15 meters in length and weigh more than 9,000 kilograms. Most skates and rays live on the ocean floor, where they feed on mollusks and other invertebrates buried in the sediments. Nearly all cartilaginous fishes live in the oceans.

Swim bladders allow control of buoyancy

The bony fishes (class Osteichthyes) have internal skeletons of bone rather than cartilage, giving them their common name. Their bony skeleton is lighter than that of the cartilaginous fishes. In most species, the outer surface is covered with flat, smooth, thin, lightweight scales that provide some protection. The gills of bony fishes open into a single chamber cov- _____

A U U A Hagfishes

ered by a hard

flap. Movement Lampreys

of the flap improves the flow of water over the gills, where gas exchange takes place.

Early bony fishes also evolved gas-filled sacs that supplemented the action of the gills in respiration. These features enabled po< ^

early bony fishes to live where oxygen was periodically in short supply, as it often is in estuarine and freshwater environments. They still serve this function in lungfishes and a few other modern fishes, but in the ray-finned fishes— a group that includes most of the many species of bony fish—these lunglike sacs evolved into swim bladders,

Cartilaginous fishes

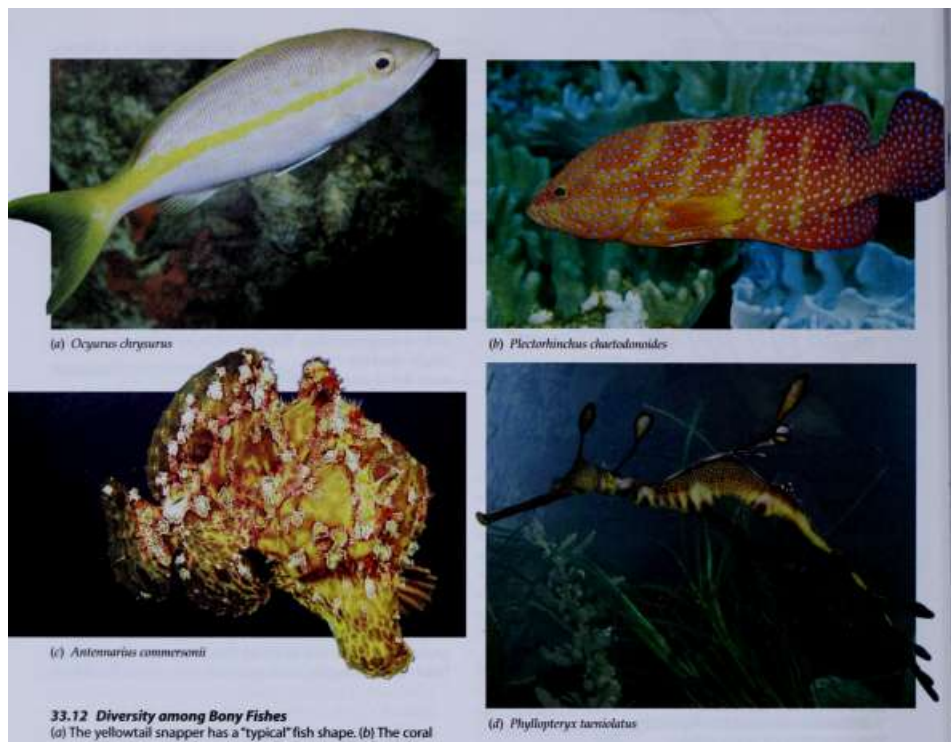

33.11 Cartilaginous Fishes

(a) Most sharks, such as this whitetip reef shark, are active marine predators, (b) Skates and rays, represented here by a stingray, feed on the ocean bottom. Their modified pectoral fins are used for propulsion.

(c) *Antennarius commersonii*

33.12 Diversity among Bony Fishes

(a) The yellowtail snapper has a "typical" fish shape, (b) The coral grouper lives on tropical coral reefs, (c) Commerson's frogfish can change its color in a range from pale yellow to orange-brown to deep red, thus enhancing its camouflage abilities, (d) This weedy sea dragon is difficult to see when it hides in vegetation. It is a larger "cousin" of the more familiar seahorse.

which serve as organs of buoyancy. By adjusting the amount of gas in its swim bladder, a fish can control the depth at which it is suspended in the water without expending energy.

With their lighter skeletons and protective coverings and their swim bladders, ray-finned bony fishes evolved a remarkable diversity of sizes, shapes, and lifestyles (Figure 33.12). The smallest are less than 1 cm long as adults; the largest are ocean sunfishes that weigh up to 900 kilograms. Ray-finned fishes exploit nearly all types of aquatic food sources. In the oceans they filter plankton from the water, rasp algae from rocks, eat corals and other colonial invertebrates, dig invertebrates from soft sediments, and prey on virtually all other vertebrates except large whales and Ichthyosaurs. In fresh water they eat plankton, devour insects

(d) *Phyllopteryx taeniolatus*

of all aquatic orders, eat fruits that fall into the water in flooded forests, and prey on other aquatic vertebrates.

Some fishes live buried in soft sediments, capturing passing prey or emerging at night to feed. Many are solitary, but in open water others form large aggregations called schools. Many fishes perform complicated behaviors by means of which they maintain schools, build nests, court and choose mates, and care for their young.

With their fins and swim bladders, fishes can readily control their positions in open water, but their eggs tend to sink. Therefore, most fishes attach their eggs to the substratum, although a few species discharge their small eggs directly into surface waters where they are buoyant enough to complete their development before they sink very far. Most marine fishes move to food-rich shallow waters to lay their eggs, which is why coastal waters and estuaries are so important in the life cycles of many species. Some, such as salmon, abandon salt water when they breed, ascending rivers to spawn in freshwater streams and lakes.

DEUTEROSTOMATE ANIMALS 587

Colonizing the Land: Obtaining Oxygen from the Air

Although the evolution of lunglike sacs was a response to the inadequacy of gills for respiration in oxygen-poor waters, it also set the stage for the invasion of land. Some early bony fishes probably used their lung sacs to supplement their gills when oxygen levels in the water were low. This ability would also have allowed them to breathe air, and to leave the water temporarily when pursued by predators unable to do so. But with their unjointed fins, bony fishes could only flop around on land, as most fishes do today if placed out of water. Changes in the structure of fins would help such fishes move about on land.

Two lineages of bony fishes evolved jointed fins: the lobe-finned fishes (subclass *Crossopterygii*) and the lung-fishes. The lobe-fins flourished from the Devonian period until about 25 mya, when they were thought to have become extinct. However, in 1938, a lobe-fin was caught by commercial fishermen off the Comoro Islands in the Indian Ocean. Since that time, several

dozen specimens of this extraordinary fish, *Latimeria chalumnae*, have been collected. *Latimeria*, a predator on other fishes, reaches a length of about 1.5 meters and weighs up to 82 kilograms (Figure 33.13). Although it belongs to the bony fish lineage, the skeleton of *Latimeria* is composed mostly of cartilage, not bone.

Some descendants of early fishes with jointed fins began to use terrestrial food sources and over time became more fully adapted to life on land. This lineage became the tetra-pods: the four-legged amphibians, reptiles, birds, and mammals that are common today.

Amphibians invade the land

During the Devonian period, amphibians (class Amphibia) arose from ancestors they shared with the lung-fishes. In this lineage, the stubby, jointed fins of their ancestors evolved into walking legs. The design of those legs has

Tetrapod

vertebrate

ancestor

33.73 A Modern Lobe-Fin

Latimeria chalumnae, found in deep waters of the Indian Ocean, is the sole surviving species of its lineage, which had been thought to be extinct.

33.14 A Probable Phytogeny of Tetrapods

In the birds (Class Aves), the paired forelimbs evolved into wings.

remained largely unchanged throughout the evolution of terrestrial vertebrates (Figure 33.14).

The Devonian predecessors of amphibians were probably able to crawl from one pond or stream to another by pulling themselves along on their finlike legs, as do some modern species of catfishes. They gradually evolved to be able to live on swampy land and, eventually, on dry land. Living amphibians have relatively small lungs, and most species exchange gases through their skins. Most terrestrial species are confined to moist environments because they lose water rapidly through their skins when exposed to dry air.

About 4,500 species of amphibians live on Reptilia

Earth today, many fewer than the number known only from fossils. Living amphibians belong to three orders (Figure 33.15):

the wormlike, tropical, burrowing caecilians (order Gymno-phiona); frogs and toads (order Anura, which means "tailless"); and salamanders (order Urodela, which means "tailed"). Most species of frogs and toads live in tropical and warm temperate regions, although a few are found at very high latitudes and altitudes. Salamanders are more diverse in temperate regions, but many species are found in cool, moist environments in the mountains of Central America.

Most species of amphibians live in water at some time in their lives. In the typical amphibian life cycle, part or all of the adult stage is spent on land, usually in a moist habitat, but adults return to fresh water to lay their eggs (Figure 33.16). An amphibian egg can survive only in a moist environment because it is enclosed by a delicate envelope that cannot prevent water loss in dry conditions. The fertilized eggs of most species give rise to larvae that live in water until they change into terrestrial adults.

Amphibians are the focus of much attention today because populations of many species are declining rapidly. The golden

toad, for example, has disappeared from the Monteverde Cloud Forest Reserve in Costa Rica, which was established primarily to protect this rare species. Several possible reasons for the declines, including drought, in-

588 CHAPTER THIRTY-THREE

(b) *Scaphiophryne gottlebei*

(c) *Salamandra salamandra*

creased ultraviolet radiation, and diseases, have been identified. Biologists are monitoring amphibian populations closely to learn more about the causes of their difficulties and to determine the implications of their declines for other organisms, including humans.

The frog respire with lungs; its tail is resorbed.

Amniotes colonize dry environments

Most amphibians, as we have just seen, are limited to moist environments. Two morphological changes contributed to the ability of one lineage of vertebrates to control water loss and, therefore, to exploit a wider range of terrestrial habitats. One was the evolution of an egg with a shell that is relatively impermeable to water. The other was a combination of traits that

reduced water loss, including a tough skin impermeable to water and kidneys that could excrete concentrated urine. The vertebrates that evolved both of these traits are called amniotes. They were the first vertebrates to become widely distributed over the terrestrial surface of Earth.

The amniote egg has a leathery or brittle calcium-impregnated shell that retards evaporation of the fluids inside, but permits O_2 and CO_2 to pass through. Such an egg

does not require a moist environment, but can be laid anywhere. Within the shell and surrounding the embryo are membranes that protect the embryo from desiccation and assist its respiration and excretion of waste nitrogen. The egg also stores large quantities of food as yolk, permitting the embryo to attain a relatively advanced state of development before it hatches and *vs.* must feed itself (Figure 33.17).

An early amniote lineage, the reptiles (class Reptilia) arose from the tetrapods during the Carboniferous period. As we discussed in Chapter 23, Rep-

dpole respire with internal gills; hind legs appear.

The larva (tadpole) respire with external gills.

The egg hatches.

33.16 In and Out of the Water

Most stages in the life cycle of temperate-zone frogs take place in water. The aquatic tadpole is transformed into a terrestrial adult through metamorphosis.

The evolution of the amniote egg, with its shell, three extraembryonic membranes and embryo-nourishing yolk, was a major step in the colonization of the terrestrial environment.

tilia, as we use the term here, is a paraphyletic group because it does not include the birds, a major lineage that split off relatively recently during reptilian evolution. (Figure 33.18). However, because all reptiles are structurally similar, they serve as a convenient example for discussing the characteristics of amniotes. Therefore, we use this traditional classification as a basis for our discussion while recognizing that the birds should technically be included within it.

About 6,000 species of reptiles live today. Most reptiles do not care for their eggs after laying them. In some species the eggs do not develop shells, but are retained inside the female's body until they hatch. Still other species evolved structures called placentas that nourish the developing embryos.

Amphibia

Aves

Mammalia

33.18 The Reptiles Form a Paraphyletic Group

The traditional classification of the reptiles creates the paraphyletic group Reptilia. As used here, Reptilia does not include the birds (Aves), even though this major lineage split off from the crocodilian reptiles relatively recently (in evolutionary terms).

The skin of a reptile is covered with horny scales that greatly reduce loss of water from the body surface. These scales, however, make the skin unavailable as an organ of gas exchange. In reptiles, gases are exchanged almost entirely by the lungs, which are proportionally much larger in surface area than those of amphibians. A reptile forces air into and out of its lungs by bellows-like movements of its ribs. Unlike the amphibian heart, the reptilian heart is divided into chambers that partially separate oxygenated from unoxygenated blood. With this type of heart, reptiles can generate higher blood pressures than amphibians and can sustain higher levels of muscular activity.

Reptilian lineages diverge

The lineages leading to modern reptiles began to diverge about 250 mya when the ancestors of the subclass Squamata (lizards, snakes, and amphisbaenians—a group of legless, wormlike, burrowing animals with greatly reduced eyes) diverged from the lineage leading to all other reptiles (Figure 33.19a, b). Most lizards are insectivores, but some are herbivores, and a few prey upon other vertebrates. The largest lizards, which may grow as long as 3 meters, are some species of monitors that live in the East Indies. Most lizards walk on four limbs, but some are limbless, as are all snakes, which are descendants of burrowing lizards.

All snakes are carnivores, and many can swallow objects

much larger in diameter than themselves. The combination

of poison glands and the ability to inject venom rapidly

into their prey evolved several times. The largest snakes are

pythons more than 10 meters long.

The tuataras (subclass Sphenodontida), which today are represented by only two species restricted to a few islands off the coast of New Zealand (Figure 33.19c), superficially resemble lizards, but differ from them in several internal anatomical features. Their phylogenetic relationships are uncertain.

Considerable uncertainty surrounds the next lineage split. Traditionally turtles were thought to have separated from other reptiles early in the history of the group, but new molecular analyses suggest that turtles are closely related to crocodilians, which diverged later. Both turtles and ancestral crocodiles have dorsal and ventral armored plates, and such plates have characterized those groups for many millions of years.

The dorsal and ventral bony plates of modern turtles and tortoises (subclass Chelonia) form a shell into which the head and limbs can be withdrawn (Fig-

(b) *Ocyurus chrysurus*

(c) *Sphenodon punctatus*

ure 33.19d). Most turtles live in lakes and ponds, but tortoises are terrestrial; some live in deserts. Sea turtles spend their entire lives at sea except when they come ashore to lay eggs; all seven species are endangered. A few species of turtles and tortoises are carnivores, but most species are omnivores that eat a variety of aquatic and terrestrial plants and animals.

(e) *Alligator mississippiensis*

Figure 33.19 Reptilian Diversity

(a) This Sumatran pit viper is prepared to strike, (b) This African chameleon, a lizard, has a long tail with which it can grasp branches and large eyes that move independently in their sockets, (c) The tuatara looks like a typical lizard, but it is one of only two survivors of a lineage that separated from lizards long ago. (d) The green sea turtle is widely distributed in tropical oceans, (e) Most crocodilians are tropical; alligators live in warm temperate environments in China and, like this one, in the southeastern United States.

The crocodilians (subclass Crocodylia)—crocodiles, caimans, gharials, and alligators—are confined to tropical and warm temperate environments (Figure 33A9e). Crocodilians spend much of their time in water, but they build nests on land or on floating piles of vegetation. Their eggs are warmed by heat generated by the decay of organic matter that they place in the nest. Typically the eggs are guarded by the female until they hatch. All crocodilians are carnivorous; they prey on vertebrates of all classes, including large mammals.

Another lineage led to the dinosaurs, reptiles that rose to dominance about 215 mya and dominated terrestrial environments for about 150 million years. During this time, vir-

Amphibia

Reptilia

Mammalia

tually all terrestrial animals more than 1 meter in length were dinosaurs. Some of the largest dinosaurs weighed up to 100 tons. Many were agile and could run rapidly. Some small predatory dinosaurs evolved feathers.

The ability to breathe and run simultaneously, which we take for granted, was a major innovation in the evolution of terrestrial vertebrates. Not until the evolution of the lineages leading to the mammals, dinosaurs, and birds did the legs assume vertical positions, which reduced the lateral forces on the body during locomotion. Special ventilatory muscles that

enabled the lungs to be filled and emptied while the limbs moved also evolved. These muscles are visible in living birds and mammals; we can infer their existence in dinosaurs from the structure of the vertebral column in their fossils and the capacity of many dinosaurs for bounding bipedal (using two legs) locomotion.

Birds: Feathers and Flight

During the Mesozoic era, a dinosaur lineage gave rise to the birds (subclass Aves). The oldest known avian fossil, Archaeopteryx, which lived ^^^^^^ about 150 mya, was covered with feathers that are virtually identical to those of modern birds. It also had well-developed wings, a long tail (Figure 33.20a), and a wishbone, which in modern birds serves as an anchoring site for flight muscles. Archaeopteryx had typical perching bird claws, suggesting that it lived in trees and shrubs and used the clawed fingers on its forearms to assist it in clambering over branches.

Another early bird, Confuciusornis sanctus, which is known from hundreds of complete fossils from China, lived only slightly more recently than Archaeopteryx. Well-preserved fossils show that males had greatly elongated tail feathers (Figure 33.20b), which they probably used in communal courtship displays. Large numbers of these fossils have been found together, as would be expected if a number of males displayed together on communal display grounds.

Because the avian lineage separated from the other reptiles long before Archaeopteryx lived, existing data are insufficient to identify the ancestors of birds with certainty. Most paleontologists (scientists who study fossils) believe that birds evolved from terrestrial bipedal dinosaurs that used their forelimbs for capturing prey. According to this view, these small dinosaurs evolved feathers for insulation or display, and eventually were able to become airborne for short distances.

During the Cretaceous period, birds underwent an extensive evolutionary radiation. The dominant Cretaceous lineage was the "opposite birds," so named because the tarsal bones of their legs fused in the opposite direction from the way fusion happens in all modern birds. All lineages of opposite birds died out at the end of the Cretaceous,

33.20 Mesozoic Birds

(a) An artist's recreation of Archaeopteryx shows its modern feathers, arboreal habits, and flight. (fc>) The elongated tail feathers of a male Confuciusornis sanctus ("sacred bird of Confucius") fossil suggest that the males used them in courtship displays.

but scientists disagree over how many other avian lineages survived the mass extinction. Paleontologists believe that members of only one lineage, collectively known as the transitional shorebirds, survived the end of the Cretaceous, because no later fossils of other lineages have been found. Other scientists, who base their conclusions on molecular clocks, believe that at least some representatives of many Cretaceous avian lineages must have survived, because modern birds are too different to have come from a single lineage.

33.21 Diversity among the Birds

(a) Penguins such as these gentoos are widespread in the cold waters of the southern hemisphere. They are expert swimmers, although they have lost the ability to fly. (b) Parrots are a diverse group of birds, especially in the tropics of Asia and the Pacific islands. This Australian king parrot is one member of Australia's rich parrot fauna, (c) Perching birds, represented here by a male northern cardinal, are the most species-rich of all the bird lineages.

(a) *Pygoscelis papua*

■ HHHBHHHBHHBHSIMi

(b) *Alisterus scapularis*

As a group, birds eat almost all types of animal and plant material. A few aquatic species have bills modified for filtering small food particles from the water. Insects are the most important dietary item for terrestrial birds. In addition, they eat fruits and seeds, nectar and pollen, leaves and buds, carrion, and other vertebrates. Birds are major predators of flying insects during the day, and some species exploit that food source at night. By eating the fruits and seeds of plants, birds serve as major agents of seed dispersal.

The feathers developed by some dinosaurs may originally have had thermoregulatory or display functions. Birds use them for these purposes as well as for flying. The flying surface of the wings is created by large quills that arise from the forelimbs. Other strong feathers sprout like a fan from the shortened tail and serve as stabilizers during flight. The contour feathers and down feathers provide insulation to control loss of body heat.

The bones of birds are also modified for flight. They are hollow and have internal struts for strength. The sternum as a bone forms a large, vertical keel to which the breast muscles are attached. These muscles pull the wings downward during the main propulsive movement in flight.

(c) *Cardinalis cardinalis*

Flight is metabolically expensive, and a flying bird consumes energy at a very high rate—about eight times the amount of energy per day as a lizard of the same weight! Because birds have such high metabolic rates, they generate large amounts of heat. They control the rate of heat loss using their feathers, which may be held close to the body or elevated to alter the amount of air trapped as insulation. The brain of a bird is larger in proportion to its body size than lizard or crocodile brains, primarily because the cerebellum, the center of sight and muscular coordination, is enlarged. The beaks of modern birds lack teeth.

Most birds lay their eggs in a nest, where they are warmed by the body heat of an adult that sits on them. Because birds have high body temperatures, the eggs of most species develop rapidly, hatching in less than 2 weeks. The offspring of many species hatch at a relatively helpless stage and are fed for some time by their parents. The young of other bird species, such

as chickens, sandpipers, and ducks, can feed themselves shortly after hatching. Adults of all species attend their offspring for some time, warning them of and protecting them from predators, leading them to good foraging places, sheltering them from bad weather, and feeding them.

As adults, birds range in size from the 2-gram bee hummingbird of the West Indies to the 150-kg ostrich. Some flightless birds of Madagascar and New Zealand known from fossils were even larger, but they were exterminated by the humans that first colonized those islands. There are about 9,600 species of living birds, more than in any other major vertebrate group except fishes (Figure 33.21).

Amphibia

Aves

The Origin and Diversity of Mammals

Mammals (class Mammalia) appeared in the early part of the Mesozoic era, branching from a lineage of mammal-like reptiles. Small mammals coexisted with reptiles and dinosaurs for at least

150 million years. After the large reptiles and dinosaurs disappeared during the mass extinction at the close of the Mesozoic, mammals increased dramatically in numbers, diversity, and size.

Skeletal simplification accompanied the evolution of small mammals from their larger reptilian ancestors. During mammalian evolution, bones from the lower jaw were incorporated into the middle ear, leaving a single bone in the lower jaw, and the number of bones in the skull decreased. The bulk of both the limbs and the bony girdles from which they are suspended was reduced. Mammals have far fewer, but more highly differentiated teeth than reptiles. Differences in the number, type, and arrangement of teeth in mammals reflect their varied diets.

These skeletal features are readily preserved as fossils, but the soft parts of mammals are seldom fossilized. Therefore we do not know when mammalian features such as mammary glands, sweat glands, hair, and a four-chambered heart evolved. As is the case with birds, the mammalian fossil record suggests that most of the modern mammalian orders evolved rapidly after the end of the Cretaceous, whereas molecular data suggest that they had already evolved during the Cretaceous.

Mammals are unique among animals in providing their young with a nutritive fluid (milk) secreted by mammary glands. Mammalian eggs are fertilized within the female's body, and the embryos undergo some development within a uterus prior to being born. In addition, mammals have a protective and insulating covering of hair, which is luxuriant in some species but has been almost entirely lost in whales, dolphins, and humans. In whales and dolphins thick layers of insulating fat (blubber) replace hair. Clothing assumes the same role for humans.

Mammals range in size from tiny shrews weighing only about 2 grams to the endangered blue whale, which measures up to 31 meters long and weighs up to 160,000 kilograms—the largest animal ever to live on Earth. The approximately 4,000 species of living mammals are divided into two major subclasses: Prototheria and Theria.

The subclass Prototheria contains a single order, the Monotremata, with only three species, which are found only in Australia and New Guinea. These mammals, the duck-billed platypus and spiny anteaters, or echidnas, differ from other mammals in that they lack a placenta, lay eggs, and have legs that poke out to the side (Figure 33.22). Monotremes nurse their young on milk, but they have no nipples on their mammary glands; rather, the milk simply oozes out and is lapped off the fur by the offspring.

(a) *Tachyglossus aculeata*

(b) *Ornithorhynchus anatinus*

33.22 Monotremes

{a) The short-beaked echidna is one of two surviving species of echidnas. (fc») The duck-billed platypus is the third surviving monotreme species.

Two major groups of mammals are members of the subclass Theria. Females of one group, the Marsupialia, have a ventral pouch in which they carry and feed their offspring (Figure 33.23fl). Gestation (pregnancy) in marsupials is short; the young are born tiny but with well-developed fore-limbs, with which they climb to the pouch. They attach to a nipple but cannot suck. The mother ejects milk into the tiny offspring until they grow large enough to suckle. Once her offspring have left the uterus, a female marsupial may become sexually receptive again. She can then carry fertilized eggs capable of initiating development and replacing the offspring in the pouch should something happen to them.

There are about 240 living species of marsupials. At one time marsupials were widely distributed on Earth, but today the majority of species are restricted to the Australian region, with a modest representation in South America

594 CHAPTER THIRTY-THREE

33.23 Marsupials

Too few fossil primates have been discovered to reveal with certainty their evolutionary relationships, but this phylogenetic tree is consistent with existing evidence.

grams, but much larger marsupials existed in Australia until they were exterminated by humans soon after they reached Australia about 50,000 years ago.

Most living mammals are eutherians. (Eutherians are sometimes called placental mammals, but this name is not accurate because some marsupials also have placentas.) Eutherians are more highly developed at birth than are marsupials, and no external pouch houses them after birth. The nearly 4,000 species of eutherians are divided into 16 major groups, the largest of which is the rodents, with about 1,700 species (Figure 33.24f). The next largest group, the bats, has about 850 species (Figure 33.24b), followed by the insectivores (moles and shrews) with slightly more than 400 species.

Eutherians are extremely varied in form and ecology. Several lineages of terrestrial mammals subsequently colonized marine environments, to become whales, dolphins, seals, and sea lions (Figure 33.24c). Eutherian mammals are—or were, until they were greatly reduced in numbers by humans—the most important grazers and browsers in most terrestrial ecosystems

(Figure 33.24d). Grazing and browsing have been an evolutionary force intense enough to select for the spines, tough leaves, and difficult-to-eat growth forms found in many plants, a striking example of coevolution.

DEUTEROSTOMATE ANIMALS 595

Primates and the Origins of Humans

Another eutherian lineage that has had dramatic effects on ecosystems worldwide is the primate lineage, to which humans belong. Primates have undergone extensive recent evolutionary radiation. They probably descended from small arboreal (tree-living) insectivores sometime during the Cretaceous period. The major traits that distinguish primates from other mammals are all adaptations to arboreal life. They include:

- ▶ Dexterous hands with opposable thumbs that can grasp branches and manipulate food.
- ▶ Nails rather than claws.
- ▶ Eyes on the front of the face that provide good depth perception.
- ▶ Very small litters of offspring (usually just one) that receive extended parental care.

Early in its evolutionary history, the primate lineage split into two main branches, prosimians and anthropoids (Figure 33.25). Prosimians — lemurs, bush babies, and lorises—once lived on all continents, but today they are restricted to Africa, Madagascar, and tropical Asia. All of the mainland species are arboreal and nocturnal (Figure 33.26). However, on Madagascar, the site of a remarkable prosimian radiation, there are also diurnal and terrestrial species.

The anthropoids —tarsiers, monkeys, apes, and humans—evolved from an early primate lineage about

55 million years ago in Africa or Asia. New World monkeys have been evolving separately from Old World monkeys long

enough that they could have reached South America from Africa when those two continents were still close to each other. Perhaps because tropical America has been

heavily forested for a long time, all New World monkeys are arboreal (Figure 33.27a). Many of them have long, prehensile tails with which they can grasp branches. Many Old World primates are arboreal as well, but a number of species are terrestrial. Some of these species, such as baboons and macaques, live and travel in large groups (Figure 33.27b). No Old World primates have prehensile tails.

DEUTEROSTOMATE ANIMALS 597

Dots indicate the sites where australopithecine fossils have been found.

Adult female australopith

apes separated from the other Old World primates. The first apes were arboreal, but some species came to live in drier habitats with scattered trees, where they obtained most of their food on the ground. Apes are known to have lived in Africa, the Near East, and Asia 15-20 mya. Africa was especially rich in ape species, but the DNA sequences of living primates and some fossil evidence suggests that a European ape that dispersed into Africa about 10 mya may be the ancestor of modern apes. Four of the living genera of apes—gorillas (*Gorilla*), chimpanzees (*Pan*), orangutans (*Pongo*), and gibbons (*Hylobates*) — are restricted to tropical Africa and Asia (Figure 33.28). The fifth (*Homo*) has a worldwide distribution.

Human ancestors descended to the ground

The primate lineage that led to humans began with the ardipithecines. These apes had distinct morphological adaptations for bipedalism — locomotion in which the body is held erect and moved exclusively by movements of the hind legs. Bipedal locomotion frees the hands to manipulate objects and to carry them while walking. It also elevates the eyes, enabling the animal to see over tall vegetation to spot predators and prey. Both advantages were probably important for early ardipithecines and their descendants, the australopithecines.

The first australopithecine skull was found in South Africa in 1924; since then other fragments have been found in a number of sites in Africa (Figure 33.29). The most complete fossil skeleton of an australopithecine, approximately 3.5 million years old, was discovered in Ethiopia in 1974. That individual, a young female known to the world as Lucy, attracted a great deal of attention because her remains were so complete and well preserved. Lucy has been assigned to the species *Australopithecus afarensis*, the most likely ancestor of humans. All the evidence from different parts of her skeleton suggests that Lucy was only about 1 meter tall and walked upright.

From *Australopithecus afarensis* ancestors, a number of species of australopithecines evolved. Several million years ago, two distinct types of australopithecines lived together over much of eastern Africa. The larger type (about 40 kg) is represented by at least two species, both of which died out suddenly about 1.5 million years ago. The 25-30-kg *A. africanus* is much rarer as a fossil, suggesting that it was less common than the other species.

Humans arose from australopithecine ancestors

Many experts believe that the recently discovered *Australopithecus garhi* or a similar species gave rise to the genus *Homo*. *A. garhi*, a small-brained, big-toothed hominid with

Few fossilized remains are complete, but skull shapes can be reconstructed accurately.

humanlike leg proportions, began using tools to obtain food about 2.5 mya. They butchered animals to get at bone marrow, which is rich in fat.

Early hominids —members of the genus *Homo*—lived contemporaneously with australopithecines for perhaps half a million years. Two major changes accompanied the evolution of *Homo* from *Australopithecus*: an increase in body size and a doubling of brain size.

The oldest fossil remains of a member of the genus *Homo*, named *H. habilis*, were discovered in the Olduvai Gorge, Tanzania, and are estimated to be 2 million years old. Other fossils of *H. habilis* have been found in Kenya and Ethiopia. Tools used by these early hominids were found with the fossils. *H. habilis* lived in relatively dry areas where, for much of the year, the main food reserves are subterranean roots, bulbs, and tubers. To exploit these food resources, an animal must dig into hard, dry soils, something that cannot be done with an unaided primate hand. However, roots can be dug in large quantities in a relatively short time by an individual with a simple digging tool. *H. habilis* females carrying infants could have done so, freeing males to hunt animal prey to provide the proteins that roots lack.

The only other known extinct species of our genus, *Homo erectus*, evolved in Africa about 1.6 million years ago. Soon thereafter it had spread as far as eastern Asia. As it expanded its range and increased in abundance, *H. erectus* may have exterminated *H. habilis*. Members of *H. erectus* were as large as modern people, but their bones were considerably heavier. *H. erectus* used fire for cooking and for hunting large animals, and made characteristic stone tools

that have been found in many parts of the Old World. These tools were probably used for digging, capturing animals, cleaning and cutting meat, scraping hides, and cutting wood. Although *H. erectus* survived in Eurasia until about 250,000 years ago, it was replaced in tropical regions by our species, *Homo sapiens*, about 200,000 years ago.

Brains steadily became larger

The trends that accompanied the transition from *Australopithecus* to *H. erectus* continued during the evolution of our own species (Figure 33.30). The earliest members of *Homo sapiens* had larger brains than members of the earlier species of *Homo*, a change that was probably favored by an increasingly complex social life. The ability of group members to communicate with one another was valuable for cooperative hunting and gathering and for improving one's status in the complex social interactions that must have characterized those societies, just as they do ours today.

Several types of *H. sapiens* existed during the mid-Pleistocene epoch, from about 1.5 million to about 300,000 years ago. All were skilled hunters of large mammals, but plants continued to be important components of their diets. During this period another distinctly human trait emerged: rituals and a concept of life after death. Deceased individuals were buried with tools and clothing, presumably for their existence in the next world.

One type of *H. sapiens*, generally known as Neanderthals because they were first discovered in the Neander Valley in Germany, was widespread in Europe and Asia between

about 75,000 and 30,000 years ago. Neanderthals were short, stocky, and powerfully built humans whose massive skulls housed brains somewhat larger than our own. They manufactured a variety of tools and hunted large mammals, which they probably ambushed and subdued in close combat. For a short time, their range overlapped that of a more modern form of *H. sapiens* known as Cro-Magnons, but then the Neanderthals abruptly disappeared. Many scientists believe that they were exterminated by the Cro-Magnons, just as *H. habilis* may have been exterminated by *H. erectus*.

Cro-Magnon people made and used a variety of sophisticated tools. They created the remarkable paintings of large mammals, many of them showing scenes of hunting, that have been discovered in caves in various parts of Europe (Figure 33.31f). The animals depicted were characteristic of the cold steppes and grasslands that occupied much of Europe during periods of glacial expansion. Cro-Magnon people spread across Asia, reaching North America perhaps as early as 20,000 years ago, although the date of their arrival in the New World is still uncertain. Within a few thousand years they had spread southward through North America to the southern tip of South America.

Humans evolved language and culture

As our ancestors evolved larger brains, their behavioral capabilities increased, especially the capacity for language. Most animal communication consists of a limited number of signals, which pertain mostly to immediate circumstances

DEUTEROSTOMATE ANIMALS 599

These rice terraces are on the island of Bali in Indonesia.

and axe associated with changed emotional states induced by those circumstances. Human language is far richer in its symbolic character than any other animal vocalizations. Our words can refer to past and future times and to distant places. We are capable of learning thousands of words, many of them referring to abstract concepts. We can rearrange words to form sentences with complex meanings.

The expanded mental abilities of humans are largely responsible for the development of culture, the process by which knowledge and traditions are passed along from one generation to another by teaching and observation. Culture can change rapidly because genetic changes are not necessary for a cultural trait to spread through a population. The primary disadvantage of culture is that its norms must be taught to each generation. The tools and other implements associated with human fossils, as well as the cave paintings early humans created, reveal cultural traditions.

Cultural learning greatly facilitated the spread of domesticated plants and animals and the resultant conversion of most human societies from ones in which food was obtained by hunting and gathering to ones in which pastoralism (herding large animals) and agriculture dominated (Figure 33.31b,c). The development of agriculture led to an increasingly sedentary life, the growth of cities, greatly expanded food supplies, a rapid increase in the human population, and the appearance of occupational specializations, such as artisans and healers.

Agriculture developed in the Middle East approximately 11,000 years ago. From there it spread rapidly northwest-

(b)

'ft** Ai&

(c)

ward across Europe, finally reaching the British Isles about 4,000 years ago. The first plants and animals to be domesticated were cereal grains such as wheat and barley; legumes (beans, lentils, and peas); and woody plant crops such as grapes and olives. Others, such as rye, cabbage, celery, and carrots, were domesticated later. Cattle, sheep, goats, horses, dogs, and cats were the most important domesticated animals.

Agriculture developed independently in eastern Asia, contributing to our modern diet soybeans, rice, citrus fruits,

33.32 Human Population Surges

The human population surged following (1) the invention of tools, (2) the domestication of plants and animals, and (3) the Industrial Revolution.

mangoes, pigs, and chickens. There was some exchange, even at early times, among agricultural centers in the Old World, but when people spread across the cold and barren Bering land bridge into the New World, they apparently brought no domesticated plants with them. These people subsequently developed rich and varied agricultural systems based on corn, tomatoes, kidney and lima beans, peanuts, potatoes, chili peppers, and squashes. The largest animals domesticated by humans in the New World were llamas and alpacas in the Andes of South America—animals not large enough to carry a person. The Amerindians of Mexico and Central America had no domesticated animals larger than turkeys.

The human population has grown rapidly

The human population has experienced three major phases of increase (Figure 33.32). The first, stimulated by tool use, lasted about a million years. At the end of that period, the human population is estimated to have been approximately 5 million. During the second surge, which followed the domestication of plants and animals and the invention of agriculture, the human population may have increased to about 500 million people within 8,000 years.

We are currently in the middle of the third great population surge, triggered in the eighteenth century by the Industrial Revolution. In the industrialized countries of the world, death rates fell and life spans increased. By the end of the nineteenth century, human numbers had passed 1 billion. Despite the devastation of two World Wars and countless minor conflicts, the twentieth century saw the human population reach its current level of more than 6 billion. It is projected to increase to more than 11 billion by 2050.

The first two human population surges were followed by periods of relative stability. Whether the current surge will follow the same pattern, at what size it might level off, what hardships might ensue if it does not, and what the

consequences will be for other species are questions that are fiercely debated. We will discuss these issues further in Chapter 58.

irn

Chapter Summary

Deuterostomes and Protostomes

- The deuterostome lineage separated from the protostome lineage early in the history of animal life on Earth.
- There are fewer major lineages and fewer species of deuterostomes than protostomes, but as members of the deuterostome lineage we have a special interest in its members. Review Figure 33.1

Echinoderms: Complex Biradial Symmetry

- Echinoderms have a radially symmetrical body plan, a unique water vascular system, and a calcified internal skeleton. Review Figure 33.2a
- Nearly all living species of echinoderms have a bilaterally symmetrical, ciliated larva that feeds as a planktonic organism. Review Figure 33.2b

- ▶ Six major groups of echinoderms survive today, but 23 other lineages existed in the past. Some groups of echinoderms have arms, but others do not.

Chordates: New Ways of Feeding

- ▶ Evolution among the hemichordates and chordates led to new ways of capturing and handling food.
- ▶ The large proboscis of acorn worms is both a digging and a food-capturing organ.
- ▶ Members of the chordates evolved enlarged pharyngeal slits as feeding devices and a dorsal supporting rod, the notochord.
- ▶ Tunicates are sessile as adults and filter prey from seawater with large pharyngeal baskets. Their larvae have notochords and dorsal, hollow nerve cords.

Origin of the Vertebrates

- ▶ Vertebrates evolved jointed internal skeletons centered around a vertebral column, a body plan that enabled them to swim rapidly. Early vertebrates fed by filtering small animals from mud. Review Figure 33.7
- ▶ Jaws evolved from anterior gill arches and enabled their possessors to grasp and chew their prey, expanding food sources and improving nutrition. Jawed fishes rapidly became the dominant animals in both marine and fresh waters. Review Figures 33.8, 33.10
- ▶ Fishes evolved unjointed fins with which they could control their swirring movements and stabilize themselves in the water, and lunglike sacs that helped them stay suspended in open water.
- ▶ Bony fishes come in a wide variety of sizes and shapes, and many species have complex behaviors.

Colonizing the Land: Obtaining Oxygen from the Air

- ▶ Two fish lineages—lobe-fins and lungfishes—evolved jointed fins. Amphibians, the first terrestrial vertebrates, arose from one of these lineages. Review Figure 33.14
- ▶ Most amphibians live in water at some time in their lives, and their eggs must remain moist. Review Figure 33.16
- ▶ About 4,500 species of amphibians live today. They belong to three orders: caecilians, frogs and toads, and salamanders.

DEUTEROSTOMATE ANIMALS 601

- ▶ Amniotes evolved eggs with shells impermeable to water and thus became the first vertebrates to be independent of water for breeding. Review Figure 33.17
- ▶ Modern reptiles are members of four lineages—turtles and tortoises; tuataras; snakes and lizards; and crocodilians. Review Figure 33.18
- ▶ Dinosaurs rose to dominance about 215 mya and dominated terrestrial environments for about 150 million years until their extinction at the end of the Mesozoic era.

Birds: Feathers and Flight

- ▶ Birds arose about 175 mya, but much controversy surrounds their origins.
- ▶ The 9,600 species of living birds are characterized by feathers, high metabolic rates, and parental care.

The Origin and Diversity of Mammals

- ▶ Mammals evolved during the Mesozoic era, about 225 mya.
- ▶ Eggs of mammals are fertilized within the bodies of females, and embryos develop there for some time before being born. Mammals are unique in suckling their young with milk secreted by mammary glands.
- ▶ The three species of mammals in subclass Prototheria lay eggs, but all other mammals give birth to developed young.
- ▶ Therian mammals are divided into two major groups: the marsupials, which give birth to tiny young that are raised in a pouch on the female's belly, and eutherians, which give birth to relatively well-developed offspring.

Primates and the Origins of Humans

- ▶ The primates split into two major lineages, one leading to the prosimians—lemurs, lorises, and pottos—and the other leading to the anthropoids—tarsiers, monkeys, apes, and humans. Review Figure 33.25
- ▶ Hominids evolved in Africa from terrestrial, bipedal ancestors. Review Figures 33.29, 33.30
- ▶ Early humans evolved large brains, language, and culture. They made and used tools, developed rituals, and domesticated plants and animals. In combination, these traits enabled humans to increase greatly in numbers.

► The human population has increased greatly three times. We are currently in the middle of the third population surge. When and how it will end is hotly debated. Review Figure 33.32

For Discussion

1. In what animal phyla has the ability to fly evolved? How do structures used for flying differ among these animals?
2. Extracting suspended food from the water column is a common mode of foraging among animals. Which groups contain species that extract prey from the air? Why is this mode of obtaining food so much less common than extracting prey from water?
3. Large size both confers benefits and poses certain risks. What are these risks and benefits?
4. Amphibians have survived and prospered for many millions of years, but today many species are disappearing and populations of others are declining seriously. What features of amphibian life histories might make them especially vulnerable to the kinds of environmental changes now happening on Earth?
5. The evolution of jaws allowed vertebrates to utilize a remarkably wide array of food types; yet jawless animals are able to eat most of those kinds of foods. Compare the ways that jawed and jawless animals would eat the following kinds of food:
 - a. a snail
 - b. an insect
 - c. a fish
 - d. a bird
 - e. a plant leaf
6. The body plan of all vertebrates is based on four appendages. Describe the varied forms that these appendages take and how they are used. How do the vertebrates that have lost their four appendages move?
7. Compare the ways that different animal lineages colonized the land. How were those ways influenced by the body plans of animals in the different lineages?

Part Five

The Biology of

Flowering Plants

34

The Plant Body

\[m The oldest known plant is a bristlycone

pine that has been living for more than 4,900
years —almost 50 centuries. In contrast, it is
"hardly doubtful that any animal has ever lived as long
as 2 centuries. The extreme ages achieved by
some trees prove that plants can cope very successfully
with their environments.

Plants cannot move, but they have mechanisms for coping with environmental changes that they can't escape. They create and maintain an internal environment that differs from the external environment. They also regulate their own metabolism, which enables them to perform their necessary functions.

Motion is not a characteristic of plants; instead, we may think of plants as "growing machines." By growing, plants accomplish some of the same things that animals achieve through motion. Growing roots, for example, can reach into new supplies of water and nutrients.

Although they have simpler nutritional needs than animals do, plants must nevertheless obtain nutrients—not only the raw materials of photosynthesis (carbon dioxide and water), but also mineral elements such as nitrogen, potassium, and calcium. Seed plants—even the tallest trees—transport water from the soil to their tops, and they transport the products of photosynthesis from the leaves to their roots and other parts.

Plants also interact with their living and nonliving environments. They respond to environmental cues as they grow and develop. Their responses are mediated by chemical signals that move within cells and throughout the plant body. Among the resulting changes are ones that lead to growth, development, and reproduction.

Because we can understand the function of these growing machines only in terms of their underlying structure, this chapter focuses on the structure of the plant body, with primary emphasis on flowering plants. We'll examine plant structure at the level of

An Ancient Individual

Bristlecone pines (*Pinus aristata*) can live for centuries. The oldest known living organism is a bristlecone pine that has been alive for almost 5,000 years—long enough to have witnessed all of recorded human history.

the organs, cells, tissues, and tissue systems. Then we'll see how meristems—organized groups of dividing cells—serve the growth of the plant body, both in length and, in woody plants, in width. The chapter concludes with a consideration of how leaf structure supports photosynthesis.

Vegetative Organs of the Flowering Plant Body

You will recall from Chapter 29 that flowering plants (angiosperms) are tracheophytes that are characterized by double fertilization, a triploid endosperm, and seeds en-

The possession of a single cotyledon clearly distinguishes the monocots from the other angiosperms. Several other anatomical characteristics also differ between the monocots and the eudicots. Most angiosperms that do not belong to either lineage resemble eudicots in the characteristics shown here.

closed in modified leaves called Eudicots carpels. Their xylem contains cells called vessel elements and fibers, and their phloem contains companion cells.

Flowering plants possess three kinds of vegetative (nonreproduc-

tive) organs: roots, stems, and leaves. Flowers, which are the plant's devices for sexual reproduction, consist of other types of organs that will be considered in a later chapter.

Most flowering plants belong to one of two major lineages. Monocots (Monocotyledones) are generally narrow-leaved flowering plants such as grasses, lilies, orchids, and palms. Eudicots (Eudicotyledones) are broad-leaved flowering plants such as soybeans, roses, sunflowers, and maples. These two monophyletic classes account for 97 percent of the species of flowering plants (Figure 34.1). Most of the remaining species (including water lilies and the lineage that includes magnolias) are structurally similar to the eudicots.*

Usually parallel Usually in Scattered

multiples of three

Usually netlike

Usually in fours or fives

In a ring

The basic body plans of a generalized monocot and a generalized eudicot are shown in Figure 34.2. In both lineages, the vegetative plant body consists of two systems: the shoot system and the root system.

The shoot system of a plant consists of the stems and the leaves, as well as flowers (which contain leaflike parts). Broadly speaking, the leaves are the chief organs of photosynthesis. The stems hold and display the leaves to the sun and provide connections for the transport of materials between roots and leaves. The points where leaves attach to a stem are called nodes, and the stem regions between successive nodes are internodes.

traditionally, botanists have referred to all flowering plants other than monocots as dicots. However, the dicots do not constitute a monophyletic lineage (see Figure 29.13). Because we wish to emphasize lineages, we do not use that term here.

34.2 Vegetative Organs and Systems

The basic plant body plan and the principal vegetative organs are similar in monocots and eudicots.

The root system anchors and provides nutrients for a shoot system.

Flowers, made up of specialized "leaves," are adapted for sexual reproduction.

The shoot system consists of stems and leaves, in which photosynthesis takes place.

Apical bud

Lateral bud

(a)

34.3 Root Systems

The taproot system of a beet (a) contrasts with the fibrous root system of a grass (b)

The root system provides support and nutrition. Roots anchor the plant in place, and their extreme branching and high surface area-to-volume ratio adapt them to absorb water and mineral nutrients from the soil.

Each of the vegetative organs can be understood in terms of its structure. By structure we mean both its overall form and the anatomy of its component cells and tissues, as well as their arrangement. Let's first consider the overall forms of roots, stems, and leaves.

Roots anchor the plant and take up water and minerals

Water and minerals usually enter the plant through the root system, which usually lies in the soil, mostly in complete darkness. There are two principal types of root systems. Many eudicots have a taproot system: a single, large, deep-growing primary root accompanied by less prominent lateral roots (Figure 34.3a). The taproot itself often functions as a food storage organ, as in carrots and radishes.

By contrast, monocots and some eudicots have a fibrous root system, which is composed of numerous thin roots roughly equal in diameter (Figure 34.3b). Many fibrous root systems have a large surface area for the absorption of water and minerals. A fibrous root system holds soil very well. Grasses with fibrous root systems, for example, may protect steep hillsides where runoff from rain would otherwise cause erosion.

Some plants have what are called adventitious roots. These roots arise from points along the stem where roots would not usually occur; some even arise from the leaves. In many species, adventitious roots also form when a piece of shoot is cut from the plant and placed in water or soil. Adventitious rooting enables the cutting to establish itself in the soil. Some plants—corn, banyan trees, and some palms, for example—use adventitious roots as props to help support the shoot.

THE PLANT BODY 605

Stems bear buds, leaves, and flowers

Unlike roots, stems bear buds of various types. A bud is an embryonic shoot. A stem bears leaves at its nodes, and where each leaf meets the stem there is a lateral bud (see Figure 34.2), which can develop into a new branch, or extension of the stem, if it becomes active. The branching patterns of plants are highly variable, depending on the species, environmental conditions, and a gardener's pruning activities.

At the tip of each stem or branch is an apical bud, which produces the cells for the growth and development of that stem or branch. At times that vary depending on the species, buds form that develop into flowers. Some stems are highly modified. The tuber of a potato, for example—the part of the plant eaten by humans—is a portion of the stem rather than a root. Its "eyes" contain lateral buds; thus, a sprouting potato is just a branching stem (Figure 34.4rt). The runners of strawberry plants and Bermuda grass are horizontal stems from which roots grow at frequent intervals (Figure 34.4b). If the links between the rooted portions are broken, independent plants can develop on each side of the break. This is a form of vegetative reproduction, which we will discuss in a later chapter.

Unlike most roots, stems may be green and capable of photosynthesis. But stems are not the principal sites of photosynthesis.

Leaves are the primary sites of photosynthesis

In gymnosperms and most flowering plants, the leaves are responsible for most of the plant's photosynthesis, producing energy-rich organic molecules and releasing oxygen gas. Most leaves also carry out metabolic reactions that make nitrogen available to the plant for the synthesis of proteins and nucleic acids. In certain plants, leaves are highly modified for more specialized functions, as we will see below.

As photosynthetic organs, leaves are marvelously adapted for gathering light. Typically, the blade of a leaf is a thin, flat structure attached to the stem by a stalk called a petiole. During the daytime the leaf blade is held by its petiole at an angle almost perpendicular to the rays of the sun. This placement, with the leaf surface facing the sun, maximizes the amount of light available for photosynthesis. Some leaves track the sun, moving so that they constantly face it. If leaves were thicker than they are, the outer layers of cells would absorb so much of the light that the interior layers would be too dark and would be unable to photosynthesize.

The leaves at different sites on a single plant may have quite different shapes. These shapes result from a combination of genetic, environmental, and developmental influences. Most species, however, bear leaves of a particular broadly defined type. A leaf may be simple, consisting of a

34.4 Modified Stems

(a) A potato is a modified stem called a tuber; the sprouts that grow from its eyes are branches, not roots, (b) Runners produce roots at intervals, providing a local water supply and allowing rooted portions to live independently if the runner is cut. (c) The thorny spines are leaves on the enlarged stem of a cactus plant.

The runners of beach strawberry are horizontal stems.

Root

single blade, or compound, with blades, or leaflets, arranged along an axis or radiating from a central point (Figure 34.5). In a simple leaf, or in a leaflet of a compound leaf, the veins may be parallel to one another, as in mono-cots, or in a netlike arrangement, as in eudicots.

The general development of a specific leaf pattern is programmed in the plant's genes and is expressed by differential growth of the leaf veins and of the tissue between the veins. As a result, plant taxonomists have often found leaf forms (outlines, margins, tips, bases, and patterns of arrangement) to be reliable characters for classification and identification. At least some of the forms in Figure 34.5 probably look familiar to you.

In some plant species, leaves are highly modified for special functions. Some leaves serve as storage depots for energy-rich molecules, as in the bulbs of onions. In other species—some of the succulents—the leaves store water. The spines of cacti are modified leaves. Certain leaves of poinsettias, dogwoods, and some other plants are brightly colored and help attract pollinating animals to the often less striking flowers. Many plants, such as peas, have tendrils—modified leaves that support the plant by wrapping around other plants.

Leaves and other plant organs are composed of cells, tissues, and tissue systems. Let's now consider plant cells— the basic building blocks of plant organs.

Shapes

Margins

Apices

Bases

34.5 The Diversity of Leaves

Simple leaves are those with a single blade. Compound leaves consist of leaflets arranged along a central axis. Further division of leaflets results in a doubly compound leaf. Other characters of leaves can also be used to identify plants.

Middle lamella Primary cell wall

The cell plate is the first barrier to form.

Each daughter cell secretes a primary wall.

Middle lamella

After the cell stops expanding, it may secrete more layers forming secondary walls.

Secondary wall Primary wall Middle lamella

34.6 Cell Wall Formation

Cell walls form as the final step in plant cell division.

Plant Cells

Living plant cells have all the essential organelles common to eukaryotes (see Figure 4.7). In addition, they have some distinguishing structures and organelles.

- Some plant cells contain chloroplasts or other plastids.
- Many plant cells contain vacuoles.
- Every plant cell is surrounded by a cellulose-containing cell wall.

Although most kinds of plant cells are alive when they perform their functions, certain others function only after their

THE PLANT BODY 607

living parts have died and disintegrated. Other plant cells develop special chemical capabilities; for example, some can

perform photosynthesis, and others produce and secrete waterproofing materials. Several plant cell types differ dramatically in the structure of their cell walls.

Cell walls may be complex in structure

The cytokinesis of a plant cell is completed when cell walls form, separating the two daughter cells. The daughter cells secrete a glue that constitutes the middle lamella, which forms a layer between them. Then each daughter cell secretes cellulose and other polysaccharides to form a primary wall, which continues to grow as the cell grows to its final size (Figure 34.6).

Once cell expansion stops, a plant cell may deposit more polysaccharides, sometimes impregnated with further materials—such as lignin, characteristic of wood, or suberin, a complex lipid characteristic of cork—in one or more layers internal to the primary wall. These layers collectively form the secondary wall, which often serves supporting or waterproofing roles.

Although the cell wall lies outside the plasma membrane of the cell, it is not a chemically inactive region. Chemical reactions in the wall play important roles in cell expansion and defense. Cell walls may thicken or be sculpted or perforated as part of differentiation into specialized cell types. Except where the secondary wall is made waterproof by added substances, the wall is porous to water and to most small molecules.

Localized modifications in the walls of adjacent cells allow water and dissolved materials to move easily from cell to cell. In cells that have not developed a secondary wall, the primary wall usually has thin regions. Strands of cytoplasm called plasmodesmata (singular plasmodesma) pass through the primary wall in these regions, allowing substances to move freely from cell to cell without having to cross a plasma membrane (Figure 34.7a). The plasmodes-

34.7 Plasmodesmata

Pits

-^.' Primary

1 walls

Plasmodesmata^—?jkO o]

Secondary walls

34.8 Pits Allow Materials to Move between Cells with Secondary Walls

Secondary cell walls may be interrupted by pits that allow the passage of water and other materials between cells.

Plasmodesmata allow direct communication between plant cells, as discussed in Chapter 15.

A plasmodesma is wide enough so that portions of the endoplasmic reticulum extend between cells (Figure 34.7b). Under certain circumstances, a plasmodesma can enlarge dramatically, allowing even macromolecules and viruses to pass directly between cells. Even in cells with a waterproofed secondary wall, water and dissolved materials can pass from cell to cell by way of structures called pits (Figure 34.8). Pits are interruptions in the secondary wall that leave the thin regions of the primary wall, and thus the plasmodesmata, unobstructed.

Parenchyma cells are alive when they perform their functions

The most numerous cell type in young plants is the parenchyma cell (Figure 34.9f). Parenchyma cells usually have thin walls, consisting only of a primary wall and the shared middle lamella. Many parenchyma cells have shapes similar to those of soap bubbles crowded into a limited space—shapes with 14 faces. They are usually not elongated or otherwise asymmetrical. Most have large central vacuoles.

The photosynthetic cells in leaves are parenchyma cells filled with chloroplasts. Some nonphotosynthetic parenchyma cells store substances such as starch or lipids. In the cytoplasm of these cells, starch is often stored in specialized plastids called leucoplasts. Lipids may be stored as oil droplets, also in the cytoplasm. Some parenchyma cells appear to serve as "packing material" and play a vital role in supporting the stem. Others retain the capacity to divide and hence may give rise to new cells, as when a wound results in cell proliferation.

Collenchyma cells provide flexible support while alive

Collenchyma cells are supporting cells that lay down pri-

cell walls that are characteristically thick in the cor-

of the cells (Figure 34.9b). Collenchyma cells are gener-

ally elongated. In these cells the primary wall thickens, but no secondary wall forms. Collenchyma provides support to leaf petioles, nonwoody stems, and growing organs. Tissue made of collenchyma cells is flexible, permitting stems and petioles to sway in the wind without snapping. The familiar "strings" in celery consist primarily of collenchyma.

Sclerenchyma cells provide rigid support after they die

In contrast to collenchyma, sclerenchyma cells have a thickened secondary wall that performs their major function: support. Many sclerenchyma cells function when dead. There are two types of sclerenchyma cells: elongated fibers and variously shaped sclereids. Fibers, often organized into bundles, provide relatively rigid support both in wood and in other parts of the plant (Figure 34.9c). The bark of trees owes much of its mechanical strength to long fibers. Sclereids may pack together densely, as in a nut's shell or in some seed coats (Figure 34.9d). Isolated clumps of sclereids, called stone cells, in pears and some other fruits give them their characteristic gritty texture.

Xylem transports water from roots to stems and leaves

The xylem of tracheophytes conducts water from roots to aboveground plant parts. It contains conducting cells called tracheary elements, which undergo programmed cell death before they assume their function of transporting water and dissolved minerals. The evolutionary more ancient tracheary elements, found in gymnosperms and other tracheophytes, are tracheids—spindle-shaped cells interconnected by numerous pits in their cell walls (Figure 34.9e). When the cell contents—nucleus and cytoplasm—disintegrate upon cell death, water can move with little resistance from one tracheid to its neighbors by way of pits.

Flowering plants evolved a water-conducting system made up of vessels. The individual cells that form vessels, called vessel elements, also die and become empty before they can transport water. These cells secrete a waterproofing substance into their cell walls, then break down their end walls, and finally die and disintegrate. The result is a hollow tube through which water can flow freely. Vessel elements are generally larger in diameter than tracheids; they are laid down end-to-end, so that each vessel is a continuous hollow tube consisting of many vessel elements and providing an open pipeline for water conduction (Figure 34.9f). In the course of angiosperm evolution, vessel elements have become shorter, and their end walls have become less and less obliquely oriented and less obstructed (Figure 34.10). The xylem of many angiosperms also includes tracheids.

Phloem translocates carbohydrates and other nutrients

The transport cells of the phloem, unlike those of the xylem, are living cells. In flowering plants the characteristic

This type is the most recently evolved.

This cell type is evolutionarily the most ancient.

34.10 Evolution of the Conducting Cells of Vascular Systems

The xylem of tracheophytes has changed over time.The cells that conduct water and mineral nutrients have become shorter and the end walls have become more perpendicular to the side walls.

Pores of sieve plate Sieve plate

Phloem sap passes through the holes in sieve plates from one sieve tube member to the next.

34.11 Sieve Tubes

) Individual sieve tube members join to form long tubes that transport carbohydrates and other nutrient molecules, (b) Sieve plates form at the ends of each sieve tube member.

cell of the phloem is the sieve tube member (Figure 34.11a). Like vessel elements, these cells meet end-to-end. They form long sieve tubes, which transport carbohydrates and many other materials from their sources to tissues that consume or store them. In plants with mature leaves, for example, excess products of photosynthesis move from leaves to root tissues.

As sieve tube members mature, plasmodesmata in the end walls enlarge, enhancing the connection between the contents of neighboring cells. The result is end walls that look like sieves, and are called sieve plates (Figure 34.11b). As the holes in the sieve plates expand, the tonoplast (the membrane around the central vacuole) disappears. The nucleus and some of the other organelles in the sieve tube member also break down and thus do not clog the holes of the sieve.

At functional maturity, a sieve tube is filled with sieve tube sap, consisting of water, sugars, and other solutes. This mixture moves from cell to cell along the sieve tube, carrying its dissolved sugars and other important materials with it. At the periphery of a sieve tube member, next to the cell wall and distinct from the sieve tube sap, is a layer of cytoplasm. This stationary layer of cytoplasm confines the remaining organelles.

The sieve tube members have adjacent companion cells (see Figure 34.11a), produced along with the sieve tube member when a parent cell divides. Companion cells retain all their organelles and may, through the activities of their nuclei, regulate the performance of the sieve tube members.

All these kinds of plant cells play important roles. Next let's see how they are organized into tissues and tissue systems.

Plant Tissues and Tissue Systems

A tissue is an organized group of cells, working together as a functional unit. Parenchyma cells make up parenchyma tissue, a simple tissue—that is, a tissue composed of only one type of cell. Sclerenchyma and collenchyma are other simple tissues, composed, respectively, of sclerenchyma and collenchyma cells.

Different cell types also combine to form complex tissues. Xylem and phloem are complex tissues, composed of more than one type of cell. As a result of its cellular complexity, xylem can perform a variety of functions, including transport, support, and storage. The xylem of angiosperms contains vessel elements and tracheids as conducting cells, thick-walled sclerenchyma fibers for support, and parenchyma cells that store food. The phloem of angiosperms includes sieve tube members, companion cells, fibers, sclereids, and parenchyma cells.

Tissues, in turn, are grouped into tissue systems that extend throughout the body of the plant, from organ to organ. There are three tissue systems: vascular, dermal, and ground (Figure 34.12).

The vascular tissue system, which includes the xylem and phloem, is the conductive, or "plumbing," system of

The dermal tissue system is the outer covering of the plant.

The vascular tissue system

conducts water and solutes throughout the plant.

The ground tissue system conducts photosynthesis, stores photosynthetic products, and helps support the plant.

Dermal /Of "XV/ Ground Vascular

34.12 Three Tissue Systems Extend throughout the Plant Body

The arrangement shown here is typical of eudicots.

the plant. All the living cells of the plant body require a source of energy and chemical building blocks. The phloem transports carbohydrates from sites of production—called sources (commonly the leaves)—to sites of utilization or storage—called sinks—elsewhere in the plant. The xylem distributes water and mineral ions taken up by the roots to the stem and leaves.

The dermal tissue system is the outer covering of the plant. All parts of the young plant body are covered by an epidermis, which may be a single layer of cells or several layers. The epidermis contains epidermal cells and may also include specialized cell types, such as the guard cells that form stomata (pores) in leaves. The shoot epidermis secretes a layer of wax-covered cutin, the cuticle, that helps retard water loss from stems and leaves. The stems and roots of woody plants have an additional protective covering called the periderm, which will be discussed later in this chapter.

The ground tissue system makes up the rest of a plant and consists primarily of parenchyma tissue, often supplemented by collenchyma or sclerenchyma. Ground tissue functions primarily in storage, support, photosynthesis, and the production of defensive and attractive substances.

In the discussions that follow, we'll examine how the tissue systems are organized in the different organs of a flowering plant. Let's begin by seeing how this organization develops as the plant grows.

Forming the Plant Body

In its early embryonic stages, a plant establishes the basic body plan for its mature form (Figure 34.13). Two patterns contribute to the plant body plan:

- The apical-basal pattern is the arrangement of cells and tissues along the main axis from root to shoot.
- The radial pattern is the concentric arrangement of tissue systems.

Both patterns arise through orderly development and are best understood in developmental terms.

Plants and animals develop differently

As the plant body grows, it may lose parts, and it forms new parts that may grow at different rates. The growing stem consists of modules or units, laid down one after another. Each unit consists of a node with its attached leaf or leaves, the internode below that node, and the lateral bud or buds at the base of that internode. New units are formed as long as the stem continues to grow.

Each branch of a plant may be thought of as a unit that is in some ways independent of the other branches. A branch of a plant does not bear the same relationship to the remainder of the plant body as an arm does to the remainder of the human body. Among other things, branches form one after another, unlike arms, which form simultaneously during embryonic development. Also, branches often differ from one another in number of leaves and in the degree to which they themselves branch.

34.13 Patterns in the Plant Body Plan

The embryonic plant establishes the basic body plan for its mature form. Two patterns are evident in this body plan: the apical-basal pattern and the radial pattern.

612 CHAPTER THIRTY-FOUR

Leaves are units of another sort, produced in fresh batches to take over the daily function of gathering energy for the plant. Leaves are usually short-lived, lasting weeks to a few years. Branches and stems are longer-lived, lasting from years to centuries.

Root systems are also branching structures, and lateral roots are semi-independent units. As the root system grows, penetrating and exploring the soil environment, many roots die and are replaced by new ones.

All parts of the animal body grow as an individual develops from embryo to adult, but this growth is determinate. That is, the growth of the individual and its parts ceases when the adult state is reached. The growth of stems and roots, by contrast, is indeterminate and is generated from specific regions of active cell division and cell expansion.

The localized regions of cell division in plants are called meristems. Meristematic tissues are forever young, retaining the ability to produce new cells indefinitely. They are comparable to the stem cells found in animals. When a meristem cell divides, the two resulting cells initially take up no more volume than did the single cell prior to division. One daughter cell develops into another meristem cell the size of its parent, while the other daughter cell develops into a more specialized cell.

A hierarchy of meristems generates a plant's body

There are two types of meristems:

- Apical meristems give rise to the primary plant body, which is the entire body of many plants.
- Lateral meristems give rise to the secondary plant body. The stems and roots of some plants (most obviously trees) form wood and become thick; it is the lateral meristems that give rise to the tissues responsible for this thickening.

apical meristems. Apical meristems are located at the tips of roots and stems, and in buds. They elongate the plant body by producing the cells that subsequently expand and differentiate to form all plant organs (Figure 34.14).

- Shoot apical meristems supply the cells that extend stems and branches, allowing more leaves to form and photosynthesize.
- Root apical meristems supply the cells that extend roots, enabling the plant to "forage" for water and minerals.

Both root and shoot apical meristems give rise to a set of cylindrical primary meristems that produce the primary tissues of the plant body. From the outside to the inside of the root or shoot, which are both cylindrical organs, the primary meristems are the protoderm, the ground meristem,

Tissue systems

Root or shoot apical meristem

<E

Protoderm -

Ground meristem-

Procambium -

► Dermal tissue system

Ground tissue system

► Vascular tissue system

Apical meristems are responsible for primary growth, which leads to elongation and organ formation. All plant organs arise ultimately from cell divisions in the apical meristems, followed by cell expansion and differentiation. Primary growth gives rise to the entire body of many plants.

Because meristems can continue to produce new organs, the plant body is much more variable in form than the animal body, whose organs are laid down only once.

lateral meristems. Some roots and stems develop a secondary body—what we commonly refer to as wood and bark. In an oak tree, for example, the secondary body constitutes almost the entire stem and root system. These complex tissues are derived from two lateral meristems: the vascular cambium and the cork cambium (see Figure 34.14).

The vascular cambium is a cylindrical tissue consisting of vertically elongated cells that divide frequently. Toward the inside of the stem or root the dividing cells form new xylem, and toward the outside they form new phloem.

As a tree grows in diameter, the outermost layers of the stem crack and fall off. Without the activity of the cork cambium, this sloughing off of the dermal tissues would expose the tree to potential damage, including excessive water loss or invasion by microorganisms. The cork cambium produces new protective cells, primarily in the outward direction. The walls of these cells become impregnated with suberin, which makes them waterproof. The layer of growth produced by the cork cambium is called the periderm.

Growth in the diameter of stems and roots, produced by the vascular and cork cambia, is called secondary growth. It is the source of wood and bark. Wood is secondary xylem. Bark (periderm plus secondary phloem) is everything external to the vascular cambium.

In some plants, meristems may remain active for years— even centuries. The bristlecone pine mentioned at the beginning of this chapter provides a dramatic example. Such plants grow in size, or at least in diameter, throughout their lives. Recall that this pattern of continuous growth is known as ∞ determinate growth. Determinate growth, which stops at some point, is characteristic of some plant parts, such as leaves, flowers, and fruits, as well as most animals.

In the sections that follow, we'll examine how the various meristems give rise to the plant body.

The root apical meristem gives rise to the root cap and the primary meristems

The root apical meristem produces all the cells that contribute to growth in the length of the root. Some of the

daughter cells from the apical end of the root apical meristem contribute to a root cap, which protects the delicate growing region of the root as it pushes through the soil. Cells of the root cap are often damaged or scraped away and must therefore be replaced constantly. The root cap is also the structure that detects the pull of gravity and thus controls the downward growth of roots.

The daughter cells that are produced at the other end of the meristem elongate and lengthen the root. Following elongation, these cells differentiate, giving rise to the various tissues of the mature root. The growing region above the apical meristem— away from the root cap—comprises the three cylindrical primary meristems that give rise to the three tissue systems of the root: the protoderm, the ground meristem, and the procambium (Figure 34.15).

The apical and primary meristems constitute the zone of cell division, the source of all the cells of the root's primary tissues. Just above this zone is the zone of cell elongation, where the newly formed cells are elongating and thus causing the root to reach farther into the soil. Above this is the zone of cell differentiation, where the cells are taking on specialized forms and functions. These three zones grade imperceptibly into one another; there is some cell division even as far up as the zone of cell differentiation, and some cells differentiate even in the zone of cell division.

The products of the root's primary meristems become root tissues

What are the products of the three primary meristems? The protoderm gives rise to the outer layer of cells—the epidermis—which is adapted for protection of the root and for the absorption of mineral ions and water (Figure 34.16). Epi-

dermal cells are flattened, and many of them produce amazingly long, delicate root hairs that vastly increase the surface area of the root (Figure 34.16b). It has been estimated that the root system of a mature rye plant has a total absorptive surface of more than 600 square meters. Root hairs grow out among the soil particles, probing nooks and crannies and taking up water and minerals.

Internal to the epidermis, the ground meristem gives rise to a region of ground tissue that is many cells thick, called the cortex. The cells of the cortex are relatively un-specialized and often function in food storage.

In many plants, but especially in trees, epidermal and sometimes cortical cells form an association with a fungus. This association, called a mycorrhiza, increases the absorption of minerals and water by the plant (see Figure 30.16). Some plant species have poorly developed root hairs or no root hairs. These plants cannot survive unless they develop mycorrhizae that help them with mineral absorption.

Proceeding inward, we come to the endodermis of the root, a single cylindrical layer of cells that is the innermost cell layer of the cortex. The cell walls of the endodermal cells differ markedly from those of the other cortical cells. Endodermal cell walls contain suberin, which forms a waterproof seal wherever it is present. The placement of the seal in just certain parts of the wall enables endodermal cells to control the access of water and dissolved ions to the vascular tissues.

Moving inward past the endodermis, we enter the vascular cylinder, or stele, produced by the procambium. The stele consists of three tissues: pericycle, xylem, and phloem (Figure 34.17). The pericycle consists of one or more layers of relatively undifferentiated cells. It is the tissue within which lateral roots arise (see Figure 34.16f). The pericycle also contributes to secondary growth.

At the very center of the root of a eudicot lies the

lem—seen in cross section as a star with a variable number of points. Between the points are bundles of phloem. In

The monocot has a central pith region; the eudicot does not.

monocots, a region of parenchyma cells, called the pith, lies in the center of the root. The pith often stores carbohydrate reserves. It is useful to try picturing these structures in three dimensions (as in Figure 34.17), rather than attempting to understand their functions solely on the basis of two-dimensional cross sections (as in Figure 34.16c, d).

The products of the stem's primary meristems become stem tissues

The shoot apical meristem, like the root apical meristem, forms three primary meristems, which in turn give rise to the three tissue systems. Leaves arise from bulges called leaf

34.77 The Stele

The distribution of tissues in the stele—the region internal to the endodermis—differs in the roots of eudicots and monocots.

primordia, which form as cells divide on the sides of shoot apical meristems (see Figure 34.14). The growing stem has no cap analogous to the root cap, but the leaf primordia can act as a protective covering.

The plumbing of angiosperm stems differs from that of roots. In a root, the vascular tissue lies deep in the interior, with the xylem at or near the very center. The vascular tissue of a young stem, however, is divided into discrete vascular bundles,

which in eudicots generally form a cylinder but in monocots are seemingly scattered throughout a cross section of the stem (Figure 34.18). Each vascular bundle contains both xylem and phloem.

The stem contains other important tissues in addition to the vascular tissues. Internal to the vascular bundles of eudicots is a storage tissue, the pith, and to the outside lies a similar storage tissue, the cortex. The cortex may contain strengthening collenchyma cells with thickened walls. The pith, the cortex, and the regions between the vascular bundles in eudicots—called pith rays—constitute the ground tissue system of the stem. The outermost cell layer of the young stem is the epidermis, the primary function of which is to minimize the loss of water from the cells within.

Many stems and roots undergo secondary growth

Some stems and roots remain slender and show little or no growth in diameter (secondary growth). However, in many eudicots, stems and roots thicken considerably. This thickening is of great importance and interest because it gives rise to wood and bark, and it makes the support of tall trees possible.

Secondary growth results from the activity of the two lateral meristems: vascular cambium and cork cambium (see Figure 34.14). Vascular cambium consists of cells that divide to produce new (secondary) xylem and phloem cells, while cork cambium produces mainly waxy-walled cork cells.

Initially, the vascular cambium is a single layer of cells

k 34.18 Vascular Bundles in Stems

(a) In eudicots the vascular bundles are arranged in a cylinder, with pith in the center and cortex outside the ring. (b) This scattered arrangement of bundles is typical of monocot stems.

lying between the primary xylem and the primary phloem. The root or stem increases in diameter when the cells of the vascular cambium divide, producing secondary xylem cells toward the inside of the root or stem and producing secondary phloem cells toward the outside (Figure 34.19). In the stems of woody plants, cells of the pith rays between the vascular bundles also divide, forming a continuous cylinder of vascular cambium running the length of the stem. This cylinder in turn gives rise to complete cylinders of secondary xylem (wood) and secondary phloem from which bark will develop.

As the vascular cambium produces secondary xylem and phloem, its principal cell products are vessel elements, supportive fibers, and parenchyma cells in the xylem, and sieve tube members, companion cells, fibers, and parenchyma cells in the phloem. The parenchyma cells in the xylem and phloem store carbohydrate reserves in the stem and root.

Living tissues such as this storage parenchyma must be connected to the sieve tubes of the phloem, or they will starve to death. The connections are provided by vascular rays, which are composed of cells derived from the vascular cambium. The rays, laid down progressively as the cam-

bium divides, are rows of living parenchyma cells that run perpendicular to the xylem vessels and phloem sieve tubes (Figure 34.20). As the root or stem continues to increase in diameter, new vascular rays are initiated so that this storage and transport tissue continues to meet the needs both of the bark and of the living cells in the xylem.

The vascular cambium itself increases in circumference with the growth of the root or stem. To do this, some of its cells divide in a plane at right angles to the plane that gives rise to secondary xylem and phloem. The products of each of these divisions lie within the vascular cambium itself and increase its circumference.

^ -J Rays conduct | nutrients horizontally.

Vessel elements conduct water vertically.

When a vascular cambium cell divides, it produces either a new xylem cell toward the inside of the stem or root, or a new phloem cell toward the outside.

Vascular

cambium

cell New

secondary xylem cell

Next new secondary xylem cell

Older xylem and phloem cells are pushed farther from the cambium with each division of the cambium.

Only eudicots have a vascular cambium and a cork cambium and thus undergo secondary growth. In the rare cases in which monocots form thickened stems—palm trees, for example—they do so without using vascular cambium or cork cambium. Palm trees have a very wide apical meristem that produces a wide stem, and dead leaf bases also add to the diameter of the stem. Basically, monocots grow in the same way as do other angiosperms that lack secondary growth.

Wood and bark are unique to plants showing secondary growth. These tissues have their own patterns of organization and development.

wood. Cross sections of most tree trunks (stems) in temperate-zone forests show annual rings (Figure 34.21), which result from seasonal environmental conditions. In spring, when water is relatively plentiful, the tracheids or vessel elements produced by the vascular cambium tend to be large in diameter and thin-walled. As water becomes less available during the summer, narrower cells with thicker walls are produced, making this summer wood darker and perhaps more dense than the wood formed in spring. Thus each year is usually recorded in a tree trunk by a clearly visible annual ring consisting of one light and one dark layer. Trees in the wet tropics do not lay down such obvious regular rings.

The difference between old and new regions also contributes to the appearance of wood. As a tree grows in di-

Rings of secondary xylem are the most noticeable feature of this cross section from a 3-year-old basswood stem.

bark. As secondary growth of stems or roots continues, the expanding vascular tissue stretches and breaks the epidermis and cortex, which ultimately flake away and are lost. Tissue derived from the secondary phloem then becomes the outermost part of the stem. Before the dermal tissues are broken away, cells lying near the surface of the secondary phloem begin to divide and produce layers of cork, a tissue composed of cells with thick walls, waterproofed with suberin. The cork soon becomes the outermost tissue of the stem or root. The dividing cells, derived from the secondary phloem, form a cork cambium. Sometimes the cork cambium produces cells to the inside as well as to the outside; these cells constitute what is known as the phelloderm.

Cork, cork cambium, and phelloderm make up the periderm of the secondary plant body. As the vascular cambium continues to produce secondary vascular tissue, the corky layers are in turn lost, but the continuous formation of cork cambium in the underlying phloem gives rise to new corky layers.

When bark forms on stems and roots, the underlying tissues still need to release carbon dioxide and take up oxygen. Lenticels are spongy regions in the cork of stems and roots that allow such gas exchange (Figure 34.22).

ameter, the xylem toward the center becomes clogged with water-insoluble substances and ceases to conduct water and minerals; this is heartwood and appears darker in color. The portion of the xylem that is actively conducting all water and minerals in the tree is called sapwood and is lighter in color and more porous than heartwood.

The knots that we find attractive in knotty pine but regard as a defect in structural timbers are cross sections of branches: As a trunk grows, the bases of branches become buried in the trunk's new wood and appear as knots when the trunk is cut lengthwise.

Leaf Anatomy Supports Photosynthesis

We can think of roots and stems as important supporting actors that sustain the activities of the real stars of the plant body, the leaves—the organs of photosynthesis. Leaf anatomy is beautifully adapted to carry out photosynthesis and to support photosynthesis by exchanging the gases O_2 and CO_2 with the environment, limiting evaporative water loss, and transporting the products of photosynthesis to the rest of the plant. Figure 34.23f shows a typical eudicot leaf in cross section.

34.23 The Eudicot Leaf

(a) Cross section of a eudicot leaf, (b) The network of fine veins in this maple leaf carries water to the mesophyll cells and carries photosynthetic products away from them, (c) These paired cells on the lower epidermis of a eudicot leaf are guard cells; the gaps between them are stomata, through which carbon dioxide enters the leaf.

Most eudicot leaves have two zones of photosynthesizing parenchyma tissue referred to as mesophyll, which means "middle of the leaf." The upper layer or layers of mesophyll consist of roughly cylindrical cells. This zone is referred to as palisade mesophyll. The lower layer or layers consist of irregularly shaped cells; this zone is called spongy mesophyll. Within the mesophyll is a great deal of air space through which carbon dioxide can diffuse to surround all photosynthesizing cells.

Vascular tissue branches extensively in the leaf, forming a network of veins (Figure 34.23b). Veins extend to within a few cell diameters of all the cells of the leaf, ensuring that the mesophyll cells are well supplied with water and minerals. The products of photosynthesis are loaded into the phloem of the veins for export to the rest of the plant.

Covering the entire leaf is a layer of nonphotosynthetic cells constituting the epidermis. The epidermal cells have an overlying waxy cuticle that is highly impermeable to water. But this impermeability poses a problem: While keeping water in the leaf, the epidermis also keeps carbon dioxide, the other raw material of photosynthesis, out.

The problem of balancing water retention and carbon dioxide availability is solved by an elegant regulatory system that will be discussed in more detail in the next chapter. Guard cells are modified epidermal cells that change their shape, thereby opening or closing pores called stomata, which serve as passageways between the environment and the leaf's interior (Figure 34.23c). When the stomata are open, carbon dioxide can enter and oxygen can leave, but some water can also be lost.

Guard cells

Stomata

(c)

In Chapter 8 we described C₄ plants, which can fix carbon dioxide efficiently even when the carbon dioxide supply in the leaf decreases to a level at which the photosynthesis of C₃ plants is inefficient. One adaptation that helps C₄ plants do this is their modified leaf anatomy, as shown in Figure 8.19. Notice that the photosynthetic cells in the C₄ leaf are grouped around the veins in concentric layers, forming an outer mesophyll layer and an inner bundle sheath. These layers each contain different types of chloroplasts, leading to the biochemical division of labor described in Chapter 8.

Leaves receive water and mineral nutrients from the roots by way of the stems. In return, the leaves export products of photosynthesis, providing a supply of chemical energy to the rest of the plant body. And, as we have just seen, leaves exchange gases, including water vapor, with the environment by way of the stomata. All three of these processes will be considered in detail in the next chapter.

Chapter Summary

Vegetative Organs of the Flowering Plant Body

- Monocots typically have a single cotyledon, narrow leaves with parallel veins, flower parts in threes or multiples of three, and stems with scattered vascular bundles.
- Eudicots typically have two cotyledons, broad leaves with netlike veins, flower parts in fours or fives, and vascular bundles in a ring. Flowering plants that are neither monocots nor eudicots are generally similar in structure to eudicots. Review Figure 34.1
- The vegetative organs of flowering plants are roots, which form a root system, and stems and leaves, which form a shoot system. Review Figure 34.2

THE PLANT BODY 619

- Roots anchor the plant and take up water and minerals.
- Stems bear leaves and buds. Lateral buds form branches. Apical buds produce cells that contribute to the elongation of the stem.
- Leaves are responsible for most photosynthesis, for which their flat blades, oriented perpendicular to the sun's rays, are well adapted. Review Figure 34.5

Plant Cells

- The walls of plant cells have a structure that often corresponds to the special functions of the cell. The walls of individual cells are separated by a middle lamella common to two neighboring cells; each cell also has its own primary wall. Review Figure 34.6
- Some cells produce a thick secondary wall. Adjacent cells are connected by plasmodesmata that extend through both cell walls. Review Figures 34.7, 34.8
- Parenchyma cells have thin walls. Many parenchyma cells store starch or lipids; some others carry out photosynthesis. Review Figure 34.9a
- Collenchyma cells provide flexible support. Review Figure 34.9b
- Sclerenchyma cells provide strength and function when dead. Review Figure 34.9c, d

► Tracheids and vessel elements are xylem cells that conduct water and minerals after the cells die. Review Figures 34.9e, /, 34.10

► Sieve tube members are the conducting cells of the phloem. Their activities are often controlled by companion cells. Review Figure 34.11

Plant Tissues and Tissue Systems

► Three tissue systems extend throughout the plant body. The vascular tissue system, consisting of xylem and phloem, conducts water, minerals, and the products of photosynthesis. The dermal tissue system protects the body surface. The ground tissue system produces and stores food materials and performs other functions. Review Figure 34.12

Forming the Plant Body

► The apical-basal pattern and the radial pattern are parts of the plant body plan; they arise through orderly development. Review Figure 34.13

► The plant body is modular, and the growth of stems and roots is indeterminate. Leaves, flowers, and fruits show determinate growth.

► Meristems are localized regions of cell division. A hierarchy of meristems generates the plant body.

► Apical meristems at the tips of stems and roots produce the primary growth of those organs. Review Figure 34.14

► Shoot apical meristems and root apical meristems give rise to primary meristems: the protoderm, the ground meristem, and the procambium. Review Figure 34.15

► In some plants, the products of primary growth constitute the entire plant body. Many other plants show secondary growth. Two lateral meristems, the vascular cambium and cork cambium, are responsible for secondary growth. Review Figure 34.14

► The young root has an apical meristem that gives rise to the root cap and to the three primary meristems, which in turn produce the three tissue systems. The protoderm produces the dermal tissue system, the ground meristem produces the ground tissue system, and the procambium produces the vascular tissue system. Review Figure 34.15

► Root tips have three overlapping zones: the zone of cell division, the zone of cell elongation, and the zone of cell differentiation. Review Figure 34.15

► The dermal tissue system consists of the epidermis, part of which forms the root hairs that are responsible for absorbing water and minerals. Review Figure 34.16

► The ground tissue system of a young root is the cortex, whose innermost cell layer, the endodermis, controls access to the stele.

► The stele, consisting of the pericycle, xylem, and phloem, is the root's vascular tissue system. Lateral roots arise in the pericycle. Monocot roots have a central pith region. Review Figure 34.17

► The shoot apical meristem also gives rise to three primary meristems, with roles similar to their counterparts in the root. Leaf primordia on the sides of the apical meristem develop into leaves.

► The vascular tissue in young stems is divided into vascular bundles, each containing both xylem and phloem. Pith occupies the center of the eudicot stem. Cortex lies to the outside of the vascular bundles in eudicots, with pith rays lying between the vascular bundles. Review Figure 34.18

► Many eudicot stems and roots show secondary growth, in which vascular and cork cambia give rise to secondary xylem and secondary phloem. As secondary growth continues, the products are wood and bark. Review Figure 34.19

► The vascular cambium lays down layers of secondary xylem and phloem. Living cells within these tissues are nourished by vascular rays. Review Figure 34.20

► The periderm consists of cork, cork cambium, and phello-derm, all pierced at intervals by lenticels that allow gas exchange.

Leaf Anatomy Supports Photosynthesis

► The photosynthetic tissue of a leaf is called mesophyll. Veins bring water and minerals to the mesophyll and carry the products of photosynthesis to other parts of the plant body.

► A waxy cuticle prevents water loss from the leaf, but is impermeable to carbon dioxide. Guard cells control the opening of stomata, openings in the leaf that allow CO_2 to enter but also allow some water to escape. Review Figure 34.23

For Discussion

1. When a young oak was 5 m tall, a thoughtless person carved his initials in its trunk at a height of 1.5 m above the ground. Today that tree is 10 m tall. How high above the ground are those initials? Explain your answer in terms of the manner of

plant growth.

2. Consider a newly formed sieve tube member in the secondary phloem of an oak tree. What kind of cell divided to produce the sieve tube member? What kind of cell divided to produce that parent cell? Keep tracing back until you arrive at a cell in the apical meristem.
3. Distinguish between sclerenchyma cells and collenchyma cells in terms of structure and function.
4. Distinguish between primary and secondary growth. Do all angiosperms undergo secondary growth? Explain.
5. What anatomical features make it possible for a plant to retain water as it grows? Describe the plant tissues and how and when they form.

Transport in Plants

About 40 years ago the biologist Per Scholander was studying water movement to the top of an 80-meter Douglas fir. To collect samples rapidly from the treetop, he hired a sharpshooter, who aimed a high-powered rifle at a twig high in the tree and fired. From high above, a twig fluttered to the ground, and Scholander quickly inserted it into an instrument for measuring tension in the xylem sap. As we will soon see, Scholander's measurements increased our understanding of how water and minerals reach the tops of tall trees.

The water and minerals in a plant's xylem must be transported to the entire shoot system, all the way to the highest leaves and apical buds. Carbohydrates produced in all the leaves, including the highest, must be translocated to all the living nonphotosynthetic parts of the plant. Before we consider the mechanisms underlying these processes, we should consider two questions: How much water is transported? And how high can water be transported?

In answer to the first question, consider the following example: A single maple tree 15 meters tall was estimated to have some 177,000 leaves, with a total leaf surface area of 675 square meters—half again the area of a basketball court. During a summer day, that tree lost 220 liters of water per hour to the atmosphere by evaporation from the leaves. To prevent wilting, the xylem needed to transport 220 liters of water from the roots to the leaves every hour. (By comparison, a 50-gallon drum holds 189 liters.)

The second question can be rephrased: How tall are the tallest trees? The tallest gymnosperms, the coast redwoods—*Sequoia sempervirens*—exceed 110 meters in height, as do the tallest angiosperms, the Australian *Eucalyptus regnans*. Any successful explanation of water transport in the xylem must account for transport to these great heights.

In this chapter we consider the uptake and transport of water and minerals by plants, the control of evaporative water loss through the stomata, and the translocation of substances in the phloem.

A Long Way to the Top

Water and minerals must defy gravity and climb over 80 meters to reach the top branches of these Douglas firs (*Pseudotsuga menziesii*).

Uptake and Transport of Water and Minerals

Terrestrial plants obtain both water and mineral nutrients from the soil, usually by way of their roots. You already know that water is one of the ingredients required for carbohydrate production by photosynthesis in the leaves. Water is also essential for transporting solutes, for cooling the plant, and for developing the internal pressure that supports the plant body.

How do leaves high in a tree obtain water from the soil? What are the mechanisms by which water and mineral ions enter the plant body through the roots and ascend as sap in the xylem? Because neither water nor minerals can move through the plant into the xylem without crossing at least

one plasma membrane, we focus first on osmosis. Then we examine the uptake of mineral ions, and follow the pathway by which both water and minerals move through the root to gain entry to the xylem.

Water moves through a membrane by osmosis

Osmosis, the movement of water through a membrane in accordance with the laws of diffusion, was described in Chapter 5. The solute potential (osmotic potential) of a solution is a measure of the effect of dissolved solutes on the osmotic behavior of the solution. The greater the solute concentration of a solution, the more negative its solute potential, and the greater the tendency of water to move into it from another solution of lower solute concentration (and less negative solute potential). For osmosis to occur, the two solutions must be separated by a membrane permeable to water but relatively impermeable to the solute. Recall, too, that osmosis is a passive process—energy is not required.

Unlike animal cells, plant cells are surrounded by a relatively rigid cell wall. As water enters a plant cell, the entry of more water is increasingly resisted by an opposing pressure potential (turgor pressure), owing to the rigidity of the wall. As more and more water enters, the pressure potential becomes greater and greater.

Pressure potential is a hydraulic pressure analogous to the air pressure in an automobile tire; it is a real pressure that can be measured with a pressure gauge. Cells with walls do not burst when placed in pure water; instead, water enters by osmosis until the pressure potential exactly balances the solute potential. At this point, the cell is turgid; that is, it has a high pressure potential.

The overall tendency of a solution to take up water from pure water, across a membrane, is called its water potential, represented as ψ , the Greek letter psi (Figure 35.1). The water potential

is simply the sum of the (negative) solute potential (ψ_s) and the (usually positive) pressure potential (ψ_p):

$$\psi = \psi_s + \psi_p$$

For pure water under no applied pressure, all three of these parameters are zero.

We can measure solute potential, pressure potential, and water potential in megapascals (MPa), a unit of pressure. (Atmospheric pressure is about 0.1 MPa, or 14.7 pounds per square inch; typical pressure in an automobile tire is about 0.2 MPa.)

In all cases in which water moves between two solutions separated by a membrane, the following rule of osmosis applies: Water always moves across a differentially permeable membrane toward the region of more negative water potential.

Osmotic phenomena are of great importance to plants. The structure of many plants is maintained by the pressure potential of their cells; if the pressure potential is lost, a plant wilts. Within living tissues, the movement of water from cell to cell by osmosis follows a gradient of water potential. Over longer distances, in open tubes such as xylem vessels and phloem sieve tubes, the flow of water and dissolved solutes is driven by a gradient in pressure potential. The movement of a solution due to a difference in pressure potential between two parts of a plant is called bulk flow.

Uptake of mineral ions requires transport proteins

Mineral ions, which carry electric charges, cannot move across a plasma membrane unless they are aided by trans-

§j Because of the difference in ψ between the solution and the distilled water, water moves from the beaker to the tube.

If the solution in the tube has a negative solute potential (ψ_s) due to the presence of dissolved solutes; its $\psi_p = 0$; thus its ψ is negative. The beaker contains distilled water ($\psi = 0$). The two liquids are not at equilibrium.

Water entering the tube dilutes the solution, making its ψ_s less negative. As the solution rises in the tube, pressure potential (ψ_p) builds up until it balances the ψ_s . This pressure corresponds to turgor pressure in plants. At equilibrium, ψ in the solution is equal to ψ in the beaker.

35.1 Water Potential, Solute Potential, and Pressure Potential

Water potential (ψ) is the tendency of a solution to take up water from pure water. The water potential is the sum of the solute potential (ψ_s) and the pressure potential (ψ_p). For pure water under no applied pressure, all three of these parameters are equal to zero.

A piston resists the entry of water, as does the wall of a plant cell. The solution in the tube is not diluted, so its ψ_s does not change. However, the system is not initially at equilibrium. Enough water squeezes in to raise ψ_p until equilibrium is reached, with equal water potentials.

622 CHAPTER THIRTY-FIVE

transport proteins. (You may wish to review the description of transport proteins in Chapter 5.) When the concentration of these charged ions in the soil is greater than that in the plant, ion channels and carrier proteins can move them into the plant by facilitated diffusion.

The concentrations of some ions in the soil solution, however, are lower than those required inside the plant. Thus the plant must take up these ions against a concentration gradient. Electric potential also plays a role in this process: To move a negatively charged ion into a negatively charged region is to move it against an electrical gradient. The combination of concentration and electrical gradients is called an electrochemical gradient. Uptake against an electrochemical gradient is active transport, an energy-requiring process, depending on cellular respiration for ATP. Active transport, of course, requires specific carrier proteins.

Unlike animals, plants do not have a sodium-potassium pump for active transport. Rather, plants have a proton pump, which uses energy obtained from ATP to move protons out of the cell against a proton concentration gradient (Figure 35.2a). Because protons (H^+) are positively charged, their accumulation on one side of a membrane has two results:

- The region outside the membrane becomes positively charged with respect to the region inside.
- A proton concentration gradient develops.

Each of these results has consequences for the movement of other ions. Because of the charge difference across the membrane, the movement of positively charged ions, such as potassium (K^+), into the cell through their membrane channels is enhanced. These positive ions move into the now more negatively charged interior of the cell by facilitated diffusion (Figure 35.2b). In addition, the proton concentration gradient can be harnessed to drive secondary active transport, in which negatively charged ions such as

chloride (Cl^-) are moved into the cell against an electrochemical gradient by a symport protein that couples their movement with that of H^+ (Figure 35.2c). In sum, there is vigorous traffic of ions across plant membranes.

The proton pump and the coordinated activities of other membrane transport proteins cause the interior of a plant cell to be strongly negative with respect to the exterior. Such a difference in charge across a membrane is called a membrane potential. Biologists can measure the membrane potential of a plant cell with microelectrodes, just as they can measure similar charge differences in neurons (nerve cells) and other animal cells. Most plant cells have a membrane potential of at least -120 millivolts, and they maintain it at this level. The membrane potential difference affects the movements of mineral ions into and out of cells.

Water and ions pass to the xylem by way of the apoplast and symplast

Mineral ions enter and move through plants in various ways. Where bulk flow of water is occurring, dissolved minerals are carried along in the stream. Where water is moving more slowly, minerals move by diffusion. At certain points, where plasma membranes are being crossed, some mineral ions are moved by active transport. One such point is the surface of a root hair, where mineral ions first enter the cells of the plant. Later, within the stele, the ions must cross a plasma membrane before entering the lifeless cells of the xylem.

The movement of ions across membranes can also result in the movement of water. Water moves into a root because the root has a more negative water potential than does the

35.2 The Proton Pump and Its Effects

The buildup of hydrogen ions transported across the plasma membrane by the proton pump {a} triggers the movement of both cations (b) and anions (c) into the cell.

soil solution. Water moves from the cortex of the root into the stele (which is where the vascular tissues are located) because the stele has a more negative water potential than does the cortex.

Water and minerals from the soil may pass through the dermal and ground tissues to the stele via two pathways: the apoplast and the symplast. Plant cells are surrounded by cell walls that lie outside the plasma membrane, and intercellular spaces (spaces between cells) are common in many tissues. The walls and intercellular spaces together constitute the apoplast (from the Greek for "away from living material"). The apoplast is a continuous meshwork through which water and

dissolved substances can flow or diffuse without ever having to cross a membrane (Figure 35.3). Movement of materials through the apoplast is thus unregulated.

The remainder of the plant body is the symplast (from the Greek for "together with living material"). The symplast is the portion of the plant body enclosed by membranes—the continuous cytoplasm of the living cells, connected by plasmodesmata (see Figure 35.3). The selectively permeable plasma membranes of the cells control access to the symplast, so movement of water and dissolved substances into the symplast is tightly regulated.

Water and minerals can pass from the soil solution through the apoplast as far as the endodermis, the innermost layer of the cortex. The endodermis is distinguished from the rest of the ground tissue by the presence of Casparian strips. These waxy, suberin-containing structures impregnate the endodermal cell wall and form a belt surrounding the endodermal cells. The Casparian strips act as a gasket that prevents water and ions from moving between the cells (Figure 35.4).

35.3 Apoplast and Symplast

The plant cell walls and intercellular spaces constitute the apoplast. The symplast comprises the living cells, which are connected by plasmodesmata. To enter the symplast, water and solutes must pass through a plasma membrane. No such selective barrier limits movement through the apoplast.

The Casparian strips of the endodermis thus completely separate the apoplast of the cortex from the apoplast of the stele. They do not obstruct the outer or inner faces of the endodermal cells. Accordingly, water and ions can enter the stele only by way of the symplast—that is, by entering and passing through the cytoplasm of the endodermal cells. Thus transport proteins in the membranes of these cells determine which mineral ions $I. ST$ pass into the stele, and at what rates. This is one of

one of several ways in which plants regulate their chemi-

cal composition and ensure an appropriate balance of their constituents. This balance is essential to plant life. Once they have passed the endodermal barrier, water and minerals leave the symplast. Parenchyma cells in the pericycle or xylem help mineral ions move back into the apoplast. Some of these parenchyma cells, called transfer cells, are structurally modified for transporting mineral ions from their cytoplasm (part of the symplast) into their cell walls (part of the apoplast). The wall that receives the transported ions has many knobby extensions projecting into the transfer cell, increasing the surface area of the plasma membrane, the

Casparian strips prevent water in the apoplast from passing between the endodermal cells and into the stele.

Water must first enter the living endodermal cells; by entering the symplast, it can evade the Casparian strips.

35.5 A Transfer Cell

Three walls of this transfer cell in a pea leaf have knobby extensions that face the cells from which the transfer cell imports solutes. This transfer cell exports the solutes to the neighboring sieve tube member.

number of transport proteins, and thus the rate of transport (Figure 35.5).

Transfer cells also have many mitochondria that produce the ATP needed to power the active transport of mineral ions. As mineral ions move into the solution in the walls, the water potential of the wall solution (apoplast) becomes more negative; thus water moves out of the cells and into the apoplast by osmosis. Active transport of ions moves the ions directly, and water follows passively. The end result is that water and minerals end up in the xylem, where they constitute the xylem sap.

We have just seen that proteins regulate the movement of ions across membranes. We shall now see that even water movement itself is regulated by proteins.

Aquaporins control the rate, but not the direction, of water movement

Aquaporins are membrane channel proteins through which water can traverse a membrane without interacting with the hydrophobic environment of its phospholipid bilayer. These proteins, important in both plants and animals, allow water to move rapidly from environment to cell and from cell to cell. The permeability of some aquaporins is subject to regulation, changing the rate of osmosis across the membrane. However, water movement through aquaporins is always passive, so the direction of water movement is unchanged by alterations in aquaporin permeability.

Transport of Water and Minerals in the Xylem

So far in this chapter we've described the movement of water and minerals into plant roots and their entry into the root xylem. Now we will consider how xylem sap moves

throughout the remainder of the plant. Let's first consider some early ideas about the ascent of sap and then turn to our current understanding of how it works. We'll describe the experiments that ruled out some early models as well as some evidence in support of the current model—and we'll find out what Per Scholander's sharpshooter was up to in the story that opened this chapter.

Experiments ruled out some early models of transport in the xylem

Some of the earliest attempts to explain the rise of sap in the xylem were based on a hypothetical pumping action by living cells in the stem, which pushed the sap upward. However, experiments conducted and published in 1893 by the German botanist Eduard Strasburger definitively ruled out such models.

Strasburger worked with trees about 20 meters tall. He sawed them through at their bases and plunged the cut ends into buckets containing solutions of poisons such as picric acid. The solutions rose through the trunks, as was readily evident from the progressive death of the bark higher and higher up. When the solutions reached the leaves, the leaves died, too, at which point the solutions stopped being transported (as shown by the liquid levels in the buckets, which stopped dropping).

This simple experiment established three important points:

- ▶ Living, "pumping" cells were not responsible for the upward movement of the solutions, because the solutions themselves killed all living cells with which they came in contact.
- ▶ The leaves play a crucial role in transport. As long as they were alive, solutions continued to be transported upward; when the leaves died, transport ceased.
- ▶ Transport was not caused by the roots, because the trunks had been completely separated from the roots.

Root pressure does not account for xylem transport

In spite of Strasburger's observations, some plant physiologists turned to a model of transport based on root pressure—pressure exerted by the root tissues that would force liquid up the xylem. The basis for root pressure is a higher solute concentration, and accordingly a more negative water potential, in the xylem sap than in the soil solution. This negative potential draws water into the stele; once there, the water has nowhere to go but up.

There is good evidence for root pressure—for example, the phenomenon of guttation, in which liquid water is forced out through openings in the leaves (Figure 35.6). Guttation occurs only under conditions of high atmospheric humidity and plentiful water in the soil, which occur most commonly at night. Root pressure is also the source of the sap that oozes from the cut stumps of some plants, such as *Coleus*, when their tops are removed. Root pressure, however, cannot account for the ascent of sap in trees.

Root pressure seldom exceeds 0.1–0.2 MPa (one or two times atmospheric pressure). If root pressure were driving

sap up the xylem, we would observe a positive pressure potential in the xylem at all times. In fact, as we are about to see, the xylem sap is under tension—a negative pressure potential—when it is ascending. Furthermore, as Stras-

n^{ai}

Water vapor diffuses out of the stomata.

Water evaporates from mesophyll cell walls.

Tension pulls water from the veins into the apoplast about the mesophyll cells.

Tension pulls the water column upward and outward in the xylem of veins in the leaves.

35.6 Guttation

Root pressure is responsible for forcing water through openings in the tips of this strawberry leaf.

burger had already shown, materials can be transported upward in the xylem even when the roots have been removed. If the roots aren't pushing the xylem sap upward, what does cause it to rise?

The transpiration-cohesion-tension mechanism accounts for xylem transport

The obvious alternative to pushing is pulling: The leaves pull the xylem sap upward. Transpiration, the evaporative loss of water from the leaves, generates a pulling force (tension) on the water in the apoplast of the leaves. Hydrogen bonding between water molecules makes the sap in the xylem cohesive enough to withstand the tension and rise by bulk flow. Let's see how this transpiration-cohesion-tension mechanism works.

We'll start with transpiration. Water vapor diffuses from the intercellular spaces of the leaf, by way of the stomata, to the outside air because the water vapor concentration is greater inside the leaf than outside. Where did this water vapor come from? As water vapor diffuses out of the leaf, more water evaporates from the moist walls of the mesophyll cells (Figure 35.7). Evaporation of water from the thin film surrounding the cell wall causes the film to shrink into the cellulose meshwork of the wall. The surface of the film curves where the water retreats into microscopic pores. The surface tension of the curved surfaces generates a tension—a negative pressure potential, a pull—in the film. The tension increases as more water leaves the film. This tension is what causes the bulk flow of water all the way from the roots.

The tension in the mesophyll draws water from the vessels or tracheids in the xylem of the nearest vein. The water, with its dissolved solutes, moves by bulk flow through the apoplast. The removal of water from the xylem of the veins establishes tension on the entire column of water contained within the xylem, so the column is drawn upward all the way from the roots.

The ability of water to be pulled upward through tiny tubes results from the remark-

Tension pulls the water column upward in the xylem of the stem

(^Tension pulls the water column upward in the xylem of the root

Q Water molecules form a cohesive column.

Water moves into the stele by osmosis.

35.7 Water Transport in Plants

Evaporation from surface cells, tension generated by the curvature of the shrinking surface film, and the cohesive nature of water molecules all account for the bulk flow of water from the soil to the atmosphere.

able cohesiveness of water—the tendency of water molecules to cohere to one another through hydrogen bonding. The narrower the tube, the greater the tension the water column can withstand without breaking. The integrity of the column is also maintained by the adhesion of water to the cell walls. In the tallest trees, such as a 100-meter redwood, the difference in pressure potential between the top and the bottom of the column may be as great as 3 MPa. The cohesiveness of water in the xylem is great enough to withstand even that great a tension.

In summary, the key elements of water transport in the xylem are:

- ▶ Transpiration, followed by evaporation from the moist cell walls in the leaves, resulting in...
- ▶ tension in the remainder of the xylem's water owing to the...
- ▶ cohesion of water, which pulls up more water to replace water that has been lost.

These elements require no work—no expenditure of energy—on the part of the plant. At each step between soil and atmosphere, water moves passively to a region with a more strongly negative water potential. Dry air has the most negative water potential (-95 MPa at 50% relative humidity), and the soil solution has the least negative water potential (between -0.01 and -3 MPa). Xylem sap has a water potential more negative than that of cells in the root, but less negative than that of mesophyll cells in the leaf.

Mineral ions contained in the xylem sap rise passively with the solution as it ascends from root to leaf. In this way the nutritional needs of the shoot are met. Some of the mineral elements brought to the leaves are subsequently redistributed to other parts of the plant by way of the phloem, but the initial delivery from the roots is through the xylem.

In addition to promoting the transport of minerals, transpiration contributes to temperature regulation. As water evaporates from mesophyll cells, heat is taken up from the cells, and the leaf temperature drops. This cooling effect is important in enabling plants to live in hot environments. A farmer can hold a leaf between thumb and forefinger to estimate its temperature; if the leaf doesn't feel cool, that means that transpiration is not occurring, so it must be time to water.

A pressure bomb measures tension in the xylem sap

The transpiration-cohesion-tension model can be true only if the column of sap in the xylem is under tension (negative pressure potential). The most elegant demonstrations of this tension, and of its adequacy to account for the ascent of sap in tall trees, were performed by Per Scholander. He measured tension in stems with an instrument called a pressure bomb.

The principle of the pressure bomb is as follows: Consider a stem in which the xylem sap is under tension. If the stem is cut, the sap pulls away from the cut, into the stem. Now the stem is placed in a device called a pressure bomb,

in which the pressure may be raised. The cut surface remains outside the bomb. As pressure is applied to the plant parts within the bomb, the xylem sap is forced back to the cut surface. When the sap first becomes visible again at the cut surface, the pressure in the bomb is recorded. This pressure is equal in magnitude but opposite in sign to the tension (negative pressure potential) originally present in the xylem (Figure 35.8).

Scholander used the pressure bomb to study dozens of plant species, from diverse habitats, growing under a variety of conditions. In all cases in which xylem sap was ascending, it was found to be under tension. The tension disappeared in some of the plants at night, when transpiration ceased. In developing vines, the xylem sap was under no tension until leaves formed. Once leaves developed, transport in the xylem began, and tensions were recorded.

Suppose you wanted to measure tensions in the xylem at various heights in a large tree, to confirm that the tensions are sufficient to account for the rate at which sap is moving up the trunk. How would you obtain stem samples for measurement? Scholander used surveying instruments to determine the heights of particular twigs and then had a sharpshooter shoot the twigs from the tree with a high-powered rifle. As quickly as the twigs fell to the ground, Scholander inserted them in the pressure bomb and recorded their xylem tension. In every case, the differences in tensions at different heights were great enough to keep the xylem sap ascending.

Although transpiration provides the impetus for transport of water and minerals in the xylem, it also results in the loss of tremendous quantities of water from the plant. How do plants control this loss?

Transpiration and the Stomata

The epidermis of leaves and stems minimizes transpirational water loss by secreting a waxy cuticle, which is impermeable to water. However, the cuticle is also impermeable to carbon dioxide. This poses a problem: How can the leaf balance its need to retain water with its need to obtain carbon dioxide for photosynthesis?

Plants have evolved an elegant compromise in the form of stomata (singular stoma), or gaps, in the epidermis. A pair of specialized epidermal cells called guard cells controls the opening and closing of each stoma (Figure 35.9a). When the stomata are open, carbon dioxide can enter the leaf by diffusion, but water vapor is also lost in the same way. Closed stomata prevent water loss, but also exclude carbon dioxide from the leaf.

Most plants open their stomata only when the light intensity is sufficient to maintain a moderate rate of photosynthesis. At night, when darkness precludes photosynthesis, the stomata remain closed; no carbon dioxide is needed at this time, and water is conserved. Even during the day, the stomata close if water is being lost at too great a rate.

The stoma and guard cells in Figure 35.9a are typical of eudicots. Monocots typically have specialized epidermal cells associated with their guard cells. The principle of operation, however, is the same for both monocot and eudicot stomata. In what follows, we describe the regulation and mechanism of stomatal opening, the normal cycle of opening and closing, and the modified cycle used by some plants that live in dry or saline environments.

The guard cells control the size of the stomatal opening

Light causes the stomata of most plants to open, admitting carbon dioxide for photosynthesis. Another cue for stomatal opening is the level of carbon dioxide in the spaces inside the leaf. A low level favors opening of the stomata, thus allowing the uptake of more carbon dioxide.

Water stress is a common problem for plants, especially on hot, sunny, windy days. Plants have a protective response to these conditions, using the water potential of the mesophyll cells as a cue. Even when the carbon dioxide level is low and the sun is shining, if the mesophyll is too dehydrated—that is, if the water potential of the mesophyll is too negative—the mesophyll cells release a plant hormone called abscisic acid. Abscisic acid acts on the guard cells, causing them to close the stomata and prevent further drying of the leaf. This response reduces the rate of photosynthesis, but it protects the plant.

The increasing internal concentration of potassium ions makes the water potential of the guard cells more negative. Water enters the guard cells by osmosis, increasing their pressure potential. Their cell walls contain cellulose microfibrils that cause the cells to respond to this increase by changing their shapes so that a gap—the stoma—appears between them.

The stoma closes by the reverse process when the proton pump is no longer active. Potassium ions diffuse passively

Negatively charged ions traveling with K^+ maintain electrical balance and contribute to the changes in osmotic potential that open and close the stomata.

out of the guard cells, water follows by osmosis, the pressure potential decreases, and the guard cells sag together and seal off the stoma. Negatively charged chloride ions and organic ions also move out of the guard cells with the potassium ions, maintaining electrical balance and contributing to the change in the solute potential of the guard cells.

628 CHAPTER THIRTY-FIVE

35.70 Light-Induced Proton Pumping in a Guard Cell Membrane

This graph shows a trace of the tiny electric current that results from the flow of protons across the plasma membrane of a guard cell when it is exposed briefly to blue light.

What drives the opening and closing of the stomata? Certain wavelengths of blue light, absorbed by a pigment in the guard cell plasma membrane, activate a proton pump, which actively transports protons (H^+) out of the guard cells and into the surrounding epidermis (Figure 35.10). The resulting proton gradient drives the accumulation of potassium ions (K^+) (Figure 35.9b) in the guard cell.

Antitranspirants decrease water loss

Stomata are the referees of a compromise between the admission of CO_2 for photosynthesis and the loss of water by transpiration. Farmers would like their crops to transpire less, thus reducing the need for irrigation. Similarly, nurseries and gardeners would like to be able to reduce the amount of water lost by plants that are to be transplanted, because transplanting often damages the roots, causing the plant to wilt or die. What we need is a good antitranspirant: a compound that can be applied to plants, reducing water loss from the stomata without producing disastrous side effects by excessively limiting carbon dioxide uptake.

Absciscic acid and its commercial chemical analogs have been found to work as antitranspirants in small-scale tests, but their high cost has precluded commercial use. What about making plants more sensitive to their own abscisic acid? The guard cells of plants with a genetic mutation called *era* are highly sensitive to abscisic acid. These plants are resistant to wilting during

drought stress.

A totally different type of antitranspirant seals off the leaves from the atmosphere for a time. Growers use a variety of compounds, most of which form polymeric films around leaves, to form a barrier to evaporation. These compounds cause undesirable side effects, however, and can be used only for relatively short periods of time. Their most common use is in the transplanting of nursery stock.

Crassulacean acid metabolism correlates with an inverted stomatal cycle

Most plants open and close their stomata on a schedule like that shown by the blue curve in Figure 35.11. The stomata are typically open for much of the day and closed at night. (They may also close during very hot days to reduce water loss.) But not all plants follow this pattern.

A brief exposure to blue light against a background of constant, dim red light...

...causes protons to flow out of the cell for a few minutes.

35.7 7 Stomatal Cycles

Most plants open their stomata during the day. CAM plants reverse this stomatal cycle: Their stomata open during the night.

Time (minutes)

Many plants that live in dry areas or near the ocean have some unusual biochemical and behavioral features. One particularly surprising feature is their "backward" stomatal cycle: Their stomata are open at night and closed by day (as shown by the red curve in Figure 35.11). This behavior is part of the phenomenon of crassulacean acid metabolism (CAM), which was described in Chapter 8 (see Figure 8.21).

At night, while the stomata are open, carbon dioxide diffuses freely into the leaves of CAM plants and reacts in the mesophyll cells with phosphoenolpyruvic acid to produce organic acids. These acids accumulate to high concentrations. At daybreak the stomata close. Throughout the day, the organic acids are broken down to release the carbon dioxide they contain—behind closed stomata. Because the carbon dioxide cannot diffuse out of the plant, it is available for photosynthesis.

CAM is well adapted to environments where water is scarce: A leaf with its stomata open only at night—when the environment is cooler—loses much less water than does a leaf with its stomata open by day.

In both CAM and non-CAM plants, carbon dioxide is fixed and converted to the products of photosynthesis. How are these products delivered to other parts of the plant?

Translocation of Substances in the Phloem

35.12 Girdling Blocks Translocation in the Phloem

By removing a ring of bark (containing the phloem), Malpighi blocked the translocation of organic solutes in a tree.

reserves) more sugars than it requires. A sink is an organ (such as a root, a flower, a developing tuber, or an immature leaf) that does not make enough sugar for its own growth and storage needs. Sugars (primarily sucrose), amino acids, some minerals, and a variety of other substances are translocated between sources and sinks in the phloem.

How do we know that such organic solutes are translocated in the phloem, rather than in the xylem? Just over 300 years ago, the Italian scientist Marcello Malpighi performed a classic experiment in which he removed a ring of bark (containing the phloem) from the trunk of a tree—that is, he girdled the tree (Figure 35.12). The bark in the region above the girdle swelled over time. We now know that the swelling resulted from the accumulation of organic solutes that came from higher up the tree and could no longer continue downward because of the disruption of the phloem. Later,

oo

(/>) Longistigma caryae

Sap droplet

TRANSPORT IN PLANTS 629

the bark below the girdle died because it no longer received sugars from the leaves.

Any model to explain translocation of organic solutes must account for a few important facts:

- ▶ Translocation stops if the phloem tissue is killed by heating or other methods; thus the mechanism must be different from that of transport in the xylem.
- ▶ Translocation often proceeds in both directions—up and down the stem—simultaneously.
- ▶ Translocation is inhibited by compounds that inhibit respiration and thus limit the ATP supply in the source.

To investigate translocation, plant physiologists needed to obtain samples of pure sieve tube sap from individual sieve tube members. This difficult task was simplified when scientists discovered that a common garden pest, the aphid, feeds by drilling into a sieve tube. An aphid inserts its stylet, or feeding organ, into a stem until the stylet enters a sieve tube (Figure 35.13n). Within the sieve tube, the pressure is much greater than in the surrounding plant tissues, so nutritious sieve tube sap is forced up the stylet and into the aphid's digestive tract. So great is the pressure that sugary liquid is forced through the insect's body and out the anus (Figure 35.13b).

Plant physiologists use aphids to collect sieve tube sap. When liquid appears on the aphid's abdomen, indicating that the insect has connected with a sieve tube, the physiologist quickly freezes the aphid and cuts its body away from the stylet, which remains in the sieve tube member. For hours, sieve tube sap continues to exude from the cut stylet, where it may be collected for analysis. Chemical analysis of sieve tube sap collected in this manner reveals the contents of a single sieve tube member over time. We can also infer the rates at which different substances are translocated by measuring how long it takes for radioactive tracers administered to a leaf to appear at stylets at different distances from the leaf.

These methods have allowed us to understand how, at times, different substances might move in opposite directions in the phloem of a stem. Experiments with aphid stylets have shown that all the contents of any given sieve tube member move in the same direction. Thus, bidirectional translocation can be understood in terms of different sieve tubes conducting sap in opposite directions. Data obtained by these and other means led to the general adoption of the pressure flow model as an explanation for translocation in the phloem.

35.13 Aphids Collect Sieve Tube Sap

(a) Aphids feed on phloem sap drawn from the sieve tube, which they penetrate with a modified feeding organ, the stylet, (b) Pressure inside the sieve tube forces sap through the aphid's digestive tract, from which it can be harvested.

630 CHAPTER THIRTY-FIVE

The pressure flow model appears to account for phloem translocation

The tonoplast breaks down during sieve tube member development, allowing the contents of the central vacuole to combine with much of the cytosol to form the sieve tube sap (see Chapter 34). The sap flows under pressure through the sieve tubes. It moves from one sieve tube member to the next by bulk flow through the sieve plates, without crossing a membrane.

Two steps in sieve tube sap flow require metabolic energy:

- ▶ Transport of sucrose and other solutes into the sieve tubes (loading) at sources
- ▶ Removal (unloading) of the solutes where the sieve tubes enter sinks

According to the pressure flow model of translocation in the phloem, sucrose is actively transported into sieve tube members at sources, giving these cells a much greater sucrose concentration than surrounding cells. Water therefore enters the sieve tube members by osmosis. The entry of this water causes a greater pressure potential at the source end, so the entire fluid content of the sieve tube is pushed to-

ward the sink end of the tube—that is, the sap moves by bulk flow (Figure 35.14).

The pressure flow model of translocation in the phloem is contrasted with the transpiration-cohesion-tension model of xylem transport in Table 35.1.

Testing the pressure flow model

The pressure flow model was first proposed more than half a century ago, but some of its features are still debated. Other mechanisms have been proposed to account for translocation in sieve tubes. Some have been disproved, and none of the rest have been supported by a weight of evidence comparable to that for the pressure flow model, which must meet two requirements:

- The sieve plates must be open, so that bulk flow from one sieve tube member to the next is possible.
- There must be an effective method for loading sucrose and other solutes into the phloem in source tissues and removing them in sink tissues.

Let us see whether these requirements are met.

are the sieve plates clogged or open? Early electron microscopic studies of phloem samples cut from plants produced results that seemed to contradict the pressure flow

[a] The pressure flow model More concentrated

model. The pores in the sieve plates always appeared to be plugged with masses of a fibrous protein, suggesting that sieve tube sap could not flow freely. But what is the function of that fibrous protein?

One possibility is that this protein is usually distributed more or less at random throughout the sieve tube members until the sieve tube is damaged; then the sudden surge of sap toward the cut surface carries the protein into the pores, blocking them and preventing the loss of valuable nutrients. In other words, perhaps the protein does not block the pores unless the phloem is damaged. How might this possibility be tested? Could we obtain phloem for microscopic observation without causing the sap to surge to the cut surface?

One way to prevent the surge of the sap is to freeze plant tissue before cutting it. Another way is to let the tissue wilt so that there is no pressure in the phloem before cutting. When these methods were used, the sieve plates were not clogged by the protein. Thus, the first condition of the pressure flow model is met.

(a)

Mesophyll cells produce sugars.

Sugars move primarily through the symplast on their way to the sieve tube members.

NEIGHBORING CELLS LOAD AND UNLOAD THE SIEVE TUBE MEMBERS. If the pressure flow model is correct, there must be mechanisms for loading sugars and other solutes into the phloem in source regions and for unloading them in sink regions. One pathway of phloem loading has been demonstrated in some plant species.

Sugars and other solutes pass from cell to cell through the symplast in the mesophyll. When these substances reach cells adjacent to the ends of leaf veins, they leave the mesophyll cells and enter the apoplast, sometimes with the help of transfer cells. Then specific sugars and amino acids are actively transported into cells of the phloem, thus reentering the symplast (Figure 35.15).

Passage through the apoplast and back into the symplast selects substances to be accumulated for translocation because substances can enter the phloem only after passing through a differentially permeable membrane. In many plants, solutes reenter the symplast at the companion cells (see Chapter 34), which then transfer the solutes to the adjacent sieve tube members. As Figure 35.15 shows, in other plant species, sucrose or other sugars move from the mesophyll to the sieve tube members entirely within the symplast; that is, transfer of solutes from symplast to apoplast and back again is not a universal feature of phloem loading.

Companion (transfer) cell

Sieve tube member

The proton pump builds a gradient of proton concentration.

Diffusion of protons through the sucrose-proton symport protein carries sucrose, against its own concentration gradient, into the companion cells and sieve tube members.

Mesophyll cell

35.15 Pressure Flow in a Plant

(a) Sugars pass from cell to cell through the symplast in the mesophyll. After these substances reach cells adjacent to the ends of leaf veins, they may enter the apoplast, sometimes with the help of transfer cells. Specific compounds are actively transported into cells of the phloem, thus reentering the symplast. (b) Active transport of sugars into the phloem is carried out by sucrose-proton symport, which relies on a proton concentration gradient established by proton pumps.

Cytoplasm of sieve tube member (symplast)

632 CHAPTER THIRTY-FIVE

A form of secondary active transport (see Chapter 5, pages 88-90) loads sucrose into the companion cells and sieve tube members. Sucrose is carried through the plasma membrane from apoplast to symplast by sucrose-proton symport; thus the entry of sucrose and of protons is strictly coupled. For this symport to work, the apoplast must have a high concentration of protons; the protons are supplied by a primary active transport system, the proton pump. The protons then diffuse back into the cell through the symport protein, bringing sucrose with them.

In sink regions, the solutes are actively transported out of the sieve tube members and into the surrounding tissues. This unloading serves two purposes: It helps maintain the gradient of solute potential and hence of pressure potential in the sieve tubes, and it promotes the buildup of sugars and starch to high concentrations in storage regions, such as developing fruits and seeds.

Plasmodesmata and material transfer between cells

Many substances move from cell to cell within the symplast by way of plasmodesmata (see Figure 34.7). Among their other roles, plasmodesmata participate in the loading and unloading of sieve tube members. Mechanisms vary among plant species, but the story in tobacco plants is a common one. In tobacco, sugars and other compounds in source tissues enter companion cells by active transport from the apoplast and move on to the sieve tube members through plasmodesmata. In sink tissues, plasmodesmata connect sieve tube members, companion cells, and the cells that will receive and use the transported compounds.

Plasmodesmata undergo developmental changes as an immature sink leaf matures into a mature source leaf. Plasmodesmata in sink tissues favor rapid unloading: They are more abundant, and they allow the passage of larger molecules. Plasmodesmata in source tissues are few in number.

It was long thought that only substances with molecular weights less than 1,000 could fit through a plasmodesma. Then biologists discovered that cells infected with tobacco mosaic virus (TMV) could allow molecules with molecular weights of as much as 20,000 to exit. We now know that TMV encodes a "movement protein" that produces this change in the permeability of the plasmodesmata—and that plants themselves normally produce at least one such movement protein. Even large molecules such as proteins and RNAs, with molecular weights up to at least 50,000, can thus move between living plant cells. We will see some consequences of this movement of macromolecules through plasmodesmata in later chapters. Biologists are exploring possible ways to regulate the permeability, number, and form of plasmodesmata as a means of modifying traffic in the plant. Such modifications might, for example, allow the diversion of more of a grain crop's photosynthetic products into the grain, increasing the crop yield.

Chapter Summary

Uptake and Transport of Water and Minerals

- ▶ Plant roots take up water and minerals from the soil.
- ▶ Water moves through biological membranes by osmosis, always moving toward cells with a more negative water potential. The water potential of a cell or solution is the sum of the solute potential and the pressure potential. All three parameters are expressed in megapascals (MPa). Review Figure 35.1
- ▶ Mineral uptake requires transport proteins. Some minerals enter the plant by facilitated diffusion; others enter by active transport. A proton pump facilitates the active transport of many solutes across membranes in plants. Review Figure 35.2
- ▶ Water and minerals pass from the soil to the xylem by way of the apoplast and symplast. In the root, water and minerals may pass from the cortex into the stele only by way of the symplast because Casparian strips in the endodermis block water and solute movement in the apoplast. Review Figures 35.3, 35.4

Transport of Water and Minerals in the Xylem

- ▶ Early experiments established that sap does not move via the pumping action of living cells.
- ▶ Root pressure is responsible for guttation and for the oozing of sap from cut stumps, but it cannot account for the ascent of sap in trees.
- ▶ Xylem transport is the result of the combined effects of transpiration, cohesion, and tension. Evaporation in the leaf produces tension in the surface film of water on the moist-walled mesophyll cells, and thus pulls water—held together by its cohesiveness—up through the xylem from the root. Dissolved minerals go along for the ride. Review Figure 35.7
- ▶ Support for the transpiration-cohesion-tension model of xylem transport came from studies using a pressure bomb.

Review Figure 35.8

Transpiration and the Stomata

- ▶ Evaporation of water cools the leaves, but a plant cannot afford to lose too much water. Transpirational water loss is minimized by the waxy cuticle of the leaves.
- ▶ Stomata allow a compromise between water retention and carbon dioxide uptake. A pair of guard cells controls the size of the stomatal opening. A proton pump, activated by blue light, pumps protons from the guard cells to surrounding epidermal cells. As a result, the guard cells take up potassium ions, causing water to follow osmotically, swelling the cells and opening the stomata. Carbon dioxide level and water availability also affect stomatal opening. Review Figures 35.9, 35.10
- ▶ In most plants the stomata are open during the day and closed at night. CAM plants have an inverted stomatal cycle, enabling them to conserve water. Review Figure 35.11

Translocation of Substances in the Phloem

- ▶ Products of photosynthesis, and some minerals, are translocated through sieve tubes in the phloem by way of living sieve tube members. Translocation proceeds in both directions in the stem, although in a single sieve tube it goes only one way. Translocation requires a supply of ATP.

TRANSPORT IN PLANTS 633

- ▶ Translocation in the phloem proceeds in accordance with the pressure flow model: The difference in solute concentration between sources and sinks allows a difference in pressure potential along the sieve tubes, resulting in bulk flow. Review Figure 35.14, Table 35.1
- ▶ The pressure flow model succeeds because the sieve plates are normally open, allowing bulk flow, and because neighboring cells load organic solutes into the sieve tube members in source regions and unload them in sink regions. Review Figure 35.15
- ▶ The distribution and properties of plasmodesmata differ between source and sink tissues. It may become possible to regulate plasmodesmata in crop plants.

For Discussion

1. Epidermal cells protect against excess water loss. How do they perform this function?
2. Phloem transports material from sources to sinks. What is meant by "source" and "sink"? Give examples of each.
3. What is the minimum number of plasma membranes a water molecule would have to cross in order to get from the soil solution to the atmosphere by way of the stele? To get from the soil solution to a mesophyll cell in a leaf.
4. Transpiration exerts a powerful pulling force on the water column in the xylem. When would you expect transpiration to proceed most rapidly? Why? Describe the source of the pulling force.
5. Plants that perform crassulacean acid metabolism (CAM plants) are adapted to environments in which water supply is limited; these plants open their stomata only at night. Could a non-CAM plant, such as a pea plant, enjoy an advantage if it opened its stomata only at night? Explain.

36

Plant Nutrition

An insect has stepped on a trigger hair on the leaf of a Venus flytrap—a big mistake for the insect. The trigger hair sends an electrical signal that springs a mechanical trap. The two halves of the leaves close, and spiny outgrowths at the margins of the leaves interlock to imprison the insect. The leaf secretes enzymes that will digest its prey. The leaf then absorbs the products of digestion, especially amino acids, and uses them as a nutritional supplement.

Why does the Venus flytrap go to all this trouble? Few other plants are carnivorous—your petunia plant is not stalking you, after all. But the Venus flytrap (*Dionaea muscipula*) lives on soils in which nitrogen is scarce. Its carnivorous adaptation gives it another way to obtain needed nitrogen.

Why do plants need nitrogen? The answer is simple if we recall the chemical structures of proteins and nucleic acids that we looked at in Chapter 3. These vital components of all living things contain nitrogen, as do chlorophyll and many other important biochemical compounds. If a plant cannot get enough nitrogen, it cannot synthesize these compounds at a rate adequate to keep itself healthy.

In addition to nitrogen, plants need other materials from their environment. In this chapter we explore the differences

between the basic strategies of plants and animals for obtaining nutrition. Then we look at what nutrients plants require, and how they acquire them. Because most nutrients come from the soil, we discuss the formation of soils and the effects of plants on soils. As any farmer can tell you, nitrogen is the nutrient that most often limits plant growth, so we devote a section specifically to nitrogen metabolism in plants. The chapter concludes with a look at plants that use means other than photosynthesis to supplement their nutrition.

The Acquisition of Nutrients

Every living thing must obtain raw materials from its environment. These nutrients include the major ingredients of macromolecules: carbon, hy-

A Meat-Eating Plant

Dionaea muscipula, the Venus flytrap, has adapted to a nitrogen-poor environment by becoming carnivorous. It obtains this necessary mineral from the bodies of insects trapped inside the plant when its hinges snap shut.

drogen, oxygen, and nitrogen. Carbon and oxygen enter the living world through the carbon-fixing reactions of photosynthesis, in which photosynthetic organisms obtain them from atmospheric carbon dioxide. Hydrogen enters living systems through the light reactions of photosynthesis, which split water. For carbon, oxygen, and hydrogen, photosynthesis is the gateway to the living world.

The movement of nitrogen into organisms begins with processing by some highly specialized bacteria living in the soil. Some of these bacteria act on nitrogen gas, converting it into a form usable by plants. The plants in turn provide organic nitrogen and carbon to animals, fungi, and many microorganisms.

In addition to carbon, oxygen, hydrogen, and nitrogen, other mineral nutrients are essential to living systems. The proteins of organisms contain sulfur (S), and their nucleic acids contain phosphorus (P). There is magnesium (Mg) in chlorophyll, and iron (Fe) in many important compounds, such as the cytochromes. Within the soil, these and other minerals dissolve in water, forming a solution—called the soil solution—that contacts the roots of plants. Plants take up most of these mineral nutrients from the soil solution in ionic form.

Autotrophs make their own organic compounds

The plants provide carbon, oxygen, hydrogen, nitrogen, and sulfur to most of the rest of the living world. Plants, some protists, and some bacteria are autotrophs; that is, they make their own organic compounds from simple inorganic nutrients—carbon dioxide, water, nitrate or ammonium ions containing nitrogen, and a few other soluble mineral nutrients (Figure 36.1). Heterotrophs are organisms that require preformed organic compounds (compounds that contain carbon) as food. Herbivores and carnivores are heterotrophs that depend directly or indirectly on autotrophs as their source of nutrition.

Most autotrophs are photosynthesizers—that is, they use light as the source of energy for synthesizing organic compounds from inorganic raw materials. Some autotrophs, however, are chemosynthesizers, deriving their energy not from light, but from reduced inorganic substances, such as hydrogen sulfide (H_2S), in their environment. All chemosynthesizers are bacteria. Some chemosynthetic bacteria in the soil contribute to the nutrition of plants by increasing the availability of nitrogen and sulfur. But how does a plant obtain its nutrients, whether they come with or without bacterial action?

How does a stationary organism find nutrients?

An organism that cannot move must exploit energy that is somehow brought to it. Most sessile animals depend primarily on the movement of water to bring energy, in the form of food, to them, but a plant's supply of energy arrives at the speed of light from the sun. A plant's supply of nutrients, however, is strictly local, and the plant may use up the water and mineral nutrients in its local environment as it develops. How does a plant cope with such a problem?

One answer is to extend itself by growing into new re-sources. Growth is a plant's version of locomotion. Root systems mine the soil; by growing, they reach new sources of mineral nutrients and water. Growth of leaves helps a plant se-

cure light and carbon dioxide. A plant may compete with other plants for light by outgrowing them, both capturing more light for itself and preventing the growth of its neighbors by shading them.

As it grows, a plant—or even a single root—must deal with environmental heterogeneity. Animal droppings create high local concentrations of nitrogen. A particle of calcium carbonate in the soil may make a tiny area alkaline, while dead organic matter may make a nearby area acidic.

Mineral Nutrients Essential to Plants

What important mineral nutrients do plants take up from their environment, and what are their roles? Table 36.1 lists the mineral nutrients that have been proved to be essential for plants. Except for nitrogen, they all come from the soil solution and derive ultimately from rock.

There are three criteria for calling something an essential element:

- ▶ The element must be necessary for normal growth and reproduction.
- ▶ The element cannot be replaceable by another element.
- ▶ The requirement must be direct —that is, not the result of an indirect effect, such as the need to relieve toxicity caused by another substance.

In this section, we'll consider the symptoms of particular mineral deficiencies, the roles of some of the mineral nutrients, and the technique by which the essential elements for plants were identified.

The essential elements in Table 36.1 are divided into two categories: the macronutrients and the micronutrients. Plant tissues need macronutrients in concentrations of at least 1 gram per kilogram of their dry matter, and they need micronutrients in concentrations of less than 100 milligrams per kilogram of their dry matter. (Dry matter, or dry weight, is what remains after all the water has been removed from a tissue sample.) Both the macronutrients and the micronutrients are essential for the plant to complete its life cycle from seed to seed.

Deficiency symptoms reveal inadequate nutrition

Before a plant that is deficient in an essential element dies, it usually displays characteristic deficiency symptoms. Table 36.2 describes the symptoms of some common mineral deficiencies. Such symptoms help horticulturists diagnose mineral nutrient deficiencies in plants.

36.7 What Do Plants Need?

To survive, plants require only light plus carbon dioxide, water, and several essential mineral elements. These plants are growing on nothing more than a solution that contains water and mineral elements. This technique is known as hydroponic culture.

636 CHAPTER THIRTY-SIX

7 O. / Mineral Elements Required by Plants

ELEMENT

ABSORBED FORM

MAJOR FUNCTIONS

In proteins, nucleic acids, etc.

In nucleic acids, ATP, phospholipids, etc.

Enzyme activation; water balance; ion balance; stomatal opening

In proteins and coenzymes

Affects the cytoskeleton, membranes, and many enzymes; second messenger

In chlorophyll; required by many enzymes; stabilizes ribosomes

In active site of many redox enzymes and electron carriers; chlorophyll synthesis

Photosynthesis; ion balance

Activation of many enzymes

Possibly carbohydrate transport (poorly understood)

Enzyme activation; auxin synthesis

In active site of many redox enzymes and electron carriers

Activation of one enzyme

Nitrogen fixation; nitrate reduction

Nitrogen deficiency is the most common mineral deficiency in plants. Plants in natural environments are almost always deficient in nitrogen, but they seldom display deficiency symptoms. Instead, their growth slows to match the available supply of nitrogen. Crop plants, on the other hand, show deficiency symptoms if a formerly abundant supply of nitrogen runs out. The visible symptoms of nitrogen deficiency include uniform yellowing, or chlorosis, of older leaves. Chlorophyll, which is responsible for the green color of leaves, contains nitrogen. Without nitrogen there is no chlorophyll, and without chlorophyll, the yellow pigments become visible.

Zinc

yellow veins

Young leaves are abnormally small; older leaves have many dead spots

Inadequate available iron in the soil can also cause chlorosis because, although it is not contained in the chlorophyll molecule, iron is required for chlorophyll synthesis. However, iron deficiency commonly causes chlorosis of the youngest leaves, with their veins sometimes remaining green. The reason for this difference is that nitrogen is readily translocated in the plant and can be redistributed from older tissues to younger tissues to favor their growth. Iron, on the other hand, cannot be readily redistributed. Younger tissues that are actively growing and synthesizing compounds needed for their growth show iron deficiency before older leaves, which have already completed their growth.

Several essential elements fulfill multiple roles

Essential elements can play several different roles—some structural, others catalytic. Magnesium, as we have mentioned, is a constituent of the chlorophyll molecule and hence is essential to photosynthesis. It is also required as a cofactor by numerous enzymes in cellular respiration and other metabolic pathways.

Phosphorus, usually in phosphate groups, is found in many organic compounds, particularly in nucleic acids and in the intermediates of the energy pathways of photosynthesis and glycolysis. The transfer of phosphate groups occurs in many energy-storing and energy-releasing reactions, notably those that use or produce ATP. Other roles of phosphate groups include the activation and inactivation of enzymes.

Calcium plays many roles in plants. Its function in the processing of hormonal and environmental cues is the subject of great biological interest, as we'll see in the next chapter. Calcium also affects membranes and cytoskeleton activity, participates in spindle formation for mitosis and meiosis, and is a constituent of the middle lamella of cell

36.2 Identifying Essential Elements for Plants

The diagram shows the procedure for identifying nutrients essential to plants, using nitrogen as an example. The environment in such experiments must be rigorously controlled because some essential elements are needed in only tiny amounts, and may be present in sufficient quantities as contaminants.

walls. Other elements, such as iron and potassium, also play multiple roles.

All of these elements are essential to the life of all plants. How did biologists discover which elements are essential?

The identification of essential elements

An element is considered essential if a plant fails to complete its life cycle, or grows abnormally, when that element is not available, or is not available in sufficient quantities. Plant physiologists identified most of the essential elements for plants by the technique outlined in Figure 36.2. This technique is limited, however, by the possibility that some elements thought to be absent from the test solutions are actually present. Impurities and contamination are always possible.

In early experiments on plant nutrition, some of the chemicals used were so

36.3 The Complexity of Soil

Soil has both organic and inorganic components.

PLANT NUTRITION 637

impure that they provided micronutrients that the investigators thought they had excluded. Some mineral nutrients are required in such tiny amounts that there may be enough in a seed to supply the embryo and the resultant plant throughout its lifetime and leave enough in the next seed to get the next generation well started. Simply touching a plant may give it a significant dose of chlorine in the form of chloride ions from sweat. Only rarely are new essential elements reported now. Either the list is nearly complete, or more likely, we will need more sophisticated techniques to add to it.

Where does the plant find its essential mineral nutrients? How does it absorb them?

Soils and Plants

Soils are very important to plants, and plant interactions with the soil are complex. Plants obtain their mineral nutrients from the soil solution or the water in which they grow. Water for terrestrial plants also comes from the soil, as does the supply of oxygen for the roots. Soil also provides mechanical support for plants on land, and it harbors bacteria that perform chemical reactions leading to products required for plant growth. On the other hand, soil may also contain organisms harmful to plants.

In the pages that follow, we'll examine the composition and structure of soils, their formation, their role in plant nutrition, their care and supplementation in agriculture, and their modification by the plants that grow in them.

Soils are complex in structure

Soils are complex systems of living and nonliving components. The living components include plant roots, as well as populations of bacteria, fungi, and animals such as earthworms and insects (Figure 36.3). The nonliving portion of the soil includes rock fragments ranging in size from large

Soil consists of more than inorganic mineral particles such as clay and quartz.

Quartz

Living organisms such as bacteria are present.

Organic matter (from plants, animals, and fungi) can also be found.

Air and water are present in pores in soil crumbs like this one.

Aggregates of clay particles

638 CHAPTER THIRTY-SIX

boulders to tiny particles called clay that are 2 μm or less in diameter (Table 36.3). Soils also contain water and dissolved mineral nutrients, air spaces, and dead organic matter. The air spaces are crucial sources of oxygen for plant roots. Soils change constantly through natural causes—such as rain, temperature extremes, and the activities of plants and animals—as well as human activities—farming in particular.

The structure of many soils changes with depth, revealing a soil profile. Although soils differ greatly, almost all soils consist of two or more horizons—recognizable horizontal layers—lying on top of one another. Mineral nutrients tend to be leached—dissolved in rain or irrigation water and carried to deeper horizons.

Soil scientists recognize three major zones (A, B, and C) in the profile of a typical soil (Figure 36.4). Topsoil is the A horizon, from which mineral nutrients may be depleted by leaching. Most of the organic matter in the soil is in the

C horizon Weathering parent rock

(bedrock)

36.4 A Soil's Profile

The A, B, and C horizons can sometimes be seen in road cuts such as this one in Australia. The dark upper layer (A horizon) is home to most of the living organisms in the soil.

A horizon, as are most roots, earthworms, insects, nematodes, and microorganisms. Successful agriculture depends on the

presence of a suitable A horizon. Pure sand contains plenty of air spaces, but is low in water and mineral nutrients. Clay contains lots of nutrients and more water than sand does, but it is low in air. A little bit of clay goes a long way in affecting soil properties. A loam has significant amounts of sand, silt, and clay, and thus has good levels of air, water, and nutrients for plants. Most of the best topsoils for agriculture are loams.

Below the A horizon is the B horizon, or subsoil, which is the zone of infiltration and accumulation of materials leached from above. Farther down, the C horizon is the original parent rock from which the soil is derived. Some deep-growing roots extend into the B horizon, but roots rarely enter the C horizon.

Soils form through the weathering of rock

The type of soil in a given area depends on the type of rock from which it formed, the climate, the landscape features, the organisms living there, and the length of time that soil-forming processes have been acting (sometimes millions of years). Rocks are broken down in part by mechanical weathering, which is the physical breakdown—without any accompanying chemical changes—of materials by wetting, drying, and freezing. The most important parts of soil formation, however, include chemical weathering, the chemical alteration of at least some of the materials in the rocks.

The key process is the formation of clay. Both the physical and the chemical properties of soils depend on the amount and kind of clay particles they contain. Just grinding up rocks does not produce a clay that binds mineral nutrients and aggregates into particles. Such a clay results only from chemical weathering.

Soils are the source of plant nutrition

The supply of mineral nutrients for plants depends on the presence of clay particles in the soil. Many of the minerals that are important for plant nutrition, such as potassium (K^+), magnesium (Mg^{2+}), and calcium (Ca^{2+}), exist in soil as positively charged ions, or cations. Clay particles have a net negative charge, which they get from negatively charged ions that are permanently attached to them. Cations in solution are attracted to these negative ions. To become available to plants, the cations must be detached from the clay particles.

This task is accomplished by reactions with protons (hydrogen ions, H^+). Roots release protons into the soil, and they are also released by the ionization of carbonic acid (H_2CO_3), which is formed whenever CO_2 from respiring roots or from the atmosphere dissolves in water. Protons bond more strongly to the clay particles than do the mineral cations, so they trade places with the cations, thus putting the nutrients back into the soil solution. This trading of places is called ion exchange (Figure 36.5). The fertility of a soil is determined in part by its ability to provide nutrients in this manner.

Clay particles effectively hold and exchange positively charged ions, but there is no comparable mechanism for exchanging negatively charged ions. As a result, important negative ions such as nitrate (NO_3^-) and sulfate (SO_4^{2-})—the primary and direct sources of nitrogen and sulfur—leach rapidly from soil, whereas positive ions tend to be retained in the A horizon. The reservoir of soil nitrogen is the organic matter in the soil, which slowly decomposes to release nitrogen in a form available to plants.

Fertilizers and lime are used in agriculture

Agricultural soils often require fertilizers because irrigation and rainwater leach mineral nutrients from the soil, and the harvesting of crops removes the nutrients that the plants took up from the soil during their growth. Crop yields decrease if any essential element is depleted. Mineral nutrients may be replaced by organic fertilizers, such as rotted manure, or inorganic fertilizers of various types. The three elements most commonly added to agricultural soils are nitrogen (N), phosphorus (P), and potassium (K). Commercial fertilizers are characterized by their "N-P-K" percentages. A 5-10-10 fertilizer, for example, contains 5 percent nitrogen, 10 percent phosphate (P_2O_5), and 10 percent potash (K_2O) by weight.* Sulfur, in the form of a sulfate, is also occasionally added to soils.

Either organic or inorganic fertilizers can provide the necessary mineral nutrients for plants. Organic fertilizers release nutrients slowly, which results in less leaching than a one-time application of inorganic fertilizer. Organic fertilizers also contain materials that improve the physical properties of the soil, providing spaces for gas movement, root growth, and drainage. Inorganic fertilizers, on the other hand, provide an almost instantaneous supply of soil nutrients and can be formulated to meet the requirements of a particular soil and a particular crop.

The availability of nutrient ions, whether they are naturally present in the soil or added as fertilizer, is altered by changes in soil pH. The optimal soil pH for most crops is about 6.5, but so-called acid-loving crops such as blueberries prefer a pH closer to 4. Rainfall and the decomposition of

*The analysis is by weight and is not reported as elemental N, P, and K. A 5-10-10 fertilizer actually does contain 5 percent nitrogen, but only 4.3 percent phosphorus and 8.3 percent potassium on an elemental basis.

A clay particle, which is negatively charged, binds cations.

The cations are exchanged for hydrogen ions obtained from carbonic acid (H_2CO_3) or from the plant itself.

36.5 Ion Exchange

Plants obtain mineral nutrients from the soil primarily in the form of positive ions; potassium is the example shown here.

organic substances in the soil lower its pH. Such acidification of the soil can be reversed by liming—the application of compounds commonly known as lime, such as calcium carbonate, calcium hydroxide, or magnesium carbonate. The addition of these compounds leads to the removal of H^+ ions from the soil. Liming also increases the availability of calcium to plants, which require it as a macronutrient.

It is easy to guess how humans learned to use fertilizer: It didn't take much insight to notice improved plant growth around animal feces. Perhaps a similar observation of limestone, or chalk, or oyster shells—all sources of calcium carbonate—led to the practice of liming. Sometimes, on the other hand, a soil is not acidic enough. In this case, a farmer can add sulfur, and soil bacteria will convert it to sulfuric acid. Iron and some other elements are more available to plants at a slightly acidic pH. Soil pH testing is useful for home gardens and lawns as well as for agriculture.

Spraying leaves with a nutrient solution is another effective way to deliver some essential elements to growing plants. Plants take up more copper, iron, and manganese when these elements are applied as foliar (leaf) sprays than when they are added to the soil as fertilizer. Adjusting the concentrations of nutrient ions and pH in order to optimize uptake and to minimize toxicity can yield excellent results. Such foliar application of mineral nutrients is increasingly used in wheat production, but fertilizer is still delivered most commonly by way of the soil.

Plants affect soils

The soil that forms in a particular place also depends on the types of plants growing there. Plant litter, such as dead fallen leaves, is the major source of carbon-rich materials that break down to form humus—dark-colored organic material, each particle of which is too small to be recognizable with the naked eye. Soil bacteria and fungi produce

640 CHAPTER THIRTY-SIX

humus by breaking down plant litter, animal feces, and other organic material. Humus is rich in mineral nutrients, especially nitrogen. Humus in combination with clay promotes a soil structure favorable to plant growth, promoting adequate supplies of both water and oxygen to the roots.

Plants affect the pH of the soil in which they grow. Roots maintain a balance of electric charges. If they absorb more cations than anions, they excrete H^+ ions, thus lowering the soil pH. If they absorb more anions than cations, they excrete OH^- ions or HCO_3^- ions, raising the soil pH.

The mineral nutrient most commonly limiting, in both natural and agricultural situations, is nitrogen. Let's consider how nitrogen is made available to plants.

Nitrogen Fixation

Earth's atmosphere is a vast reservoir of nitrogen in the form of nitrogen gas (N_2). N_2 constitutes almost four-fifths of the atmosphere. However, plants cannot use N_2 directly as a nutrient. It is a highly unreactive substance—the triple bond linking the two nitrogen atoms is extremely stable, and a great deal of energy is required to break it.

A few species of bacteria have an enzyme that enables them to convert N_2 into a more reactive form by a process called nitrogen fixation. These prokaryotic organisms—nitrogen fixers—convert N_2 to ammonia (NH_3). There are relatively few species of nitrogen fixers, and their biomass is small relative to the mass of other organisms that depend on them for survival on Earth. This talented group of prokaryotes is just as essential to the biosphere as are the photosynthetic autotrophs.

Nitrogen fixers make all other life possible

By far the greatest share of total world nitrogen fixation is performed biologically by nitrogen-fixing organisms, which fix approximately 170 million Mg (megagrams, metric tons) of nitrogen per year. About 80 million Mg is fixed industrially by humans. A smaller amount of nitrogen is fixed in the atmosphere by nonbiological means such as lightning, volcanic eruption, and forest fires. Rain brings these atmospherically formed products to the ground.

Several groups of bacteria fix nitrogen. In the oceans, various photosynthetic bacteria, including cyanobacteria, fix nitrogen. In fresh water, cyanobacteria are the principal nitrogen fixers. On land, free-living soil bacteria make some contribution to nitrogen fixation, but they fix only what they need for their own use and release the fixed nitrogen only when they die. Other nitrogen-fixing bacteria live in close association with plant roots. They release up to 90 percent of the nitrogen they fix to the plant and excrete some amino acids into the soil, making nitrogen immediately available to other organisms.

Bacteria of the genus *Rhizobium* fix nitrogen only in close association with the roots of plants in the legume family (Figure 36.6). The legumes include peas, soybeans, clover, alfalfa, and many tropical shrubs and trees. The bacteria infect the plant's roots, and the roots develop nodules in re-

36.6 Root Nodules

Large, round, tumorlike nodules are visible in the root system of a broad bean. These nodules house nitrogen-fixing bacteria.

Response to their presence. The various species of *Rhizobium* show a fairly high specificity for the species of legume they infect. Farmers and gardeners coat legume seeds with *Rhizobium* to make sure the bacteria are present. Some farmers alternate their crops, planting clover or alfalfa occasionally to increase the available nitrogen content of the soil.

The legume-*Rhizobium* association is not the only bacterial association that fixes nitrogen. Some cyanobacteria fix nitrogen in association with fungi in lichens or with ferns, cycads, or nontracheophytes. Rice farmers can increase crop yields by growing the water fern *Azolla*, with its symbiotic nitrogen-fixing cyanobacterium, in the flooded fields where rice is grown. Another group of bacteria, the filamentous actinomycetes, fix nitrogen in association with root nodules on woody species such as alder and mountain lilacs.

How does biological nitrogen fixation work? In the four sections that follow, we'll consider the role of the enzyme nitrogenase, the mutualistic collaboration of plant and bacterial cells in root nodules, the need to supplement biological nitrogen fixation in agriculture, and the contributions of plants and bacteria to the global nitrogen cycle.

Nitrogenase catalyzes nitrogen fixation

Nitrogen fixation is the reduction of nitrogen gas. It proceeds by the stepwise addition of three pairs of hydrogen atoms (Figure 36.7). In addition to N_2 , these reactions require a strong reducing agent to transfer hydrogen atoms to nitrogen and the intermediate products, as well as a great deal of energy, which is supplied by ATP. Depending on the species of nitrogen fixer, either respiration or photosynthesis

Q Under anaerobic conditions, the enzyme nitrogenase binds a molecule of nitrogen gas.

Substrate: Nitrogen gas, N_2

^

^|The nitrogen is reduced by the addition of three successive pairs of hydrogen atoms.

Throughout the chemical reactions of nitrogen fixation, the reactants are bound to the enzyme nitrogenase. A reducing agent

transfers hydrogen atoms to nitrogen, and eventually the final product—ammonia—is released.

sis may provide both the necessary reducing agent and ATP. The reactants are firmly bound to the surface of a single enzyme, called nitrogenase.

Nitrogenase is so strongly inhibited by oxygen (O_2) that its discovery was delayed because investigators had not thought to seek it under anaerobic conditions. Because nitrogenase cannot function in the presence of oxygen, it is not surprising that many nitrogen fixers are anaerobes. Legumes respire aerobically, as do *Rhizobium*. Within a root nodule, oxygen is maintained at a level sufficient to support respiration but not so high as to inactivate nitrogenase.

Some plants and bacteria work together to fix nitrogen

The legume nodule provides an excellent example of symbiosis, in which two different organisms live in physical contact. In the form of symbiosis called mutualism, both organisms benefit from their relationship. The legume obtains fixed nitrogen from the bacterium, and the bacterium obtains the products of photosynthesis from the plant. Neither free-living *Rhizobium* species nor uninfected legumes can fix nitrogen. Only when the two are closely associated in root nodules does the reaction take place.

The establishment of this symbiosis between *Rhizobium* and a legume requires a complex series of steps, with active contributions by both the bacteria and the plant root (Figure 36.8). First the root releases flavonoids and other chemical signals that attract the *Rhizobium* to the vicinity of the root. Flavonoids trigger the transcription of bacterial nod genes, which encode Nod (nodulation) factors. These factors, secreted by the bacteria, cause cell divisions in the root cortex, leading to the formation of a primary nodule meristem. Within the nodules, the bacteria take the form of bacteroids within membranous vesicles. Bacteroids are swollen, deformed bacteria that can fix nitrogen.

Before the bacteroids can begin to fix nitrogen, the plant must produce the protein leghemoglobin, which sur-

rounds the bacteroids. Leghemoglobin is a close relative of hemoglobin, the oxygen-carrying pigment of animals. Some plant nodules contain enough of it to be bright pink when viewed in cross section. Leghemoglobin, with its iron-containing heme, transports oxygen to the bacteroids to support their respiration.

The partnership between bacterium and plant in nitrogen-fixing nodules is not the only case in which plants depend on other organisms for assistance with their nutrition. Another example that we considered earlier is that of mycorrhizae, root-fungus associations in which the fungus greatly increases the absorption of water and minerals (especially phosphorus) by the plant (see Figure 30.16). A growing body of evidence suggests that nodule formation depends on some of the same genes and mechanisms that allow mycorrhizae to develop.

Biological nitrogen fixation does not always meet agricultural needs

Bacterial nitrogen fixation is not sufficient to support the needs of agriculture. Traditional farmers used to plant dead fish along with corn so that the decaying fish would release fixed nitrogen that the developing corn could use. Industrial nitrogen fixation is becoming ever more important to world agriculture because of the degradation of soils and the need to feed a rapidly expanding population. Research on biological nitrogen fixation is being vigorously pursued, with commercial applications very much in mind.

Most industrial nitrogen fixation is done by a chemical process called the Haber process, which requires a great deal of energy. An alternative is urgently needed because of the cost of energy. At present, the manufacture of nitrogen-containing fertilizer takes more energy than does any other aspect of crop production in the United States.

One line of investigation centers on recombinant DNA technology as a means of engineering new plants that produce their own nitrogenase. Workers in many industrial

and academic laboratories are attempting to insert bacterial genes coding for nitrogenase into the cells of angiosperms, particularly crop plants. Developing crops that can fix their own nitrogen, however, will take more than just the insertion of genes for nitrogenase. Biotechnology must also find ways to exclude O_2 and obtain strong reducing agents and an energy source. Ultimately, the need for ATP represents a greater technical challenge than the insertion of nitrogenase genes. The stakes, however—especially the financial ones—are high, and a huge amount of effort is being invested in research along these lines.

Plants and bacteria participate in the global nitrogen cycle

The reduced nitrogen released into the soil by nitrogen fixers is primarily in the form of ammonia (NH_3) and ammonium ions (NH_4^+). Although ammonia is toxic to plants, ammonium ions can be taken up safely at low concentrations. Soil bacteria called nitrifiers, which we described in chapter 26, oxidize ammonia to nitrate ions (NO_3^-)—an-

other form that plants can take up—by the process of nitrification. Soil pH affects uptake: Nitrate ions are taken up preferentially under more acidic conditions, ammonium ions under more basic ones.

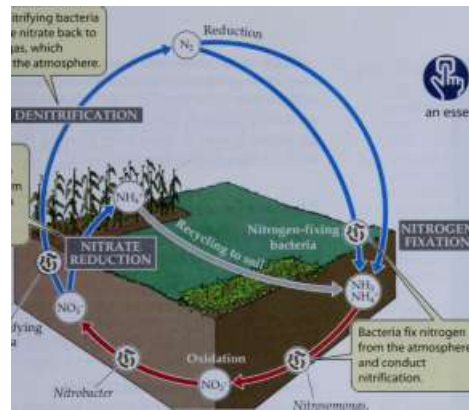

The steps that we have followed so far are carried out by bacteria: N_2 is reduced to ammonia in nitrogen fixation and ammonia is oxidized to nitrate in nitrification. The next steps are carried out by plants, which reduce the nitrate they have taken up all the way back to ammonia (Figure 36.9). All the reactions of nitrate reduction are carried on by the plant's own enzymes. The later steps, from nitrite (NO_2^-) to ammonia, take place in the chloroplasts, but this conversion is not part of photosynthesis. The plant uses the ammonia thus formed to manufacture amino acids, from which the plant's proteins and all its other nitrogen-containing compounds are formed. Animals cannot reduce nitrogen, and they depend on plants to supply them with reduced nitrogenous compounds.

Bacteria called denitrifiers return nitrogen from animal wastes and dead organisms to the atmosphere as N_2 . This process, described in Chapter 26, is called denitrification.

Some denitrifying bacteria can reduce nitrate back to nitrogen gas, which returns to the atmosphere.

Plants reduce nitrates back into ammonia, the form in which nitrogen is incorporated into proteins.

Denitrifying bacteria

Nitrobacter

HiWaWftiWI

Nitrosomonas, Nitrosococcus

In combination with leaching and the removal of crops, it keeps the level of available nitrogen in soils low.

Nitrogen metabolism, in bacteria and in plants, is complex. It is also of great importance: Nitrogen-containing compounds constitute 5 to 30 percent of a plant's total dry weight. The nitrogen content of animals is even higher, and all the nitrogen in the animal world arrives there by way of the plant kingdom.

Sulfur Metabolism

All living things require sulfur, which is a constituent of two amino acids, cysteine and methionine, and hence of almost all proteins. Sulfur is also a component of other biologically crucial compounds, such as coenzyme A. Animals must obtain their cysteine and methionine from plants, but plants can make their own, using sulfate ions obtained from the soil or from a liquid environment.

Except for oxygen, all of the most abundant elements in plants are taken up from the environment in their most oxidized forms—sulfur as sulfate, carbon as carbon dioxide, nitrogen as nitrate, phosphorus as phosphate, and hydrogen as water. In plants, sulfate is reduced and incorporated into cysteine. From this amino acid all the other sulfur-containing compounds in the plant are made. Sulfate reduction and the utilization of cysteine are analogous to the reduction of nitrate to ammonia and the subsequent utilization of ammonia by plants.

Heterotrophic and Carnivorous Seed Plants

Thus far in this chapter we have considered the mineral nutrition of plants. As you already know, another crucial aspect of plant nutrition is photosynthesis—the principal

PLANT NUTRITION 643

36.9 The Nitrogen Cycle

Nitrogen fixation, nitrification, nitrate reduction, and denitrification are the components of an essential chemical cycle.

source of energy and carbon for plants themselves and for the biosphere as a whole. Not all plants, however, are photosynthetic autotrophs. A few, in the course of their evolution, have lost the ability to sustain themselves by photosynthesis. How do these plants get their energy and carbon?

A few plants are parasites that obtain their food directly from the living bodies of other plants. Perhaps the most familiar parasitic plants are the mistletoes and dodders (Figure 36.10). Mistletoes are green and carry on some photosynthesis, but they parasitize other plants for water and mineral nutrients and may derive photosynthetic products from them as well. Mistletoes and dodders extract nutrients from the vascular tissues of their hosts by forming absorptive organs called haustoria, which invade the host plant's tissue. Another parasitic plant, the Indian pipe, once was thought to obtain its food from dead organic matter. It is

Bacteria fix nitrogen from the atmosphere and conduct nitrification.

Sundews trap insects on their sticky hairs. Secreted enzymes will digest the carcasses externally.

now known to get its nutrients, with the help of fungi, from nearby actively photosynthesizing plants. Hence it too is a parasite.

Some other plants that do not live by photosynthesis alone are the 450 or so carnivorous species—those that augment their nitrogen and phosphorus supply by capturing and digesting flies and other insects (Figure 36.11; also shown at the start of this chapter). The best-known carnivorous plants are Venus flytraps (genus *Dionaea*), sundews (genus *Drosera*), and pitcher plants (genus *Sarracenia*).

Carnivorous plants are normally found in boggy regions where the soil is acidic. Most decay-causing organisms require a less acidic pH to break down the bodies of dead organisms, so relatively little nitrogen is recycled into these acidic soils. Accordingly, the carnivorous plants have adaptations that allow them to augment their supply of nitrogen by capturing animals and digesting their proteins.

Sarracenia produces pitcher-shaped leaves that collect small amounts of rainwater. Insects are attracted into the pitchers either by bright colors or by scent and are prevented from getting out again by stiff, downward-pointing hairs. The insects eventually die and are digested by a combination of enzymes and bacteria in the water. Even rats have been found in large pitcher plants.

Sundews have leaves covered with hairs that secrete a

clear, sticky, sugary liquid. An insect touching one of these

hairs becomes stuck, and more hairs curve over the insect

and stick to it as well. The plant secretes enzymes to digest

insect and later absorbs the carbon- and nitrogen-

; products of digestion.

None of the carnivorous plants must feed on insects. They grow adequately without insects, but in their natural habitats they grow faster and are a darker green when they succeed in catching insects. The additional nitrogen from the insects is used to make more proteins, chlorophyll, and other nitrogen-containing compounds.

Chapter Summary

The Acquisition of Nutrients

- ▶ Plants are photosynthetic autotrophs that can produce all the compounds they need from carbon dioxide, water, and minerals, including a nitrogen source. They obtain energy from sunlight, carbon dioxide from the atmosphere, and nitrogen-containing ions and mineral nutrients from the soil.
- ▶ Plants explore their surroundings by growing rather than by locomotion.

Mineral Nutrients Essential to Plants

- ▶ Plants require 14 essential mineral elements, all of which come from the soil. Several essential elements fulfill multiple roles. Review Table 36.1
- ▶ The six mineral nutrients required in substantial amounts are called macronutrients; the eight required in much smaller amounts are called micronutrients. Review Table 36.1
- ▶ Deficiency symptoms suggest what essential element a plant lacks. Review Table 36.2
- ▶ Biologists discovered the essentiality of each mineral nutrient by growing plants on nutrient solutions lacking the test element. Review Figure 36.2

Soils and Plants

- ▶ Soils are complex in structure, with living and nonliving components. They contain water, gases, and inorganic and organic substances. They typically consist of two or three horizontal zones called horizons. Review Figures 36.3, 36.4, and Table 36.3
- ▶ Soils form by mechanical and chemical weathering of rock.
- ▶ Plants obtain some mineral nutrients by ion exchange between the soil solution and the surface of clay particles. Review Figure 36.5
- ▶ Farmers use fertilizer to make up for deficiencies in soil mineral nutrient content, and they apply lime to raise low soil pH.
- ▶ Plants affect soils in various ways, helping them form, adding material such as humus, and removing nutrients (especially in agriculture).

Nitrogen Fixation

- ▶ A few species of soil bacteria are responsible for almost all nitrogen fixation. Some nitrogen-fixing bacteria live free in the soil; others live symbiotically as bacteroids within the roots of plants.
- ▶ In nitrogen fixation, nitrogen gas (N_2) is reduced to ammonia (NH_3) or ammonium ions (NH_4^+) in a reaction catalyzed by nitrogenase. Review Figure 36.7
- ▶ Nitrogenase requires anaerobic conditions, but the bacteroids in root nodules require oxygen for their respiration. Leghemoglobin helps maintain the oxygen supply to the bacteroids.
- ▶ The formation of a nodule requires an interaction between the root system of a legume and Rhizobium bacteria. Review Figure 36.8

PLANT NUTRITION 645

- ▶ Nitrogen-fixing bacteria reduce atmospheric N_2 to ammonia, but most plants take up both ammonium ions and nitrate ions. Nitrifying bacteria oxidize ammonia to nitrate. Plants take up nitrate and reduce it back to ammonia, a feat of which animals are incapable. Review Figure 36.9
- ▶ Denitrifying bacteria return N_2 to the atmosphere, completing the biological nitrogen cycle. Review Figure 36.9

Sulfur Metabolism

- ▶ Plants take up sulfate ions and reduce them, forming the amino acids cysteine and methionine. Cysteine is the major precursor for other sulfur-containing compounds in plants and in animals, which must obtain their organic sulfur from plants.

Heterotrophic and Carnivorous Seed Plants

- ▶ A few heterotrophic plants are parasitic on other plants.

- Carnivorous plant species are autotrophs that supplement their nitrogen supply by feeding on insects.

For Discussion

1. Methods for determining whether a particular element is essential have been known for more than a century. Since these methods are so well established, why was the essentiality of some elements discovered only recently?
2. If a Venus flytrap were deprived of soil sulfates and hence made unable to synthesize the amino acids cysteine and methionine, would it die from lack of protein?
3. Soils are dynamic systems. What changes might result when land is subjected to heavy irrigation for agriculture after being relatively dry for many years? What changes in the soil might result when a virgin deciduous forest is cut down and replaced by crops that are harvested each year?
4. We mentioned that important positively charged ions are held in the soil by clay particles, but other, equally important, negatively charged ions are leached deeper into the soil's B horizon. Why doesn't leaching cause an electrical imbalance in the soil? (Hint: Think of the ionization of water.)
5. The biosphere of Earth as we know it depends on the existence of a few species of nitrogen-fixing prokaryotes. What do you think might happen if one of these species were to become extinct? If all of them were to disappear?

37

^J I Plant Growth Regulation

More than a century ago, Charles Darwin and his son studied the growth of plant shoots toward the light. Their findings, which we will detail in this chapter, pointed the way to the eventual discovery of the photoreceptor molecules that capture light signals and the hormones that transmit those signals to other parts of the plant. Light and hormones affect processes in plants as diverse as stem growth, flowering, bud dormancy, and the dropping of leaves in autumn. Several of the hormones now find important commercial applications, including the regulation of fruit ripening and enhanced germination of barley for the brewing industry.

Recent advances in understanding plant development have come largely from work with *Arabidopsis thaliana*, a little mustard-like weed. This plant is useful to researchers because its body and seeds are tiny, and its genome is unusually small for a flowering plant. It also flowers and forms seeds in a relatively short time after growth begins. *Arabidopsis* mutants with altered developmental patterns provide evidence for the existence of hormones and for the mechanisms of hormone and photoreceptor action.

In this chapter we first give a brief overview of the life of a flowering plant and its developmental stages. We explore the environmental cues, photoreceptors, and hormones that regulate plant development, and consider the multiple roles that each plays in normal development.

Interacting Factors in Plant Development

The development of a plant—the series of progressive changes that take place throughout its life—is regulated in complex ways. Four factors take part in this regulation:

- The plant senses and responds to environmental cues.
- The plant's genome encodes enzymes that catalyze the biochemical reactions of development, including the ones that make hormones and receptors, produce chemical building blocks, and participate in protein synthesis and energy metabolism.
- In order to sense environmental cues, the plant uses receptors, such as photoreceptors that absorb light.
- Chemical messages, or hormones, mediate the effects of the environmental cues sensed by the receptors.

Several hormones and photoreceptors regulate plant growth

Hormones are regulatory compounds that act at very low concentrations at sites distant from where they are produced. They mediate many developmental phenomena in plants, such as stem growth and autumn leaf fall. Unlike

Catching Some Rays

Most of us have observed the manner in which plants turn toward sunlight. Light signals caught by photoreceptor proteins are transmitted by hormones to other parts of the plant in a finely tuned developmental dance.

Salicylic acid Systemin

Maintains seed dormancy and winter dormancy; closes stomata

Promotes stem elongation, adventitious root initiation, and fruit growth; inhibits lateral bud outgrowth and leaf abscission

Promote elongation of stems and pollen tubes; promote vascular tissue differentiation

Inhibit leaf senescence; promote cell division and lateral bud outgrowth; affect root growth

Promotes fruit ripening and leaf abscission; inhibits stem elongation and gravitropism

Promote seed germination, stem growth, and fruit development; break winter dormancy; mobilize nutrient reserves in grass seeds

Trigger defenses against pathogens and herbivores

Trigger defenses against pathogens; limit effects of high auxin concentrations; regulate cell differentiation

Triggers resistance to pathogens

Causes jasmonate production in response to tissue damage

animals, which produce each hormone in a specific part of the body, plants produce hormones in many of their cells. Each plant hormone plays multiple regulatory roles, affecting several different aspects of development (Table 37.1). Interactions among the hormones are often complex.

Like hormones, photoreceptors regulate many developmental processes in plants. Unlike the hormones, which are small molecules, plant photoreceptors are proteins. Light (an environmental cue) acts directly on photoreceptors, which in turn regulate processes such as the many changes accompanying the growth of a young plant out of the soil and into the light.

No matter what cues direct development, ultimately the plant's genome determines the limits within which the plant and its parts will develop. The genome encodes the master plan, but its interpretation depends on conditions in the environment. It is also the target for some hormone actions. For several decades hormones and photoreceptors were the focus of most work on plant development, but recent advances in molecular genetics allow us to focus on underlying processes such as signal transduction pathways.

Signal transduction pathways mediate hormone and photoreceptor action

We introduced the topic of signal transduction pathways in Chapter 15. Plants, like other organisms, make extensive use of these pathways. Cell signaling in plant development involves three steps: a receptor (for a hormone or for light), a signal transduction pathway, and the ultimate cellular response (see Figure 15.3). Protein kinase cascades amplify responses to receptor binding in plants, as they do in other organisms (see Figure 15.11). The signal transduction pathways of plants differ from those of animals only in the details; for example, their protein kinases

phosphorylate the amino acid residues serine or threonine but not tyrosine.

Before concerning ourselves with molecular details, let's set a broader context. What is the general pattern of plant

development?

From Seed to Death: An Overview of Plant Development

Let's review the life history of a flowering plant, from seed to death, focusing on how the developmental events are regulated. As plants develop, environmental cues, photoreceptors, and hormones affect three fundamental processes: cell division, cell expansion, and cell differentiation.

The seed germinates and forms a growing seedling

All developmental activity may be suspended in a seed, even when conditions appear to be suitable for its growth. In other words, a seed may be dormant. Typically, only 5 to 20 percent of a seed's weight is water, whereas most plant parts contain far more water.

Cells in dormant seeds do not divide, expand, or differentiate. For the embryo to begin developing, seed dormancy must be broken by one of several physical mechanisms, such as exposure to light, mechanical abrasion, fire, or leaching of inhibitors by water.

As the seed germinates (begins to develop), it first imbibes (takes up) water. The growing embryo must then obtain building blocks—monomers—for its development by digesting the polysaccharides, fats, and proteins stored in the cotyledons or in the endosperm. The embryos of some plant species secrete hormones that direct the mobilization of these reserves.

If the seed germinates underground, the new seedling must elongate rapidly and cope with life in darkness or dim

648 CHAPTER THIRTY-SEVEN

^

Dormancy may be overcome by abrasion, fire, light, leaching of inhibitors, or gibberellins.

Hormones and photoreceptors regulate seedling development.

37.1 From Seed to Seedling

Environmental factors, hormones, and photoreceptors regulate the first stages of plant growth.

light. A photoreceptor controls this stage, and ends it when the shoot is exposed to sufficient light to begin photosynthesis (Figure 37.1).

Early shoot development varies among the flowering plants. Figure 37.2 presents the distinctive shoot development patterns of monocots and eudicots. Plant growth from seedling to adult, both in darkness and in light, also involves several hormones.

The plant flowers and sets fruit

Flowering—the formation of reproductive organs—may be initiated when the plant reaches an appropriate age or size.

(a) Monocots

Q A coleoptile covers the early shoot of corn and other monocots, protecting it as the shoot grows to the soil surface.

(b) Eudicots (bean)

Some plant species, however, flower at particular times of the year, meaning that the plant must sense the appropriate time. In these plants, the leaves measure the length of the night (shorter in summer, longer in winter) with great precision. Light absorbed by photoreceptors affects this time-measuring process.

Once a leaf has determined that it is time for the plant to flower, that information must be transported as a signal to the places where flowers will form. The means by which this signal is transmitted remains a mystery, but it is likely that a "flowering hormone" travels from the leaf to the point of flower formation.

After flowers form, hormones play further roles. Hormones and other substances control the growth of a pollen tube down the style of a pistil. Following fertilization, a fruit develops and ripens under hormonal control (Figure 37.3).

The plant senesces and dies

Some plants, known as perennials, continue to grow year after year. Many perennials have buds that enter a state of winter dormancy during the cold season. A hormone called abscisic acid helps maintain this dormancy.

In many species, leaves senesce (deteriorate because of aging) and fall at the end of the growing season, shortly before the onset of the severe conditions of winter. Leaf fall (abscission) is regulated by an interplay of the hormones ethylene and auxin. Finally, the entire plant senesces and dies.

fc 37.2 Patterns of Early Shoot Development

(a) In grasses and some other monocots, growing shoots are protected by a coleoptile until they reach the surface. (b) In most eudicots, the growing point of the shoot is protected by the cotyledons, (c) In some other eudicots, the cotyledons remain in the soil, and the growing point is protected by the first true leaves.

(c) Eudicots (pea)

Q The shoot apex of most eudicots, such as the bean shown here, is protected by the cotyledons as the upper part of the plant is pulled through the soil by the elongating hypocotyl.

Q When the epicotyl elongates, the first foliage leaves emerge.

Coleoptile

Seed coat

Q In other eudicots, such as peas, the shoot apex is pulled up as the bent epicotyl elongates.

Epicotyl Hypocotyl

Q After the shoot emerges from the soil, it pierces the surrounding coleoptile and grows out.

37.3 Flowering and Fruit Formation

Environmental cues, photoreceptors, and hormones regulate plant reproduction.

Death, which may be initiated by signals from the environment, follows senescent changes that are controlled by hormones such as ethylene. This life history pattern appears to be an adaptation for producing more offspring by pumping energy (food) and nutrients into the seeds; in so doing, the parent plant essentially starves itself to death.

We have reached the end of the plant's life history. Now let's examine how the various steps are regulated. We'll begin with regulation at the start of the life history—the seed and its germination.

Ending Seed Dormancy and Beginning Germination

The seeds of some species are, in effect, instant plants: All they need for germination is water. But many other species have seeds whose germination is regulated in more complex ways.

Seed dormancy may last for weeks, months, years, or even centuries. The mechanisms of dormancy are numerous and diverse, but three principal strategies dominate:

- ▶ Exclusion of water or oxygen from the embryo by means of an impermeable seed coat
- ▶ Mechanical restraint of the embryo by means of a tough seed coat
- ▶ Chemical inhibition of embryo development

The dormancy of seeds with impermeable coats can be broken if the seed coat is abraded as the seed tumbles across the ground or through creek beds, or passes through the digestive tract of an animal. Soil microorganisms probably play a major role in softening seed coats. Fire can release mechanical restraint. It can also melt wax in seed coats, removing the waterproofing and allowing water to reach the embryo (Figure 37.4). Leaching —prolonged exposure to water—is one way to reduce the level of a water-soluble chemical inhibitor and end dormancy. Scorching of seeds by fire can also break down some inhibitors.

PLANT GROWTH REGULATION 649

Seed dormancy affords adaptive advantages

What are the potential advantages of seed dormancy? For many species, dormancy assures survival through unfavorable

conditions and results in germination when conditions are more favorable. To avoid germination in the dry days of late summer, for example, some seeds must be exposed to a long cold period before they will germinate. Other seeds will not germinate until a certain amount of time has passed, regardless of how they are treated. This strategy prevents germination while the seed of a cereal grain, for example, is still attached to the parent plant.

Seeds that must be scorched by fire in order to germinate avoid competition by germinating only when an area has been cleared by fire. Light-requiring seeds, which germinate only at or near the surface of the soil, are generally tiny seeds with few food reserves. Conversely, germination of some seeds is inhibited by light; these seeds germinate only when buried and thus kept in darkness. Light-inhibited seeds are usually large and well stocked with nutrients.

Seed dormancy helps annual plants counter the effects of year-to-year variation in the environment. The seeds of some annuals remain dormant throughout an unfavorable year. The seeds of other plants germinate at different times

37.4 Fire and Seed Germination

This fireweed germinated and flourished after a great fire along the Alaska Highway.

650 CHAPTER THIRTY-SEVEN

37.5 Leaching of Germination Inhibitors

The seeds of the cypress, a swamp-adapted tree, germinate only after being leached by water, which increases the chances that they will germinate in a situation suitable for their growth.

during the year, increasing the likelihood that at least some of the seedlings will encounter favorable conditions.

Dormancy may also increase the likelihood of a seed's germinating in the right place. Some cypress trees, for example, grow in standing water, and their seeds germinate only if inhibitors are leached by water (Figure 37.5).

Seed germination begins with the uptake of water

The first step in seed germination is the uptake of water, called imbibition. A seed's water potential (see Chapter 35) is very negative, and water can be taken up readily if the seed coat allows it. The magnitude of this water potential is demonstrated by the force exerted by seeds expanding in water. Cocklebur seeds that are imbibing can exert a pressure of up to 1,000 atmospheres (about 100 megapascals) against a restraining force.

As a seed takes up water, it undergoes metabolic changes: Certain existing enzymes become activated, RNA and then proteins are synthesized, the rate of cellular respiration increases, and other metabolic pathways become activated. In many seeds there is no DNA synthesis and no cell division during these early stages of germination. Initially, growth results solely from the expansion of small, preformed cells. DNA is synthesized only after the embryonic root, called the radicle, begins to

grow and poke out beyond the seed coat (Figure 37.6).

The embryo must mobilize its reserves

Until the young plant (the seedling) becomes able to photo-synthesize, it depends on reserves stored in the endosperm or cotyledons. The principal reserve of energy and carbon

Radicle

37.6 The Radicle Emerges

The tip of this barley seed's radicle has just broken through its protective sheath. The appearance of the radicle—the embryonic root—is one of the first externally visible events in seed germination.

in many seeds is starch. Other seeds store fats or oils. Usually, the endosperm of the seed holds amino acid reserves in the form of proteins, rather than as free amino acids.

The giant molecules of starch, lipids, and proteins must be digested by enzymes into monomers that can enter the cells of the embryo. The polymer starch yields glucose for energy metabolism. The digestion of reserve proteins provides the amino acids the embryo needs to synthesize its own proteins. The digestion of lipids releases glycerol and fatty acids, both of which can be metabolized for energy. Glycerol and fatty acids can also be converted to glucose, which permits fat-storing plants to make all the building blocks they need for growth.

In germinating barley and other cereal seeds, the embryo secretes gibberellins, one of several classes of plant growth hormones. Gibberellins diffuse through the endosperm to a surrounding tissue called the aleurone layer, which lies inside the seed coat. The gibberellins trigger a crucial series of events in the aleurone layer, culminating in the release of enzymes that digest proteins and starch stored in the endosperm (Figure 37.7). Commercially, gibberellins are used in the brewing industry to enhance the "malting" (germination) of barley and the breakdown of its endosperm, producing sugar that is fermented to alcohol.

Gibberellins: Regulators from Germination to Fruit Growth

Gibberellins produce a wide variety of effects on plant development in addition to triggering digestive enzyme synthesis. We begin our discussion of the different plant growth hormones by discussing the discovery of the gibberellins, as well as their many effects.

Fruit and seed coat

Aleurone layer

Endosperm (with stored reserves)

Embryo

Nutrients

H₂O

The embryo imbibes H₂O and swells.

The embryo secretes gibberellins that diffuse into the aleurone layer and trigger the digestion of proteins to amino acids.

From the amino acids, digestive enzymes are synthesized; and the enzymes, along with other enzymes from the aleurone,

move into the endosperm.

The enzymes digest the reserve polymers in the endosperm, releasing monomers—nutrients from which the embryo synthesizes new cells.

37.7 Embryos Mobilize Polymer Reserves

Seed germination in cereal grasses consists of a cascade of processes. Gibberellins trigger the conversion of reserve polymers into monomers that can be used by the developing embryo.

Foolish seedlings led to the discovery of the gibberellins

The gibberellins are a large family of closely related compounds. Some are found in plants and others in a pathogenic (disease-causing) fungus, where they were first discovered.

HO

HO

CH₃

COOH

COOH

Gibberellin A1

(important in stem growth)

Gibberellin A3 (commercially available)

In 1809, the study of the gibberellins began indirectly with observations of the bakanae, or "foolish seedling," disease of rice. Seedlings affected by this disease grow tall more rapidly than their healthy neighbors, but this rapid growth gives rise to spindly plants that die before producing seed (the rice grain used for food). The disease has had considerable economic impacts in several parts of the world. It is caused by the ascomycete fungus *Gibberella fujikuroi*.

In 1925, the Japanese biologist Eiichi Kurosawa grew *G. fujikuroi* on a liquid medium, then separated the fungus from the medium by filtering. He heated the filtered medium to kill any remaining fungus, but the resulting heat-treated filtrate still caused rapid growth in rice seedlings. Medium that had never contained the fungus did not stimulate seedling growth. This experiment established that *G. fujikuroi* produces a growth-promoting chemical substance, which Kurosawa called a gibberellin.

Were the gibberellins simply exotic products of an obscure fungus, or did they play a more general role in the

growth of plants? Bernard O. Phinney of the University of California, Los Angeles, answered this question in part in 1956, when he reported the spectacular growth-promoting effect of gibberellins on dwarf corn seedlings. He used plants that were known to be genetic dwarfs; each phenotype was produced when a particular recessive allele (say, *dl*) was present in the homozygous condition (*dl/dl*). Gibberellins applied to nondwarf—normal—corn seedlings had almost no effect, but gibberellins applied to the dwarfs caused them to grow as tall as their normal relatives. (A comparable effect of gibberellins applied to a dwarf tomato plant is shown in Figure 37.8.)

22 days after being sprayed with a tiny amount of gibberellin, this plant reached the size of a nondwarf plant

37.8 The Effect of Gibberellins on Dwarf Plants

In this experiment, the effect of gibberellins was tested on two dwarf tomato plants. Both plants were the same size when the one on the right was treated with gibberellins.

652 CHAPTER THIRTY-SEVEN

,-j'i

This result suggested to Phinney (1) that gibberellins are normal constituents of corn, and perhaps of all plants, and (2) that dwarf plants are short because they cannot produce their own gibberellins. According to Phinney's hypothesis, nondwarf plants manufacture enough gibberellins to promote their full growth, but dwarf plants do not. Extracts from numerous plant species were found to promote growth in dwarf corn. These findings provided direct evidence that plants that are not genetic dwarfs contain gib-berellin-like substances. Phinney's work set the stage for today's use of mutant plants to investigate the control of plant development.

The roots, leaves, and flowers of a dwarf corn plant appear normal, but the stems are much shorter than those of wild-type plants. All parts of the dwarf plant contain a much lower concentration of gibberellins than do the organs of a wild-type plant. We may infer, then, that stem elongation requires gibberellins or the products of gib-berellin action. We can further conclude that gibberellins play a less essential role in the development of roots, leaves, and flowers.

Although more than 80 gibberellins have been identified, only one, gibberellin A v actually controls stem elongation in most plants. The other gibberellins found in stems are simply intermediates in the production of gibberellin A v As we will see in the next section, gibberellins affect processes other than stem elongation, but we do not yet know which gibberellin has any other particular effect.

The gibberellins have many effects

Gibberellins and other hormones regulate the growth of fruits. It has long been known that seedless grapes (an inbred strain) form smaller fruit than their seeded relatives. Experimental removal of seeds from very young seeded grapes prevented normal fruit growth, suggesting that the seeds are sources of a fruit growth regulator. It was then shown that spraying young seedless grapes with a gibberellin solution caused them to grow as large as seeded ones. It is now a standard commercial procedure to spray seedless grapes with gibberellins. Subsequent biochemical studies showed that the developing seeds produce gibberellins, which diffuse out into the immature fruit tissue.

Some biennial plants respond dramatically to an increased level of gibberellins. Biennials grow vegetatively in their first year and flower and die in their second year. In the second year, the apical meristems of biennials respond to environmental cues by producing elongated shoots that eventually bear flowers. This elongation is called bolting. When the plant senses the appropriate environmental cue—longer days or a sufficient winter chilling—it produces more gibberellins, raising the gibberellin concentration to a level that causes the shoot to bolt. Plants of some biennial species will bolt when sprayed with a gibberellin solution without the environmental cue (Figure 37.9).

Gibberellins also cause fruit to grow from unfertilized flowers, promote seed germination in lettuce and some other species, and help bring spring buds out of winter dor-

37.9 Bolting

Spraying with gibberellins causes cabbage and some other plants to bolt.

The internodes of plants treated with gibberellin elongate dramatically, resulting in towering shoots.

Untreated control plants retain their compact, leafy heads.

With gibberellin

mancy. Most hormones have multiple effects within the plant, and they often interact with one another in regulating developmental processes. In controlling stem elongation, for example, gibberellins interact with another hormone, auxin.

Auxin Affects Plant Growth and Form

If you pinch off the apical bud at the top of a bean plant, inactive lateral buds become active, developing into branches. Similarly, pruning a shrub causes an increase in branching. If you cut off the blade of a leaf but leave its petiole (stalk) attached to the plant, the petiole drops off sooner than it would have if the leaf were intact. If a plant is kept indoors, its shoot system grows toward a window. These diverse responses of shoot systems are all mediated by a plant hormone called auxin, or indoleacetic acid (IAA).

$\text{H}_2\text{C}-\text{COOH}$

Auxin (indoleacetic acid)

In the discussions that follow, we will look at the discovery of auxin, its transport within the plant, and its role as mediator of the effects of light and gravity on plant growth. We'll discover its many effects on vegetative growth and on fruit development. Then we'll examine its mechanism of action.

Plant movements led to the discovery of auxin

The discovery of auxin and its numerous physiological effects can be traced back to work done in the 1880s by Charles Darwin and his son Francis. The Darwins were interested in plant movements. One type of movement they studied was phototropism, the growth of plant structures toward light (as in most shoots) or away from it (as in roots). They asked, What part of the plant senses the light? To answer this question, the Darwins worked with canary grass (*Phalaris canariensis*) seedlings grown in the dark. A young grass seedling has a coleoptile —a cylindrical

RESULTS

o Coleoptiles responded to light only when the tip was exposed.

Conclusion: The plant's "eye" (the part that senses light) is in the tip, and it sends a message from the tip to the region of bending.

sheath a few cells thick that protects the delicate shoot as it pushes through the soil (see Figure 37.2a). When the coleoptile breaks through the surface of the soil, it soon stops growing, and the first leaves emerge unharmed. The coleoptiles of grasses are phototropic— they grow toward the light.

To find the light-receptive region of the coleoptile, the Darwins tried "blindfolding" the coleoptiles of dark-grown canary grass seedlings in various places, then illuminating them from one side (Figure 37.10). The coleoptile grew toward the light whenever its tip was exposed. If the top millimeter or more of the coleoptile was covered, however, there was no phototropic response. Thus the tip contains the photoreceptor that responds to light. The actual bending toward the light, however, takes place in a growing region a few millimeters below the tip. Therefore, the Darwins reasoned, some type of message must travel within the coleoptile from the tip to the growing region. Others later demonstrated that the message is a chemical substance by showing that it can move through certain nonliving materials, such as gelatin, but not through others, such as a metal barrier.

Further experiments showed that the tip of the coleoptile produces a hormone that moves down the coleoptile to the growing region. If the tip is removed, the growth of the coleoptile is sharply inhibited. If the tip is carefully replaced, growth resumes, even if the tip and base are separated by a thin layer of gelatin. The hormone moves down from the tip, but it does not move from one side of the coleoptile to the other. If the tip is cut off and replaced so that it covers only one side of the cut end of the coleoptile, the coleoptile curves as the cells on the side below the replaced tip grow more rapidly than those on the other side.

The Dutch botanist Frits W. Went removed coleoptile tips and placed their cut surfaces on a block of gelatin. Then he placed pieces of the gelatin block on decapitated coleoptiles—positioned to cover only one side, just as coleoptile tips had been placed in earlier experiments (Figure 37.11). As they grew, the coleoptiles curved toward the side away from the gelatin. This curvature demonstrated that a hormone had indeed diffused into the gelatin block from the isolated coleoptile tips. Went had at last isolated a hormone from a plant. Later chemical analysis showed that this hormone, named auxin, was indoleacetic acid.

Auxin transport is polar

Since being isolated, auxin has been intensively studied. Early experiments showed that its movement through certain plant tissues is strictly polar—that is, unidirectional along a line from apex to base. By inverting some plants or plant parts, scientists determined that the apex-to-base di-

\Ttim. 37.70 The Darwins'Phototropism Experiment

The top drawings show some of the ways in which seedlings grown in the dark were "blindfolded"; the lower drawings show what the Darwins observed in each case. Their observations led them to hypothesize the existence of a growth-promoting "messenger" substance produced by the coleoptile.

Question: Can a growth hormone be isolated from the coleoptile tip?

METHOD

RESULT

The tip is removed and placed on gelatin.

The gelatin is placed on one edge of another decapitated coleoptile.

The coleoptile curves away from the gelatin as it grows.

Oat coleoptile

Conclusion: A growth hormone diffused from the tip into the gelatin, and from the gelatin into another plant. It had an effect on the growth of the plants similar to that of a coleoptile tip.

37.77 Went's Experiment

Went succeeded in isolating the growth-promoting chemical substance whose existence the Darwins had hypothesized by placing coleoptile tips on a block of gelatin.

direction of auxin movement has nothing to do with gravity; the polarity of this movement is a totally biological matter. Many plant parts show complete or partial polarity of auxin transport. For example, in most leaf petioles auxin moves only from the blade end toward the stem end.

Auxin carrier proteins move auxin into and out of cells

In one of the most intense areas of current research on auxin, biologists are using *Arabidopsis* plants that have mutations affecting the transport of auxin. By cloning genes from these plants and characterizing their products, they are finding a growing number of auxin carrier proteins. In polar transport in the stem, a carrier protein imports auxin at the end of the cell toward the shoot apex, and it or another carrier exports auxin at the other end of the cell. Auxin carrier proteins contribute to the establishment of auxin gradients in the plant. As a result, auxin acts as a morphogen, telling cells where they lie within the plant and determining how they differentiate. There are probably auxin carrier proteins specific to different tissues and different cells, participating in different auxin responses.

Light and gravity affect the direction of plant growth

While polar auxin transport establishes the orientation of

auxin, (side-to-side) redistribution of auxin appears

! mechanism that explains both phototropism and

another response depending on differential growth, gravitropism. This redistribution may be carried out by other auxin carrier proteins.

When light strikes a coleoptile from one side, auxin at the tip moves laterally toward the shaded side. The imbalance thus established is maintained down the coleoptile, so that in the growing region below, there is more auxin on the shaded side, causing the unequal growth that results in a coleoptile bent toward the light. This bending toward light is phototropism (Figure 37.12a). If you have noticed a house plant bending and pointing toward a window, you have seen phototropism.

Even in the dark, auxin moves to the lower side of a shoot that has been tipped over, causing more rapid growth in the lower side and, hence, an upward bending of the shoot. Such growth in a direction determined by gravity is called gravitropism (Figure 37.12b). The upward gravitropic response of shoots is defined as negative; the gravitropism of roots, which bend downward, is positive.

rn

37.12 Plants Respond to Light and Gravity

Phototropism and gravitropism occur in response to a redistribution of auxin.

Auxin affects vegetative growth in several ways

Like the gibberellins, auxin has many roles in plant development. It affects the vegetative growth of plants in several ways, including:

- ▶ Initiating root growth in cuttings
- ▶ Stimulating the detachment of old leaves from their stems (abscission)
- ▶ Maintaining apical dominance
- ▶ Promoting stem elongation and inhibiting root elongation

Let's examine each of these aspects in turn.

Cuttings from the shoots of some plants can produce roots and grow into entire new plants. For this to happen, certain undifferentiated cells in the interior of the shoot, originally destined to function only in food storage, must set off on a new mission: They must differentiate and become organized into the apical meristem of a new root.

These changes are similar to those in the pericycle of a root when a lateral root forms (see Chapter 34). Shoot cuttings of many species can be stimulated to grow profuse roots by dipping the cut surfaces into an auxin solution; this observation suggests that the plant's own auxin plays a role in the initiation of lateral roots. Commercial preparations that enhance the rooting of plant cuttings typically contain mostly synthetic auxins.

The effect of auxin on the detachment of old leaves from stems is quite different from root initiation. This process, called abscission, is the cause of autumn leaf fall. Leaves consist of a blade and a petiole that attaches the blade to the stem. Abscission results from the breakdown of a specific part of the petiole, the abscission zone (Figure 37.13). If the blade of a leaf is cut off, the petiole falls from the plant more rapidly than if the leaf had remained intact. If the cut surface is treated with an auxin solution, however, the petiole remains attached to the plant, often longer than an intact leaf would have (Figure 37.14). The time of abscission of leaves in nature appears to be determined in part by a decrease in the movement of auxin, produced in the blade, through the petiole.

37.7 3 When a Leaf Is About to Fall

The breakdown of the abscission zone of the petiole causes the leaf to fall.

∴**

m^o^-

Abscission zone

EXPERIMENT

Question: How does auxin affect leaf abscission?

METHOD

RESULTS

The leaf blade is removed.

The petiole remains on the plant.

Conclusion: Auxin inhibits leaf abscission.

37.14 Auxin and Leaf Abscission

The leaf blade is a source of auxin throughout the growing season; without auxin, the petiole falls from the plant.

Auxin maintains apical dominance, a phenomenon in which apical buds inhibit the growth of lateral buds. This phenomenon can be demonstrated by an experiment with young seedlings. If the plant remains intact, the stem elongates, and the lateral buds remain inactive. Removal of the apical bud—the major site of auxin production—permits the lateral buds to grow out vigorously. If the cut surface of the stem is treated with an auxin solution, however, the lateral buds do not grow (Figure 37.15). Apical buds of branches also exert apical dominance: The lateral buds on the branch are inactive unless the apex of the branch is removed.

In the two experiments on leaves and stems that we have just discussed, removal of a particular part of the plant produces an effect—abscission or loss of apical dominance—and that effect is prevented by treatment with auxin. These results are consistent with other data showing that the excised part of the leaf or stem is an auxin source and that auxin in the intact plant helps maintain apical dominance and delays the abscission of leaves. As we will discover later, other hormones can modify the effects of auxin. Plant

656 CHAPTER THIRTY-SEVEN

37.15 Auxin and Apical Dominance

Auxin produced by the apical bud maintains apical dominance—the growth of a single main stem with minimal branching.

EXPERIMENT

Question: What is the role of auxin in apical dominance?

In intact plants, lateral buds are inhibited by the apical bud.

After the plant is decapitated, an agar block containing no auxin is applied to the stump.

Some lateral buds grow out.

growth is regulated more by hormone interactions than by a single hormone.

Auxin promotes stem elongation, but it inhibits the elongation of roots. The question of why different organs should respond in opposite ways to the same chemical signal remains unanswered, but is a subject of current research.

Many synthetic auxins—chemical analogs of indoleacetic acid—have been produced and studied. One of them, 2,4-dichlorophenoxyacetic acid (2,4-D), has the striking property of being lethal to eudicots at concentrations that are harmless to monocots. This property made 2,4-D an effective selective herbicide that could be sprayed on a lawn or a cereal crop to kill those weeds that are eudicots. However, because 2,4-D takes a long time to break down, it pollutes the environment, so scientists are seeking new approaches to selective weed killing.

Auxin controls the development of some fruits

Although fruit development normally depends on prior fertilization of the egg, in many species treatment of an unfertilized ovary with auxin or gibberellins causes parthenocarpy—fruit formation without fertilization of the egg. Parthenocarpic fruits form spontaneously in some plants, including dandelions, seedless grapes, and cultivated bananas.

All of these activities illustrate the great diversity of important roles that auxin plays. Now let's see how auxin plays one of its roles—promoting stem elongation through effects on the cell wall.

An agar block containing auxin is applied at the time of decapitation.

The lateral buds are inhibited.

New branch

Agar block New branch

Inhibited buds

Experimental plant: No auxin Experimental plant: Auxin

Conclusion: Apical dominance results from auxin produced by the apical bud.

Auxin promotes growth by acting on cell walls

CELL WALLS ARE A KEY TO PLANT GROWTH. The principal strengthening component of the plant cell wall is cellulose, a large polymer of glucose. In the wall, cellulose molecules tend to associate in parallel with one another. Bundles of approximately 250 cellulose molecules make up microfibrils

Plant cell

37.76 Cellulose in the Cell Wall

- Plant cell wall is a net-of cellulose microfibrils linked by other polysaccharides.

The parallel microfibrils of cellulose associate in a crisscross pattern.

Polysaccharides (other than cellulose)

Three different polysaccharides, represented by strings of cones, hexagons, and ovals, help organize cellulose microfibrils in the wall.

/

that are visible with an electron microscope (Figure 37.16). What makes the cell wall rigid is a network of cellulose microfibrils connected by bridges of other, smaller polysaccharides (Figure 37.16b). The orientation of the cellulose microfibrils determines the direction of cell expansion (Figure 37.17).

The growth of a plant cell is driven primarily by the uptake of water, which enters the cytoplasm of the cell and accumulates in its central vacuole. As the vacuole expands, the cell grows rapidly, with the vacuole often making up more than 90 percent of the volume of a mature cell. As the vacuole expands, it presses the cytoplasm against the cell wall, and the wall resists this force.

For the cell to grow, its wall must loosen and be stretched. If the wall simply stretched, it would become thinner. However, new polysaccharides are deposited throughout the wall and new cellulose microfibrils are deposited at the inner surface of the wall, maintaining its thickness. Thus the cellulose microfibrils in the outermost part of the wall are the oldest, and those in the innermost part the youngest.

The cell wall plays key roles in controlling the rate and direction of growth of a plant cell. How does the plant determine the behavior of its cell walls?

Auxin loosens the cell wall. Experiments with segments of oat coleoptiles showed that plant cell walls recover incompletely from being stretched (Figure 37.18). Reversible stretching is called elasticity, and irreversible stretching is called plasticity. Pretreating the coleoptile segments with auxin significantly increased their plasticity; in other words, it loosened the cell walls. This result suggested that auxin-induced cell expansion might result from just such a loosening effect.

Auxin acts by causing the release of a "wall-loosening factor" from the cytoplasm. Studies in the 1970s indicated that the wall-loosening factor was sometimes simply hydrogen ions (protons, H^+). Acidifying the growth medium (that is, adding H^+) causes segments of stems or coleoptiles to grow as rapidly as segments treated with auxin. Furthermore, treating coleoptile segments with auxin causes acidification of the growth medium. Treatments that block acidification by auxin also block auxin-induced growth. It was suggested that hydrogen ions secreted into the cell wall as a result of auxin action might activate one or more proteins in the wall.

Proteins called expansins, isolated from plant cell walls in the 1990s, were found to cause the extension of isolated cell walls of several species. Expansins are widespread among land plants. Expansin action is pH-dependent, and the expansins appear to be activated by hydrogen ions. These proteins apparently modify hydrogen bonding between polysaccharides in the plant cell wall. The changed hydrogen bonding pattern may allow the polysaccharide macromolecules to slip past each other, so that the wall stretches and the cell expands.

37.77 Plant Cells Expand

The orientation of cellulose microfibrils in the plant's cell walls determines the direction of cell expansion.

Cellulose microfibrils encircle the cell in a specific orientation and constrain cell expansion.

The cell expands only in the direction of least resistance.

Plants contain specific auxin receptor proteins

The initial step in the action of any plant hormone is the binding of the hormone to specific receptor proteins. Several proteins can bind various plant hormones, but some of this binding may be nonspecific. It must be shown that auxin-binding proteins actually mediate the effects of auxin.

Plant molecular biologists showed that the protein ABP1 (Auxin-Binding Protein 1) functions as an auxin receptor. They inserted the ABP1 gene of Arabidopsis into other species and then induced the expression of the gene in cells that normally show a limited response to auxin. Upon expression of the inserted ABP1 gene, the cells showed

658 CHAPTER THIRTY-SEVEN

greater responses to both endogenous and applied auxin. Subsequent work has conclusively shown the existence and importance of other auxin receptor proteins. Given the number of processes regulated by auxin, it is hardly surprising that there appear to be multiple receptors and signal transduction pathways for this hormone.

Auxin and other hormones evoke differentiation and organ formation

What plant substance signals the different types of cells and organs to form? Much of the research on such questions has been done with plant tissues grown in culture outside the plant body. One easily grown tissue is pith—the spongy, innermost tissue of a stem. Pith tissue cultures proliferate rapidly, but show no differentiation. All the cells are similar and unspecialized; they grow into a lump on the surface of a culture medium.

Cutting a notch in the cultured pith tissue and inserting a stem tip into the notch causes the pith cells below the inserted tip to differentiate. Some of them differentiate to form water-conducting xylem cells. Differentiation of pith cells can also be initiated by adding to the notch a mixture of auxin and coconut milk (a rich source of plant hormones).

A similar effect can be observed in intact plants. If notches are cut in the stems of *Coleus blumei* plants, interrupting some of the strands of vascular tissue, the strands gradually regenerate from the upper side of the cut to the lower (recall that auxin moves from the tip to the base of a stem). If the leaves above the cut are removed, regeneration is slowed. However, when the missing leaves are replaced with an auxin solution, vascular tissue regenerates. Auxin and other plant hormones signal the formation of specific cell types.

Experiments with cultured tissues have helped clarify which hormones control organ formation. Undifferentiated cultures of tobacco pith form roots when treated with an appropriate concentration of auxin. Another group of hormones—the cytokinins—causes buds and then shoots to form in such cultures. The pattern of organ formation depends on the ratio of auxin to cytokinin in the medium. A high proportion of auxin favors roots, and a high proportion of cytokinins favors buds, but both processes are most active when both hormones are present.

Cytokinins Are Active from Seed to Senescence

Besides stimulating bud formation, the cytokinins promote cell division in cultured plant tissues, an activity that led to their discovery. In addition, cytokinins aid germination, inhibit stem elongation, stimulate lateral bud growth, and delay leaf senescence.

Cytokinins are derivatives of adenine. In studies of plant cell division, botanists discovered a substance that powerfully stimulated cell division in tissue cultures. This compound, kinetin, consists of adenine with an attached group. We now know that kinetin is just one of a family of com-

pounds, which are now called cytokinins. Kinetin may be considered a synthetic cytokinin, because it has never been isolated from plant tissue. However, two closely related compounds, called zeatin and isopentenyl adenine, occur naturally in plants.

.CH,

*CH₂OH

Kinetin

(a cytokinin discovered in aged DNA)

Zeatin

(a naturally occurring

cytokinin in plants)

Cytokinins form primarily in the roots and move to other parts of the plant. They have several effects:

► Adding an appropriate combination of auxin and cytokinins to a growth medium yields rapid growth of plant tissues.

- Cytokinins can cause certain light-requiring seeds to germinate when the seeds are kept in constant darkness.
- Cytokinins usually inhibit the elongation of stems, but they cause lateral swelling of stems and roots (the fleshy roots of radishes are an extreme example).
- Cytokinins stimulate lateral buds to grow into branches; thus the balance between auxin and cytokinin levels controls the bushiness of a plant.
- Cytokinins increase the expansion of cut pieces of leaf tissue, and may regulate normal leaf expansion.
- Cytokinins delay the senescence of leaves. If leaf blades are detached from a plant and floated on water or a nutrient solution, they quickly turn yellow and show other signs of senescence. If instead they are floated on a solution containing a cytokinin, they remain green and senesce much more slowly.

Ethylene: A Gaseous Hormone That Promotes Senescence

Whereas the cytokinins oppose or delay senescence, another plant hormone promotes it. This hormone is the gas ethylene, which is sometimes called the senescence hormone. Ethylene can be produced by all parts of the plant, and like all plant hormones, it has several effects.

Ethylene

(the "senescence hormone")

H

H

C=C

H

H

Back when streets were lit by gas rather than by electricity, leaves on trees near street lamps abscised earlier than those on trees farther from the lamps. We now know that ethylene, a combustion product of the illuminating gas, is what caused the abscission. Auxin delays leaf abscission, but ethylene strongly promotes it; thus a balance of auxin and ethylene controls abscission.

PLANT GROWTH REGULATION 659

Ethylene hastens the ripening of fruit

By promoting senescence, ethylene speeds the ripening of fruit. The old saying "one rotten apple spoils the barrel" is true. That rotten apple is a rich source of ethylene, which speeds the ripening and subsequent rotting of the others in the barrel. As the fruit ripens, it loses chlorophyll and its cell walls break down. Ethylene produced in the fruit tissue promotes both processes. Ethylene also causes an increase in its own production. Thus, once ripening begins, more and more ethylene forms, and because it is a gas, it diffuses readily throughout the fruit and even to neighboring fruits on the same or other plants.

Farmers in ancient times used to slash developing figs to hasten their ripening. We now know that wounding causes an increase in ethylene production by the fruit, and that the raised ethylene level promotes ripening. Today commercial shippers and storers of fruit hasten ripening by adding ethylene to storage chambers. This use of ethylene is the single most important use of a plant hormone in agriculture and commerce. Ripening can also be delayed by the use of "scrubbers" and adsorbents to remove ethylene from the atmosphere in fruit storage chambers.

As flowers senesce, their petals may abscise, to the detriment of the cut-flower industry. Florists or their suppliers often spray their flowers with dilute solutions of silver thio-sulfate. Silver salts inhibit ethylene action, probably by interacting directly with the ethylene receptor, and thus delay senescence—enabling florists to keep their wares salable longer.

Ethylene affects stems in several ways

Although associated primarily with senescence, ethylene is active at other stages of plant development as well. The stems of many eudicot seedlings form an apical hook that protects the delicate shoot apex while the stem grows through the soil (Figure 37.19). The apical hook is maintained through an asymmetrical production of ethylene gas, which inhibits the elongation of cells on the inner surface of the hook. Once the seedling breaks through the soil

surface and is exposed to light, ethylene synthesis stops, and the cells of the inner surface are no longer inhibited. These cells now elongate, and the hook opens, raising the shoot apex and expanding leaves into the sun.

37.79 The Apical Hook of a Eudicot

Asymmetrical production of ethylene is responsible for the apical hook of this seedling, which was grown in the dark.

Ethylene also inhibits stem elongation in general, promotes lateral swelling of stems (as do the cytokinins), and causes stems to lose their sensitivity to gravitropic stimulation.

The ethylene signal transduction pathway is well understood

Analysis of Arabidopsis mutants has revealed the steps in the mechanism of ethylene action. Some of these mutants do not respond to applied ethylene, and others act as if they have been exposed to ethylene even though they haven't. Studies of genes from these mutants and their protein products, coupled with comparisons of their amino acid sequences with those of other known proteins, have revealed some of the details of the signal transduction pathway through which ethylene produces its effects (Figure 37.20).

37.20 A Signal Transduction Pathway for Ethylene

This slightly simplified scheme shows the roles of four gene products (ETR1, CTR1, EIN2, and EIN3) in the signal transduction pathway through which ethylene exerts its effects.

66o CHAPTER THIRTY-SEVEN

The pathway includes two membrane proteins: The first is an ethylene receptor (ETR1), and the second is a channel (EIN2) that acts through a second messenger to activate a transcription factor that turns on genes. The resolution of this pathway has been one of the high points of plant biological research over the last 30 years.

Absciscic Acid: The Stress Hormone

Absciscic acid is another hormone that has multiple effects in the living plant. During embryo formation, absciscic acid promotes the accumulation of storage proteins in seeds by allowing the expression of the genes that encode those proteins. It is generally present in high concentrations in dormant buds and some dormant seeds, and it is the most common inhibitor of seed germination. Absciscic acid also inhibits stem elongation. It is sometimes referred to as the stress hormone of plants because it accumulates when plants are deprived of water and because of its possible role in maintaining the winter dormancy of buds.

Absciscic acid

(the "stress hormone")

COOH

Some mutant corn plants, called vp mutants, have seeds that germinate while still attached to the cob, on the intact plant—a condition called vivipary. Several vp mutants are naturally deficient in absciscic acid, and a different kind of vp mutant fails to respond in any way to applied absciscic acid. Applying absciscic acid to the absciscic acid-deficient mutants reduces their tendency to show vivipary. The results of applying absciscic acid to both kinds of mutants indicate that it is the inhibitor that normally prevents seeds from germinating on the plant rather than in the soil.

Absciscic acid also regulates gas and water vapor exchange between leaves and the atmosphere through its effects on the guard cells of the leaf stomata (see Chapter 35). Absciscic acid causes stomata to close, and it also prevents stomatal opening normally caused by light. Both of these processes involve ion channels in the plasma membrane of the guard cells. The first response of a guard cell to absciscic acid is the opening of calcium channels and the entry of calcium into the cell. This calcium causes the cell's vacuole to release calcium, too. The increased concentration of calcium leads to a chain of events that result in the opening of potassium channels and the release of K⁺ and of water, and the closing of the stoma as the guard cells sag together.

Hormones in Plant Defenses

When bacteria, viruses, or fungi attack a plant, the plant responds in several ways, as we will see in Chapter 39. One of its first responses is to release hormones called oligosaccharins. These hormones, as their name implies, are oligosaccharides—compounds consisting of a few sugar or derivative sugar units. They are actually fragments of the cell wall,

which are released when enzymes from an attacker degrade it. They act as signals that trigger the plant's defenses.

Because auxin modifies the cell wall, it is not surprising that auxin, too, causes the release of oligosaccharins. The interactions between auxin and oligosaccharins may be complex. One oligosaccharin, at an extremely low concentration, has been found to inhibit auxin-induced growth promotion. Other oligosaccharins may regulate aspects of cell differentiation.

Three other hormones— jasmonates, salicylic acid, and sys-temin —serve as important signals in plant defenses. Their activities will be discussed in Chapter 39.

Brassinosteroids: "New" Hormones with Multiple Effects

More than 20 years ago, biologists isolated an interesting steroid from the pollen of rape, a member of the Brassi-caceae, or mustard family. When applied to various plant tissues, this brassinosteroid stimulated cell elongation, pollen tube elongation, and vascular tissue differentiation, and it inhibited root elongation. Since then, dozens of chemically related and growth-affecting brassinosteroids have been found in plants. Treatment with as little as a few nanograms of brassinosteroid per plant is enough to promote growth. However, the brassinosteroids were not at first regarded as plant hormones, in part because of similarities between their effects and those of auxin.

OH CH₃,

Brassinolide

(a brassinosteroid)

HO

HO

CH₃,

The properties of an Arabidopsis mutant called det1 made it clear that brassinosteroids are naturally occurring plant hormones. When grown in darkness, seedlings homozygous for the det1 allele differ dramatically from wild-type seedlings: In many respects, they look like wild-type seedlings grown in the light. Treatment of dark-grown det1 mutant seedlings with brassinosteroids causes them to grow normally—that is, like wild-type plants grown in the dark. The det1 plants are unable to synthesize their own brassinosteroids, and the lack of the hormone results in abnormal growth.

Brassinosteroids will probably be important in agriculture. They have increased the yields of some crops in field tests. Could they also be useful for keeping some plants small? What about limiting the growth rate of lawns and the height of trees and hedges? Joanne Chory and her colleagues at the University of California, San Diego and the

Salk Institute found a way to do this. They showed that a mutation of a gene called bas-1 in Arabidopsis results in a dwarfed plant because the gene's product inactivates brassinosteroids in the stem. By introducing the bas-1 mutation into selected plants, agriculturists could produce slow-growing plants and then adjust their growth rate by treatment with brassinosteroids.

Chory and others have shown that some of the effects of light on plant development result from effects on the signal transduction pathway for brassinosteroids. Let's now look more closely at the effects of environmental cues such as light.

Light and Photoreceptors

The length of the night determines the onset of winter dormancy. As summer wears on, the days become shorter (that is, the nights become longer). Leaves have a mechanism for measuring the length of the night, as we will see in the next chapter. Measuring night length is an accurate way to determine the season of the year. If a plant determined the season by the temperature, it could be fooled by a winter warm spell or by unseasonably cold weather in the summer. The length of the night, on the other hand, is determined by Earth's rotation around the sun and does not vary. Plants use the environmental cue of night length to time several aspects of their growth and development.

Length of the night is one of several environmental cues detected by plants, or by individual parts such as leaves. Light—its presence or absence, its intensity, its color, and its duration—provides cues to various conditions. Temperature, too, provides important environmental cues, both by its value at any particular time and by the distribution of warmer and colder stretches over a period of time. The plant "reads" an environmental cue and then "interprets" it, often by stepping up or decreasing its production of hormones.

We'll discuss an example of a temperature cue in the next chapter. Here, we'll see how certain photoreceptors interpret light, its duration, and its wavelength distribution.

Light regulates many aspects of plant development in addition to phototropism. The affected processes range from seed germination to shoot elongation to the initiation of flowering. Several photoreceptors take part in these and other processes.

Five phytochromes mediate the effects of red and dim blue light. Three or more blue-light receptors, discovered more recently, mediate the effects of higher-intensity blue light.

37.21 Sensitivity of Seeds to Light

In each case, the final exposure reverses the preceding exposure; seeds respond only to the wavelength of the final light exposure.

Phytochromes mediate the effects of red and far-red light

Some seeds will not germinate in darkness, but do so readily after even a brief exposure to light. Blue and red light are highly effective in promoting germination, whereas green light is not.

Of particular importance to plants is the fact that far-red light reverses the effect of a prior exposure to red light. Far-red light is a very deep red, bordering on the limit of human vision and centered on a wavelength of 730 nm; red wavelengths are around 660 nm. If exposed to brief, alternating periods of red and far-red light in close succession, lettuce seeds respond only to the final exposure: If it is red, they germinate; if it is far-red, they remain dormant (Figure 37.21). This reversibility of the effects of red and far-red light regulates many other aspects of plant development, including flowering and seedling growth.

The basis for the red and far-red effects resides in certain bluish photoreceptor proteins called phytochromes. They are blue because they absorb red and far-red light and transmit other light. In the cytosol of plants are two interconvertible forms of phytochromes. Light drives the interconversion of the two forms. The form that absorbs principally red light is called P_r . Upon absorption of a photon of red light, a molecule of P_r is converted into P_{fr} . The P_{fr} form absorbs far-red light; when it does so, it is converted to P_r .

662 CHAPTER THIRTY-SEVEN

P_{tr} has some important biological effects. As we have just seen, one of them is to initiate germination in certain seeds, such as lettuce.

Phytochromes have many effects

Phytochromes help to regulate a seedling's early growth. The radicle, or embryonic root, is the first portion of the seedling to escape the seed coat (see Figure 37.6); the shoot emerges later. When seeds germinate in the dark below the soil surface, a pale and spindly seedling forms, with undeveloped leaves. Such an etiolated plant cannot carry out photosynthesis. The seedling shoot must reach the soil surface and begin photosynthesis before its nutrient reserves are expended and it starves.

Plants have evolved a variety of ways to cope with the problem of germinating underground. Etiolated flowering plants, for example, do not form chlorophyll. They turn green only when exposed to light, thereby conserving the resources needed to make chlorophyll, which would be useless in the dark. An etiolated shoot uses stored resources to elongate rapidly and hasten its arrival at the soil surface, where photosynthesis quickly begins. To break through soil yet protect delicate, underdeveloped leaves, the shoot of an etiolated eu-dicot seedling forms an apical hook (see Figure 37.19).

All of these etiolation phenomena (lack of chlorophyll, rapid shoot elongation, production of an apical hook, delayed leaf expansion) are regulated by the phytochromes. In a seedling that has never been exposed to light, all the phytochrome is in the red-absorbing (P_r) form. Exposure to light converts P_r to P_{fr} (the far-red-absorbing form), and the P_{fr} initiates reversal of the etiolation phenomena: Chlorophyll synthesis begins, shoot elongation slows, the apical hook straightens out, and the leaves start to expand.

There are multiple phytochromes

For years, plant biologists had difficulty accounting for some aspects of phytochrome action. A solution to these problems may lie in the discovery of multiple forms of phytochromes and other photoreceptors. Arabidopsis has five genes that encode different phytochromes, and this diversity has been found throughout the plant kingdom and in algae as well.

The several phytochromes may play differing roles in various phytochrome-controlled responses. Some of them may even play off each other to fine-tune plant growth during the day. Consider, for example, the light spectrum available to a seedling that is growing in the shade of other plants. Because chlorophyll in the leaves above it absorbs the light first, the shaded seedling "sees" a spectrum relatively rich in far-red (and poor in red); the ratio of far-red to red is increased as much as 10-fold to 20-fold in the shade. The interplay among signal transduction pathways initiated by the different phytochromes may lead to an increased rate of stem elongation that tends to bring the leaf into full sunlight.

We do not yet know how the various phytochromes produce their many effects, although it is evident that phy-

tochromes act through the plant's genome. Phytochromes appear to activate one or more G proteins. G proteins are membrane proteins that must bind to guanosine triphosphate (GTP) to exert their effects (see Chapter 15). The phytochrome-activated G proteins may convert GTP into the second messenger cGMP (cyclic guanosine monophosphate) and open channels that admit calcium ions into the cell, where they bind to the protein calmodulin. Both cGMP and the calcium-calmodulin complex can trigger changes leading eventually to the activation of specific genes.

Cryptochromes and phototropin are blue-light receptors

Cryptochromes are yellow photoreceptor pigments that absorb blue and ultraviolet light. They affect some of the same developmental processes, including seedling development and flowering, as do phytochromes. Unlike phytochromes, cryptochromes are present and play important roles in animals as well as plants.

In contrast to phytochromes, cryptochromes are located primarily in the plant nucleus. The exact mechanism of cryptochrome action is not yet known. It may be significant that phytochromes behave like protein kinases, and that cryptochromes can be substrates of such enzymes. It is likely that both classes of photoreceptors participate in protein kinase-based signaling pathways (see Chapter 15).

We began this chapter with a photo of a plant's phototropic response. Later we saw that the study of phototro-

Figure 37.22 A Nonphototropic Mutant

(a) The four etiolated wild-type Arabidopsis seedlings in the top row are demonstrating normal phototropism. (b) These mutant seedlings cannot produce phototropin, the photoreceptor that signals the plant to curve toward light.

PLANT GROWTH REGULATION 663

pism led to the discovery of auxin. But a question remained: What is the photoreceptor for phototropism? Plant scientists working with phototropic mutants of Arabidopsis have recently showed convincing evidence that it is a yellow protein, which they named phototropin. Upon absorbing blue light, phototropin initiates a signal transduction pathway leading to phototropic curvature (Figure 37.22). Still another type of blue-light receptor may be responsible for the light-induced closure of stomata.

Plants respond to light in many ways, and their responses are mediated by interactions of several photoreceptors, as we have seen.

Chapter Summary

Interacting Factors in Plant Development

- ▶ The environment, photoreceptors, hormones, and the plant's genome all play roles in the regulation of plant development.
- ▶ Hormones mediate many developmental phenomena in plants. Each plant hormone plays multiple regulatory roles, affecting several different aspects of development. Interactions among the hormones are often complex. Review Table 37.1
- ▶ Hormones and photoreceptors act through signal transduction pathways.

From Seed to Death: An Overview of Plant Development

- ▶ Cell division, cell expansion, and cell differentiation all contribute to plant development.
- ▶ The dormant seed eventually germinates and forms a growing seedling. Photoreceptors and hormones regulate seedling development, including growth. Review Figures 37.1, 37.2
- ▶ Eventually the plant flowers and forms fruit. Flowering in some plants is controlled by the length of the night. Hormones, probably including a flowering hormone, play roles in plant reproduction. Review Figure 37.3
- ▶ Some plant buds demonstrate winter dormancy. Eventually, all plants senesce and die. Dormancy and senescence are triggered by environmental cues, mediated by photoreceptors and hormones.

Ending Seed Dormancy and Beginning Germination

- ▶ Seed dormancy may be caused by exclusion of water or oxygen from the embryo, mechanical restraint of the embryo, or chemical inhibition of embryo development. In nature, seed dormancy is broken in various ways, including scarification, fire, leaching, and low temperatures.
- ▶ Seed dormancy offers adaptive advantages, such as an increased likelihood of germination in a place and at a time favorable for seedling growth.
- ▶ Seed germination begins with the imbibition of water. Then the embryo mobilizes its reserves to obtain building blocks and energy. The embryos of cereal seeds secrete gibberellins, which cause the aleurone layer to synthesize and secrete digestive enzymes that break down large molecules stored in the endosperm. Review Figure 37.7

Gibberellins: Regulators from Germination to Fruit Growth

- ▶ There are dozens of gibberellins. One, gibberellin A_v regulates stem growth in most plants.
- ▶ Mutant plants that cannot produce normal amounts of gibberellins are dwarfs: Their stems are shorter than wild-type stems.
- ▶ Gibberellins regulate the growth of some fruits and cause bolting in some biennial plants. Review Figure 37.9

Auxin Affects Plant Growth and Form

- ▶ Studies of phototropism led to the discovery and isolation of auxin (indoleacetic acid). In grass seedlings, the photoreceptor for phototropism is in the tip of the coleoptile, and auxin is a messenger from the photoreceptor to the growing region of the coleoptile. Review Figures 37.10, 37.11
- ▶ Auxin transport is polar. Lateral movement of auxin establishes shoot and root responses to light and gravity: phototropism and gravitropism, respectively. Auxin carrier proteins move auxin into and out of cells. Review Figure 37.12
- ▶ Auxin plays roles in root formation, leaf abscission, apical dominance, and parthenocarpic fruit development. Certain synthetic auxins are used as selective herbicides. Review Figures 37.13, 37.14
- ▶ The arrangement of cellulose microfibrils in the plant cell wall limits the rate and direction of cell growth. Auxin increases the plasticity of the cell wall, promoting cell expansion. Part of the auxin response results from the pumping of protons from the cytoplasm into the cell wall, where the lowered pH activates proteins called expansins. Review Figures 37.15, 37.16, 37.17
- ▶ Like all plant hormones, auxin is bound by receptor proteins.
- ▶ Auxin and other plant hormones signal cell differentiation and organ formation.

Cytokinins Are Active from Seed to Senescence

- ▶ Cytokinins are adenine derivatives. Zeatin and isopentenyl adenine are naturally occurring cytokinins, and kinetin is a synthetic cytokinin.
- ▶ First studied as promoters of plant cell division, cytokinins also promote seed germination in some species, inhibit stem

elongation, promote lateral swelling of stems and roots, stimulate the growth of lateral buds, promote the expansion of leaf tissue, and delay leaf senescence.

Ethylene: A Gaseous Hormone That Promotes Senescence

- ▶ A balance between auxin and ethylene controls leaf abscission.
- ▶ Ethylene promotes senescence and fruit ripening.
- ▶ Ethylene causes the formation of a protective apical hook in eudicot seedlings that have not been exposed to light. In stems, it inhibits elongation, promotes lateral swelling, and causes a loss of gravitropic sensitivity.
- ▶ Ethylene acts through a signal transduction pathway that includes two proteins in the plasma membrane and that leads to the expression of genes. Review Figure 37.20

Abscisic Acid: The Stress Hormone

- ▶ Abscisic acid appears to maintain winter dormancy in buds. It prevents seeds from germinating while still attached to the parent plant, and it inhibits stem elongation. Through its effects on stomatal opening, it also regulates gas and water exchange between leaves and the atmosphere.

Hormones in Plant Defenses

- ▶ Oligosaccharins are hormones released by the cell wall in response to an attack by a pathogen. They participate in

664 CHAPTER THIRTY-SEVEN

plant defenses against pathogens, and they interact in complex ways with auxin.

Brassinosteroids: "New" Hormones with Multiple Effects

- ▶ There are dozens of brassinosteroids. They affect cell elongation, pollen tube elongation, vascular tissue differentiation, and root elongation.

Light and Photoreceptors

- ▶ Photochromes are bluish proteins found in the cytosol. Each phytochrome exists in two forms, P_r and P_{fr} , that are interconvertible by light. P_r absorbs red light (with a maximum at 660 nm), and P_{fr} absorbs far-red light (730 nm). Review Figure 37.21
- ▶ Photochromes have many effects, including the various manifestations of etiolation.
- ▶ There are five phytochromes. They may play different roles in development, and their signal transduction pathways may interact to mediate the effects of light environments of differing spectral distribution. They mediate the effects of red and low-energy blue light.
- ▶ Cryptochromes, yellow photoreceptor proteins that absorb blue and ultraviolet light, interact with phytochromes in controlling seedling development and floral initiation. Cryptochromes mediate high-energy blue light effects.
- ▶ The signaling pathways for phytochromes and cryptochromes are based on protein kinases.
- ▶ Phototropin, another yellow protein, is the photoreceptor for phototropism.

For Discussion

1. How may it be advantageous for some species to have seeds whose dormancy is broken by fire?
2. Cocklebur fruits contain two seeds each, and the two seeds are kept dormant by two different mechanisms. How may this use of two mechanisms of dormancy be advantageous to cockleburs?
3. Corn stunt virus causes a great reduction in the growth rate of infected corn plants, so the diseased plants take on a dwarfed form. Since their appearance is reminiscent of the genetically dwarfed corn studied by Phinney, you suspect that the virus may inhibit the synthesis of gibberellins by the corn plants. Describe two experiments you might conduct to test this hypothesis, only one of which should require chemical measurement.
4. Whereas relatively low concentrations of auxin promote the elongation of segments cut from young plant stems, higher concentrations generally inhibit growth, as shown in the figure.

Inhibition

Auxin concentration

In some plants, the inhibitory effects of high auxin concentrations appear to be secondary: High auxin concentrations cause the synthesis of ethylene, which is what causes the growth inhibition. Silver thiosulfate inhibits ethylene action. How do you think the addition of silver thiosulfate to the solutions in which the stem segments grew would affect the appearance of the above graph?

Some etiolated seedlings develop hairs on their epidermis when exposed to dim light. Describe an experiment to test the hypothesis that a phytochrome is the photoreceptor for this effect.

Reproduction in Flowering Plants

Biologists have known for more than 60 years that the leaves of some plants, such as the cocklebur, contain built-in timers that measure the length of every night. When the night is of the appropriate length, the leaves—even a single leaf on a plant stripped of all other leaves—send a signal to other parts of the plant, telling them to form flowers. The evidence for this signal is substantial and convincing, yet nobody has been able to isolate and identify it.

After years of frustration, we may soon solve this mystery. The probable key lies in recent discoveries, described earlier in this book, about the functioning of plasmodesmata, the minute passageways connecting adjacent plant cells. Studies using mutant plants may allow scientists to identify the signal and learn how it triggers flowering. This knowledge will be a major advance in our understanding of reproduction in plants.

Why do plants expend energy and resources to produce flowers? The answer is simple: Flowers are sexual reproductive structures, and reproduction is one of the most important events in a plant's—or any organism's—life.

In this chapter we look at several aspects of plant reproduction, including some that are still not well understood. We contrast sexual and asexual reproduction, and we consider sexual reproduction in detail. In doing so, we look at angiosperm gametophytes, pollination, double fertilization, embryonic development, and the roles of fruits in seed dispersal. The transition to the flowering state is a key event in plant development, and we'll see how changing seasons trigger flowering in some plants—and speculate on the existence of a flowering hormone. We conclude the chapter with an examination of asexual reproduction in nature and in agriculture.

Many Ways to Reproduce

Plants have many ways of reproducing themselves—and with humans helping, there are even more ways. Flowers contain the sex organs of plants; it is thus no surprise that almost all flowering plants reproduce sexually. But many reproduce asexually as well; some even reproduce asexually most of the time. What are the advantages and disadvantages

Where It All Began

Some of the best early evidence for a flowering hormone came from studies of cockleburs (*Xanthium* sp.).

What are the advantages and disadvantages of these two kinds of reproduction? The answers to this question involve genetic recombination. As we have seen, sexual reproduction produces new genetic combinations and diverse phenotypes. Asexual reproduction, in contrast, produces a clone of genetically identical individuals.

Both sexual and asexual reproduction are important in agriculture. Many important annual crops are grown from seeds, which are the products of sexual reproduction. Seed-grown crops include wheat, rice, millet, and corn—the great grain crops, all of which are grasses—as well as plants in other families, such as soybeans and safflower. Other crops are produced asexually from grafts, or by other asexual means.

Orange trees, which have been under cultivation for centuries, can be grown from seed—except for one type, the navel orange. This plant apparently arose only once in history. Early in the nineteenth century, on a plantation on the Brazilian coast, one seed gave rise to one tree that had aberrant flowers. Parts of the flowers aborted, and seedless

666 CHAPTER THIRTY-EIGHT

fruits formed. Every navel orange in the world comes from a navel orange tree derived asexually from that original Brazilian tree. Asexual reproduction is the only way of propagating this plant.

Unlike navel oranges, strawberries need not be propagated asexually, because they are capable of forming seeds. Nonetheless, asexual propagation of strawberries is common because vast numbers of plants that are genetically identical to a particularly desirable plant can be produced in this way.

We will treat asexual reproduction in greater detail at the end of this chapter. We begin, however, by considering sexual reproduction.

Sexual Reproduction

Sexual reproduction provides genetic diversity through recombination (see Chapter 9). Meiosis and mating shuffle genes into new combinations, giving a population a variety of genotypes in each generation. This genetic diversity may serve the population well as the environment changes or as the population expands into new environments. The adaptability resulting from genetic diversity is the major advantage of sexual reproduction over asexual reproduction.

DIPLOID (2n) I

Each ovule consists of a megasporangium, its protective layer of surrounding integuments, and its stalk.

Three of the four meiotic products degenerate.

'«&§&

38.1 Development of Gametophytes and Nuclear Fusion

The embryo sac (left) is the female gametophyte; the pollen grain (right) is the male gametophyte. The male and female nuclei meet and fuse within the embryo sac.

The flower is an angiosperm's device for sexual reproduction

A complete flower consists of four groups of organs that are modified leaves: the carpels, stamens, petals, and sepals (see Figure 29.6 for review). The carpels and stamens are, respectively, the female and male sex organs. A pistil is a structure composed of one or more carpels. The base of the pistil, called the ovary, contains one or more ovules, each of which contains a megasporangium. The stalk of the pistil is the style, and the end of that stalk is the stigma. Each stamen is composed of a filament bearing a two-lobed anther, which consists of four microsporangia fused together.

The petals and sepals of many flowers are arranged in whorls (circles) around the carpels and stamens. Together, the petals constitute the corolla. Below them, the sepals constitute the calyx. The petals are often colored; the sepals are often green and photosynthetic. All the parts of the flower are borne on a stem tip, the receptacle.

Flowering plants have microscopic gametophytes

Before reading this section, you may wish to review the section in Chapter 28 entitled "Life cycles of plants feature alternation of generations." The concept of alternation of generations is central to an understanding of plant reproduction.

In plants, the sporophyte generation produces flowers. The flowers produce spores, which develop into tiny gametophytes. The flower is more than just a place where the egg and sperm are eventually found—it is also the place where the alternate generation resides.

The gametophytes—the gamete-producing generation— of flowering plants develop from haploid spores in sporangia within the flower (Figure 38.1).

- Female gametophytes (megagametophytes), which are called embryo sacs, develop in megasporangia.
- Male gametophytes (microgametophytes), which are called pollen grains, develop in microsporangia.

Within the ovule, a megasporocyte—a cell within the megasporangium—divides meiotically to produce four haploid megaspores. All but one of these megaspores then degenerate. The surviving megaspore undergoes mitotic divisions, usually producing eight haploid nuclei, all initially contained within a single cell—three nuclei at one end, three at the other, and two in the middle. Subsequent cell wall formation leads to an elliptical, seven-celled megagametophyte with a total of eight nuclei.

- At one end of the elliptical megagametophyte are three tiny cells: the egg and two cells called synergids. The egg is the female gamete, and the synergids participate indirectly in fertilization.
- At the opposite end of the megagametophyte are three antipodal cells, which eventually degenerate.
- In the large central cell are two polar nuclei.

Cherry pollen

38.2 A Pollen Grain Sampler

Each species' pollen has a characteristic size, shape, and cell wall formation.

Hornbeam pollen

Daisy pollen

100 urn

Pollen is transferred by the direct contact of anther and stigma within the same flower, resulting in self-fertilization. Wind is the vehicle for pollen transport in many species. Wind-pollinated flowers have sticky or featherlike stigmas, and they produce pollen grains in great numbers (Figure 38.3). Some aquatic angiosperms are pollinated by water action, with water carrying

pollen grains from plant to

The embryo sac is the entire seven-celled, eight-nucleus structure. (Follow the arrows down the left-hand side of Figure 38.1 to review the development of the embryo sac.)

The male gametophyte, or pollen grain, consists of fewer cells than the female gametophyte. The development of a pollen grain begins when a microsporocyte within the anther divides meiotically. Each resulting haploid microspore normally undergoes one mitotic division within the spore wall before the anthers open and release these two-celled pollen grains. Further development of the pollen grain, which we will describe shortly, is delayed until the pollen arrives at a stigma. In angiosperms, the transfer of pollen from the anther to the stigma is referred to as pollination.

Pollination enables fertilization in the absence of liquid water

Gymnosperms and angiosperms evolved independence from liquid water as a medium for gamete travel and fertilization—a freedom not shared by other plant groups. The male gametes of gymnosperms and angiosperms travel within pollen grains (Figure 38.2). But how do angiosperm pollen grains travel from an anther to a stigma?

Many different mechanisms have evolved for pollen transport. In some plants, such as peas and their relatives, pollination is accomplished before the flower bud opens.

Corylus cornuta

38.3 Wind Pollination

The numerous anthers on these inflorescences (groups of flowers) of a hazelnut tree all point away from the stalk and stand free of the plant, promoting dispersal of the pollen by wind.

668 CHAPTER THIRTY-EIGHT

plant. Animals, including insects, birds, and bats, carry pollen among the flowers of many plants.

Some plants practice "mate selection"

In our discussion of Mendel's work (see Chapter 10), we saw that some plants can reproduce sexually either by cross-pollinating or by self-pollinating. Many plants demonstrate self-incompatibility; that is, they reject pollen from their own flowers. This rejection promotes genetic variation and limits inbreeding. A single gene, the S gene, is responsible for self-incompatibility. The S gene has dozens of alleles. A pollen grain is haploid and possesses a single S allele; the recipient stigma is diploid. In self-incompatible plants, pollen fails to germinate, or develops abnormally, on a stigma that possesses the same S allele (Figure 38.4).

The stigma plays an important role in "mate selection" by flowering plants. The stigmas of wind-pollinated plants are exposed to the pollen of many other species as well as their own, and even the flowers of plants with coevolved, specific animal pollinators may receive pollen from other plant species. Pollen from the same species binds strongly to the stigma due to cell-cell signaling by the cell wall of pollen grains of the same species. In contrast, foreign pollen falls off readily, without germinating.

A pollen tube delivers male cells to the embryo sac

When a pollen grain lands on the stigma of a compatible pistil, a pollen tube develops from the pollen grain (Figure 38.5). The pollen tube either digests its way through the spongy tissue of the style or, if the style is hollow, grows downward on the inner surface of this female organ. The pollen tube grows millimeters or even centimeters in the process.

S₃ and S₄ pollen are compatible with S₁S₂ stigma.

...but S₁ and S₂ pollen do not germinate. They are self-incompatible.

38.4 Self-Incompatibility

Pollen grains do not germinate normally if their S allele matches one of the S alleles of the stigma. Thus, the egg cannot be fertilized by a sperm from the same plant.

38.5 Pollen Tubes Begin to Grow

Pollen grains have landed on hairlike structures on the stigma of an Arabidopsis flower. Pollen tubes have started to form.

The rapid growth of the pollen tube requires calcium ions, taken up at the growing tip of the tube, as well as cell adhesion proteins. The downward growth of the pollen tube is guided by a long-distance signal from the ovule.

Angiosperms perform double fertilization

The pollen grain consists of two cells. The larger tube cell encloses the much smaller generative cell (Figure 38.6). Guided by the tube cell nucleus, the pollen tube eventually grows through megasporangial tissue and reaches the embryo sac. The generative cell meanwhile has undergone one mitotic division and cytokinesis to produce two sperm cells.

Both of the sperm cells enter the embryo sac, where they are released into the cytoplasm of one of the synergids. This synergid degenerates, releasing the sperm cells. Each sperm cell then fuses with a different cell of the embryo sac. One sperm cell fuses with the egg cell, producing the diploid zygote. The other fuses with the central cell, and that sperm cell nucleus and the two polar nuclei unite to form a triploid (3n) nucleus. While the zygote nucleus begins division to form the new sporophyte embryo, the triploid nucleus undergoes rapid mitosis to form a specialized nutritive tissue, the endosperm. The antipodal cells and the remaining synergid eventually degenerate, as does the pollen tube nucleus.

The fusion of a sperm cell nucleus with polar nuclei to form endosperm takes place only in angiosperms. This and the possession of flowers are the two most definitive characteristics shared by all angiosperms.

Embryos develop within seeds

Shortly after fertilization, highly coordinated growth and development of embryo, endosperm, integuments, and carpel

ensues. The integuments develop into a double-layered seed coat, and the carpel ultimately becomes the wall of the fruit that encloses the seed.

Polar nuclei

Egg Synergids

The generative cell divides mitotically, producing two haploid sperm cells.

The sperm cells enter the cytoplasm of a synergid.

| The synergid breaks down; one sperm nucleus unites with the two polar nuclei, forming the first cell of the $3n$ endosperm generation.

The other sperm nucleus fertilizes the egg, forming the zygote, the first cell of the $2n$ sporophyte generation.

t 38.6 Pollen Nuclei and Double Fertilization

The sperm nuclei contribute to the formation of the diploid zygote and the triploid endosperm. Double fertilization is a characteristic feature of angiosperm reproduction.

The first step in the normal formation of the embryo is a mitotic division of the zygote—the fertilized egg—giving rise to two daughter cells. Even at this stage, the two cells face different fates. An asymmetrical (uneven) distribution of cytoplasm within the zygote causes one end to produce the embryo proper and the other end to produce a supporting structure, the suspensor (Figure 38.7). The suspensor pushes the embryo against or into the endosperm, and provides one route by which nutrients enter the embryo.

With the asymmetrical division of the zygote, polarity has been established, as has the longitudinal axis of the new plant. A filamentous suspensor and a globular embryo are distinguishable after just four mitotic divisions. The suspensor soon ceases to elongate. In the embryo, the primary meristems form. As development continues, the first organs take form within the embryo.

In eudicots (monocots are somewhat different), the initially globular embryo takes on a characteristic heart-stage form as the cotyledons start to grow. Further elongation of the cotyledons and of the main axis of the embryo gives rise to what is called the torpedo stage (see Figure 38.7), during which some of the internal tissues begin to differentiate. The elongating region below the cotyledons is the hypocotyl. At the top of the hypocotyl, between the cotyledons, is the shoot apex; at the other end is the root apex. Each of these apical regions contains an apical meristem whose dividing cells will give rise to the organs of

the mature plant.

Large amounts of nutrients are moved in from other parts of the plant, and the endosperm accumulates starch,

670 CHAPTER THIRTY-EIGHT

lipids, and proteins. In many species, the cotyledons absorb the nutrient reserves from the surrounding endosperm and grow very large in relation to the rest of the embryo (Figure 38.8rt). In others, the cotyledons remain thin (Figure 38. 8b); they draw on the reserves in the endosperm as needed when the seed germinates.

In the late stages of embryonic development, the seed loses water—sometimes as much as 95 percent of its original water content. In its dried state, the embryo is incapable of further development. It remains in this quiescent state until the conditions are right for germination. (Recall from Chapter 37 that a necessary first step in seed germination is the massive imbibition of water.)

Some fruits assist in seed dispersal

After fertilization, the ovary wall of a flowering plant—together with its seeds—develops into a fruit. A fruit may consist of only the mature ovary and its seeds, or it may include other parts of the flower or structures that are closely related to it. Some major variations on this theme are illustrated in Figure 29.11, which shows only fleshy, edible fruits. Many other fruits are dry or inedible.

Some fruits help disperse seeds over substantial distances. Various trees, including ash, elm, maple, and tree of heaven, produce a dry, winged fruit that may be blown some distance from the parent tree by the wind (Figure 38.9a). Water disperses some fruits; coconuts have been spread in this way from island to island in the Pacific (Figure 38.9b). Still other fruits travel by hitching rides with animals—either inside or outside them. Fleshy fruits such as berries provide food for mammals or birds; their seeds travel safely through the animal's digestive tract and are deposited some distance from the parent plant.

We have traced the sexual life cycle from the flower to the fruit to the dispersal of seeds. We discussed seed germination and vegetative development of the seedling in

In some eudicots, the cotyledons absorb much of the endosperm and fill most of the seed.

In other eudicots, the endosperm remains separate and the cotyledons remain thin.

In monocots, the single cotyledon is pressed against the endosperm.

Chapter 37. Now let's complete the sexual life cycle by considering the transition from the vegetative to the flowering state, and how this transition is regulated.

The Transition to the Flowering State

Flowering may terminate, interrupt, or accompany vegetative growth. The transition to the flowering state marks the end of vegetative growth for some plants. If we view a plant as something produced by a seed for the purpose of bearing more seeds, then the act of flowering is one of the supreme events in a plant's life.

Apical meristems can become inflorescence meristems

The first visible sign of the transition to the flowering state may be a change in one or more apical meristems in the shoot system. During vegetative growth, an apical meristem continually produces leaves, lateral buds, and internodes (regions of stem between the nodes where leaves and buds form: Figure 38.10f). This unrestricted growth is indeterminate (see Chapter 34).

Flowers may appear singly or in an orderly cluster that constitutes a structure called an inflorescence. If a vegetative meristem becomes an inflorescence meristem, it generally produces several other structures: smaller leafy structures called bracts, as well as new meristems in the angles between the bracts and the internodes (Figure 38.10b).

(«)

An internode is a section of stem between two nodes (places where leaves or buds form).

38.10 Flowering and the Apical Meristem

A vegetative apical meristem (a) grows without producing flowers. Once the transition to the flowering state is made, inflorescence meristems (b) give rise to bracts and to floral meristems (c), which become the flowers.

These new meristems may also be inflorescence meristems, or they may be floral meristems, which give rise to the flowers themselves.

Each floral meristem typically produces four consecutive whorls of organs—the sepals, petals, stamens, and carpels—separated by very short internodes, keeping the flower compact (Figure 38.10c). In contrast to vegetative meristems and some inflorescence meristems, floral meristems are responsible for determinate growth—the limited growth of the flower to a particular size and form.

A cascade of gene expression leads to flowering

How do apical meristems become inflorescence meristems, and how do inflorescence meristems give rise to floral meristems? How does a floral meristem give rise, in short order, to four different organs? How does each flower come to have the correct number of each of the floral organs? Numerous genes collaborate to produce these results. We'll refer here to some of the genes whose actions have been most thoroughly understood in *Arabidopsis* and snapdragons.

In order for an inflorescence meristem to give rise to a floral meristem, a group of floral meristem identity genes must be expressed. Expression of these genes initiates a cascade of further gene expression. Another set of genes, part of this cascade, participates in pattern formation—the spatial organization of the whorls of organs, which are still to be

determined. These genes, in turn, trigger the expression of a group of organ identity genes that work in concert to specify the successive whorls (see Figure 16.11). They are homeotic genes, and their products are transcription factors that mediate the expression of still further genes.

Now that we have seen how flowering occurs, we will consider how the transition from the vegetative to the flowering state is initiated.

Photoperiodic Control of Flowering

The life cycles of flowering plants fall into three categories: annual, biennial, and perennial. Annuals, such as many food crops, complete their life cycle (seed to flower) in less than a year. Biennials, such as carrots and cabbage, grow for all or part of one year and live on into a second year, during which they flower, form seeds, and die. Perennials, such as oak trees, live for a few to many years, during which both growth and flowering occur. What control systems give rise to these and other differences in flowering behavior?

In 1920, W. W. Garner and H. A. Allard of the U.S. Department of Agriculture studied the behavior of a newly discovered mutant tobacco plant. The mutant, named 'Maryland Mammoth,' had large leaves and exceptional height. When the other plants in the field flowered, the 'Maryland Mammoth' continued to grow. Garner and Allard took cuttings of the 'Maryland Mammoth' into their greenhouse, and the plants that grew from the cuttings finally flowered in December.

Garner and Allard guessed that this pattern had something to do with the seasons. They tested several likely seasonal variables, such as temperature, but the key variable proved to be the length of the day (as they saw it). By moving plants between light and dark rooms at different times to vary the day length artificially, they were able to establish a direct link between flowering and day length. (We now know that the key variable is the length of the night, rather than the day, but Garner and Allard did not make that distinction.)

The 'Maryland Mammoth' plants did not flower if the light period was longer than 14 hours each day, but flowering commenced after the days became shorter than 14 hours. Thus, the critical day length for 'Maryland Mammoth' tobacco is 14 hours (Figure 38.11). This phenomenon of control by the length of day or night is called photoperiodism.

There are short-day, long-day, and day-neutral plants

Poinsettias, chrysanthemums, and 'Maryland Mammoth' tobacco are short-day plants (SDP's), which flower only when the day is shorter than a critical maximum. Spinach and clover are examples of long-day plants (LDP's), which flower only when the day is longer than a critical minimum.

38.11 Day Length and Flowering

By artificially varying the length of the day, Garner and Allard showed that the flowering of Maryland Mammoth tobacco is initiated when the days become shorter than a critical length. Maryland Mammoth tobacco is thus called a short-day plant. Henbane, a long-day plant, shows an inverse pattern of flowering.

Generally, LDP's are triggered to flower in midsummer and SDP's in late summer, or sometimes in the spring.

Some plants require photoperiodic signals that are more complex than just short or long days in order to flower. One group, the short-long-day plants, must first experience short days and then long ones. Accordingly, white clover and other short-long-day plants flower during the long days before midsummer. Another group, the long-short-day plants, cannot flower until the long days of summer have been followed by shorter ones, so they bloom only in the fall. Kalanchoe, seen in Figure 38.17b, is a long-short-day plant.

Other effects besides flowering are also under photoperiodic control. We have learned, for example, that short days trigger the onset of winter dormancy in plants. (Animals, too, show a variety of photoperiodic behaviors.)

The flowering of some angiosperms, such as corn and tomatoes, is not photoperiodic. In fact, there are more of these day-neutral plants than there are short-day and long-day plants. Some plants are photoperiodically sensitive only when young and become day-neutral as they grow older. Others require specific combinations of day length and other factors—especially temperature—to flower.

The length of the night determines whether a plant will flower

The terms "short-day plant" and "long-day plant" became entrenched before scientists learned that plants actually measure the length of the night, or of a period of darkness, rather than the length of the day. This fact was demonstrated by Karl

Hamner of the University of California at Los Angeles and James Bonner of the California Institute of Technology (Figure 38.12).

Working with cocklebur, an SDP, Hamner and Bonner ran a series of experiments using two sets of conditions:

- ▶ The light period was kept constant—either shorter or longer than the critical day length—and the dark period was varied.
- ▶ The dark period was kept constant and the light period was varied.

The plants flowered under all treatments in which the dark period exceeded 9 hours, regardless of the length of the light period. Thus it is the length of the night that matters; for cocklebur, the critical night length is about 9 hours. Thus, it would be more accurate to call cocklebur a "long-night plant" than a short-day plant.

EXPERIMENT

Question: Do short-day plants measure the length of day or night?

METHOD

Plants were moved between light and dark rooms for specified numbers of hours.

RESULTS

Light constant/Darkness varied

16

16

> ■ No flowering

16

Flowering

Conclusion: Photoperiodic plants measure the length of the night, not the day. Interrupting a long night with a brief period of light inhibits flowering. Long-day plants flower when the night is short, but interrupting their long day has no effect.

38.13 The Effect of Interrupted Days and Nights

(a) Experiments suggest that plants are able to measure the length of a continuous dark period and use this information to trigger flowering, (b) Phytochromes seem to be involved in the photoperiodic timing mechanism.

the dark period by light, however, completely nullified the effect of a long night (Figure 38.13fl). An SDP flowered only if the long nights were uninterrupted. An LDP experiencing long nights flowered if those nights were broken by exposure to light. Thus a plant must have a timing mechanism that measures the length of a continuous dark period. Despite much study, the nature of this timing mechanism is still unknown.

Phytochromes and blue-light receptors, which affect several aspects of plant development (see Chapter 37), also participate in the photoperiodic timing mechanism. In the interrupted-night experiments, the most effective wavelengths of light were in the red range (Figure 38.13i>), and the effect of a red-light interruption of the night could be fully reversed by a subsequent exposure to far-red light. It was once thought that the timing mechanism might simply be the slow conversion of phytochrome during the night from the Pfr form—produced during the light hours—to the Pr form. But this suggestion is inconsistent with most of the experimental observations and must be wrong. Phytochrome must be only a photoreceptor. The timekeeping role must be played by a biological clock.

Circadian rhythms are maintained by a biological clock

It is abundantly clear that organisms have some way of measuring time, and that they are well adapted to the 24-hour day-night cycle of our planet. Some sort of biological clock resides within the cells of all eukaryotes. The major outward manifestations of this clock are known as circadian rhythms (from the Latin *circa*, "about," and *dies*, "day").

We can characterize circadian rhythms, as well as other regular biological cycles, in two ways: The period is the length of one cycle, and the amplitude is the magnitude of the change over the course of a cycle (Figure 38.14).

In cocklebur, a single long night is enough of a photoperiodic stimulus to trigger full flowering some days later, even if the intervening nights are short ones. Most plants are less sensitive than cocklebur, requiring from two to many nights of appropriate length to induce flowering. For some plants, a single shorter night in a series of long ones, even one day before flowering would have commenced, inhibits flowering.

Hamner and Bonner showed that plants measure the length of the night using another method as well. They grew SDP's and LDP's under a variety of light conditions. Under some conditions, the dark period was interrupted by a brief exposure to light; in others, the light period was interrupted briefly by darkness. Interruptions of the light period by darkness had no effect on the flowering of either short-day or long-day plants. Even a brief interruption of

Effect

Circadian rhythms are characterized on the basis of time, measured in periods of about 24 hours...

?...and on the basis of the magnitude of the rhythmic effect, measured by the cycle's amplitude.

38.14 Features of Circadian Rhythms

The circadian rhythms of plants, like those of other organisms, can be characterized in two ways.

674 CHAPTER THIRTY-EIGHT

Circadian rhythms of protists, animals, fungi, and plants have been found to share some important characteristics:

- ▶ The period is remarkably insensitive to temperature, although lowering the temperature may drastically reduce the amplitude of the fluctuation.
- ▶ Circadian rhythms are highly persistent; they continue even in an environment in which there is no alternation of light and dark.
- ▶ Circadian rhythms can be entrained, within limits, by light-dark cycles that differ from 24 hours. That is, the period an organism expresses can be made to coincide with that of the light-dark regime.
- ▶ A brief exposure to light can shift the rhythm—it can cause a phase shift.

Plants provide innumerable examples of approximately 24-hour cycles. The leaflets of a plant such as clover or the tropical tree *Albizia* normally hang down and fold at night and rise and expand during the day. Flowers of many plants show similar "sleep movements," closing at night and opening during the day. They continue to open and close on an approximately 24-hour cycle even when the light and dark periods are experimentally modified (Figure 38.15).

The period of circadian rhythms in nature is approximately 24 hours. If an *Albizia* tree, for example, were to be

EXPERIMENT

Question: Do plants exhibit circadian rhythms?

Hours in total darkness

Conclusion: *Kalanchoe* flowers open and close in response to a biological clock even in the absence of external light/dark cues.

38.15 Plants Can Measure Time

Even when *Kalanchoe* is placed in continuous darkness, the opening and closing of its flowers continues to exhibit a circadian rhythm.

placed under electric light on a day-night cycle totaling exactly 24 hours, the rhythm expressed would show a period of exactly 24 hours. However, if an experimenter used a day-night cycle of, say, 22 hours, then over time the rhythm would change—it would be entrained to a 22-hour period.

If an organism is maintained under constant darkness, with its circadian rhythm being expressed on the approximately 24-hour period, a brief exposure to light can cause a phase shift—that is, it can make the next peak of activity appear either later or earlier than expected, depending on when the exposure is given. Moreover, the organism does not then return to its old schedule if it remains in darkness. If the first peak is delayed by 6 hours, the subsequent peaks are all 6 hours late. Such phase shifts are permanent—until the organism receives more exposures to light.

Phytochromes and blue-light receptors are known to affect the period of the biological clock, with the different pigments reporting on different wavelengths and intensities of light. Perhaps this diversity of photoreceptors is an adaptation to the changes in the light environment that a plant experiences.

There is now ample evidence that the photoperiodic behavior of plants is based on the interaction of night length with the

biological clock. But how the clock is coupled with flowering remains unclear.

Is there a flowering hormone?

Is the timing device for flowering located in a particular part of an angiosperm, or are all parts able to sense the length of the night? This question was resolved by "blindfolding" different parts of the plant.

It quickly became apparent that each leaf is capable of timing the night. If a short-day plant is kept under a regime of short nights and long days, but a leaf is covered so as to give it the needed long nights, the plant will flower (Experiment A in Figure 38.16). This type of experiment works best if only one leaf is left on the plant. If one leaf is given a photoperiodic treatment conducive to flowering—an inductive treatment—other leaves kept under noninductive conditions will tend to inhibit flowering.

Although it is the leaves that sense an inductive dark period, the flowers form elsewhere on the plant. Thus a message must be sent from the leaf to the site of flower formation. Three lines of evidence suggest that this message is a chemical substance—a flowering hormone.

► If a photoperiodically induced leaf is removed from the plant shortly after the inductive dark period, the plant does not flower. If, however, the induced leaf remains attached to the plant for several hours, the plant flowers. This result suggests that something must be synthesized in the leaf in response to the inductive dark period, then move out of the leaf to induce flowering.

► If two cocklebur plants are grafted together, and if one plant is given inductive long nights and its graft partner is given noninductive short nights, both plants flower (Experiment B in Figure 38.16).

EXPERIMENT A

Question: What part of the plant measures the dark period?

Cocklebur, a short-day plant, will not flower if kept under long days and short nights.

If even one leaf is masked for part of the day, however—thus shifting that leaf to short days and long nights—the plant will flower; note the burrs.

Burrs

Single leaf masked on long-night/ short-day regimen

Plant flowers

EXPERIMENT B

Question: How stable is the flowering hormone?

Five cocklebur plants are grafted together and kept under long days and short nights, with most leaves removed.

If a leaf on a plant at one end of the chain is subjected to long nights, all of the plants will flower.

Leaf induced by long nights/ short days

Branching

experimentally

induced

Conclusion: The leaves measure the dark period. Therefore, some message must move from the induced leaf to the flowering parts of the plant.

38.16 Evidence for a Flowering Hormone

If even a single leaf is exposed to inductive conditions, a "message" travels to the entire plant (and even to other plants, in grafting experiments), inducing it to flower.

► In at least one species, if an induced leaf from one plant is grafted onto another, noninduced plant, the host plant flowers.

Jan A. D. Zeevaart, a plant physiologist now at Michigan State University, performed this last experiment. He exposed a single leaf of the SDP *Perilla* to a short-day/long-night regime, inducing the plant to flower. Then he detached this leaf and grafted it onto another, noninduced, *Perilla* plant—which responded by flowering. The same leaf grafted onto successive hosts caused each of them to flower in turn. As long as 3 months after the leaf was exposed to the short-day/long-night regime, it could still cause plants to flower.

Experiments such as Zeevaart's suggest that the photoperiodic induction of a leaf causes a more or less permanent change in it, inducing it to start and continue producing a flowering hormone that is transported to other parts of the plant, switching those target parts to the reproductive state. So reasonable is this idea that biologists have named this hormone florigen, even though, after decades of active searching, it has not been isolated and characterized.

An elegant experiment suggested that the florigen of short-day plants is identical to that of long-day plants, even though SDP's produce it only under long nights and LDP's only under short nights. An SDP and an LDP were grafted together, and both flowered, as long as the photoperiodic

Conclusion: The very stable flowering message can even travel across multiple grafts.

Arrows indicate the routes of the hypothetical flowering hormone from the induced leaf.

conditions were inductive for one of the partners. Either the SDP or the LDP could be the one induced, but both would always flower. These results suggest that a flowering hormone—the elusive florigen—was being transferred from one plant to the other.

The direct demonstration of florigen activity remains a cherished goal of plant physiologists. For a long time it was thought that florigen could be neither a protein nor an RNA because these molecules were too large to pass from one living plant cell to another. However, we now know that such macromolecules can be transferred by way of plasmodesmata, and biologists are reexamining the possibility that an RNA or a protein is the long-sought florigen.

Vernalization and Flowering

In both wheat and rye, we distinguish two categories of flowering behavior. Spring wheat, for example, is sown in the spring and flowers in the same year. It is an annual plant. Winter wheat is biennial and must be sown in the fall; it flowers in the following summer. If winter wheat is not exposed to cold after its first year, it will not flower normally the next year. The implications of this finding were of great agricultural interest in Russia because winter wheat is a better producer than spring wheat, but it cannot be grown in some parts of Russia because the winters there are too cold for its survival.

Several studies performed in Russia during the early 1900s demonstrated that if seeds of winter wheat were pre-moistened and prechilled, they could be sown in the spring, and would develop and flower normally the same

676 CHAPTER THIRTY-EIGHT

year. Thus, high-yielding winter wheat could be grown even in previously hostile regions. This induction of flowering by low temperatures is called vernalization.

Vernalization may require as many as 50 days of low temperatures (in the range from about -2° to $+12^{\circ}\text{C}$). Some plant species require both vernalization and long days to flower. There is a long wait from the cold days of winter to the long days of summer, but because the vernalized state easily lasts at least 200 days, these plants do flower when they experience the appropriate night length.

Asexual Reproduction

Although sexual reproduction takes up most of the space in this chapter, asexual reproduction is responsible for many of the new plant individuals appearing on Earth. This fact suggests that in some circumstances, asexual reproduction must be advantageous.

Consider genetic recombination. When a plant self-fertilizes, there are fewer opportunities for genetic recombination than there are with cross-fertilization. A self-fertilizing plant that is heterozygous for a certain locus can produce among its progeny both kinds of homozygotes for that locus plus the heterozygote, but it cannot produce any progeny that carry alleles that it does not itself possess. Yet many plants continue to be self-compatible.

Asexual reproduction goes farther than self-fertilization: It eliminates genetic recombination altogether. When a plant reproduces asexually, it produces a clone of progeny with genotypes identical to its own. If a plant is well adapted to its

environment, asexual reproduction may spread its genotype throughout that environment. This ability to exploit a particular environment is an advantage of asexual reproduction.

There are many forms of asexual reproduction

We call stems, leaves, and roots vegetative organs, distinguishing them from flowers, the reproductive parts of the

plant. The modification of a vegetative organ is what makes vegetative reproduction possible. The stem is the organ that is modified in many cases. Strawberries and some grasses produce stolons (runners), horizontal stems that form roots at intervals and establish potentially independent plants (see Figure 34.4b). Tip layers are upright branches whose tips sag to the ground and put out roots, as in blackberry and forsythia.

Some plants, such as potatoes, form tubers, enlarged fleshy tips of underground stems (see Figure 34.4a). Rhizomes are horizontal underground stems that can give rise to new shoots. Bamboo is a striking example of a plant that reproduces vegetatively by means of rhizomes. A single bamboo plant can give rise to a stand—even a forest—of plants constituting a single, physically connected entity.

Whereas stolons and rhizomes are horizontal stems, bulbs and corms are short, vertical, underground stems. Lilies and onions form bulbs (Figure 38.17f), short stems with many fleshy, modified leaves. The leaves make up most of the bulb. Bulbs are thus large buds that store nutrients. They can give rise to new plants by dividing or by producing new bulbs from lateral buds. Crocuses, gladioli, and many other plants produce corms, underground stems that function very much as bulbs do. Corms are disklike and consist primarily of stem tissue; they lack the fleshy modified leaves that are characteristic of bulbs.

Not all vegetative organs modified for reproduction are stems. Leaves may also be the source of new plantlets, as in the succulent plants of the genus *Kalanchoe* (Figure 38.17b). Many kinds of angiosperms, ranging from grasses to trees such as aspens and poplars, form interconnected, genetically homogeneous populations by means of suckers — shoots produced by roots. What appears to be a whole stand of aspen trees, for example, may be a clone derived from a single tree by suckers (see Figure 54.1b).

Plants that reproduce vegetatively often grow in physically unstable environments, such as eroding hillsides. Plants with stolons or rhizomes, such as beach grasses,

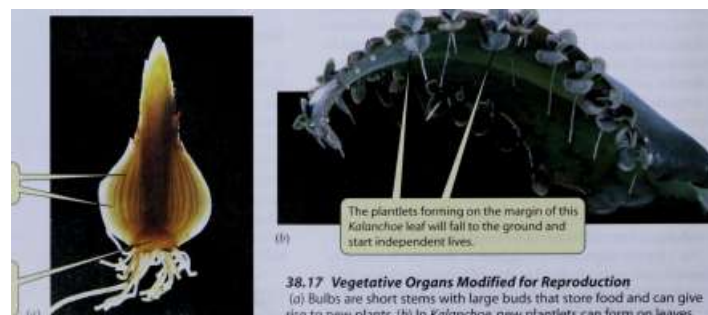

r \

Storage leaves grow

from the stem.

v

The short stem is visible at the bottom of the bulb.

38. 7 7 Vegetative Organs Modified for Reproduction

(a) Bulbs are short stems with large buds that store food and can give rise to new plants, (b) In *Kalanchoe*, new plantlets can form on leaves.

rushes, and sand verbena, are common pioneers on coastal sand dunes. Rapid vegetative reproduction enables these plants, once introduced, not only to multiply but also to survive burial by the shifting sand; in addition, the dunes are stabilized by the extensive network of rhizomes or stolons.

Dandelions, citrus trees, and some other plants reproduce by apomixis, the asexual production of seeds. As we have seen, meiosis reduces the number of chromosomes in gametes, and fertilization restores the sporophytic number of chromosomes in the zygote. Some plants can skip over both meiosis and fertilization and still produce seeds. Apomixis produces seeds within the female gametophyte without the mingling and segregation of chromosomes and without the union of gametes. The ovule simply develops into a seed, and the ovary wall develops into a fruit. An apomictic embryo has the sporophytic number (2n) of chromosomes. The result of apomixis is a fruit with seeds that are genetically identical to the parent plant.

Interestingly, apomixis sometimes requires pollination. In some apomictic species, a sperm nucleus must combine with the polar nuclei in order for the endosperm to form. In other apomictic species, the pollen provides the signals for embryo and endosperm formation, although neither sperm nucleus participates in fertilization. Pollination and fertilization are not the

same thing!

Asexual reproduction is important in agriculture

Farmers take advantage of some natural forms of vegetative reproduction. Farmers and scientists have also developed new types of asexual reproduction by manipulating plants. One of the oldest methods of vegetative reproduction used in agriculture consists simply of making cuttings of stems, inserting them in soil, and waiting for them to form roots and thus become autonomous plants. The cuttings are usually encouraged to root by treatment with a plant hormone, auxin, as described in Chapter 37.

Horticulturists reproduce many woody plants by grafting —attaching a bud or a piece of stem from one plant to the root-bearing stem of another plant. The part of the resulting plant that comes from the root-bearing "host" is called the stock; the part grafted on is called the scion (Figure 38.18). In order for a graft to succeed, the cambium of the scion must become associated with the cambium of the stock. By cell division, both cambia form masses of wound tissue. If the two masses meet and fuse, the resulting continuous cambium can produce xylem and phloem, allowing transport of water and minerals to the scion and of photosynthate to the stock. Grafts are most often successful when the stock and scion belong to the same or closely related species.

Most fruit grown for market in the United States is produced on trees grown from grafts. There are many reasons for grafting plants for fruit production. The most common is the desire to combine a hardy root system with a shoot system that produces the best-tasting fruit. This motive is

(a) Cleft grafting

Scions

(b) Whip grafting Scion

In grafting, the scions are aligned so that their vascular cambia associate with the vascular cambium in the stock.

38.18 Grafting

Grafting—attaching a piece of a plant to the stem or root of another plant—is common in agriculture. The "host" stem or root is the stock; the grafted piece is the scion.

illustrated by the story of the wine grape *Vitis vinifera*. In 1863, plant lice of the genus *Phylloxera* inflicted great damage on the root systems of grapevines in French vineyards. More than 2.5 million acres of vines were destroyed. The problem was overcome by importing *V. vinifera* plants, which have *Phylloxera*-resistant root systems, from California. These plants were used as stocks to which French vines were grafted as scions. Thus the fine French grapes could be grown using roots resistant to the lice. (But the battle continues; in recent years, a new strain of *Phylloxera* has been damaging grapevines in California.)

Scientists in universities and industrial laboratories have been developing new ways to produce valuable plant materials via tissue culture. Because many plant cells are totipotent (see Figure 16.3), cultures of undifferentiated tissue can give rise to entire plants, as can small pieces of tissue cut directly from a parent plant. Tissue cultures are used commercially to produce orchids, rhododendrons, and many crops without resorting to seeds.

Culturing tiny bits of apical meristem can produce plants free of viruses. Because apical meristems lack developed vascular tissues, viruses tend not to enter them. Such meristem cultures have been used to increase the yields of potatoes and other crops.

Recombinant DNA techniques applied to tissue cultures can provide plants with capabilities they previously lacked such as resistance to pests, or increased nutritive value to humans. There is also interest in making certain valuable, sexually reproducing plants capable of apomixis. By causing cells of different types to fuse, one can obtain plants with exciting new combinations of properties.

678 CHAPTER THIRTY-EIGHT

Chapter Summary

Many Ways to Reproduce

- ▶ Almost all flowering plants reproduce sexually, and many also reproduce asexually.
- ▶ Both sexual and asexual reproduction are important in agriculture.

Sexual Reproduction

- ▶ Sexual reproduction promotes genetic diversity in a population, which may give the population an advantage under changing environmental conditions.
- ▶ The flower is an angiosperm's device for sexual reproduction.
- ▶ Flowering plants have microscopic gametophytes that develop in the flowers of the sporophytes. The megagametophyte is the embryo sac, which typically contains eight nuclei in a total of seven cells. The microgametophyte is the pollen grain, which delivers two sperm cells to the megagametophyte by means of a long pollen tube. Review Figure 38.1
- ▶ Pollination enables fertilization in the absence of liquid water.
- ▶ In self-incompatible species, the stigma rejects pollen from the same plant. Review Figure 38.4
- ▶ Angiosperms perform double fertilization: One sperm nucleus fertilizes the egg, forming a zygote, and the other sperm nucleus unites with the two polar nuclei to form a triploid endosperm nucleus. Review Figure 38.6
- ▶ The zygote develops into an embryo (with an attached suspensor), which remains quiescent in the seed until conditions are right for germination. The endosperm is the nutritive reserve upon which the embryo depends at germination. Review Figures 38.7, 38.8
- ▶ Flowers develop into seed-containing fruits, which often play important roles in the dispersal of the species.

The Transition to the Flowering State

- ▶ For a vegetatively growing plant to flower, an apical meristem in the shoot system must become an inflorescence meristem, which gives rise to bracts and more meristems. The meristems it produces may become floral meristems or additional inflorescence meristems. Review Figure 38.10
- ▶ Flowering results from a cascade of gene expression. Organ identity genes are expressed in floral meristems that give rise to sepals, petals, stamens, and carpels.

Photoperiodic Control of Flowering

- ▶ Photoperiodic plants regulate their flowering by measuring the length of light and dark periods.
- ▶ Short-day plants flower when the days are shorter than a species-specific critical day length; long-day plants flower when the days are longer than a critical day length. Review Figure 38.11
- ▶ Some angiosperms have more complex photoperiodic requirements than short-day or long-day plants have, but most are day-neutral.
- ▶ The length of the night is what actually determines whether a photoperiodic plant will flower. Review Figure 38.12
- ▶ Interruption of the nightly dark period by a brief exposure to light undoes the effect of a long night. Review Figure 38.13
- ▶ The mechanism of photoperiodic control involves a biological clock and phytochromes. Review Figures 38.14, 38.15
- ▶ Evidence suggests that there is a flowering hormone, called florigen, but the substance has yet to be isolated from any plant. Review Figure 38.16

Vernalization and Flowering

- ▶ In some plant species, exposure to low temperatures—vernalization—is required for flowering.

-ver-

Asexual Reproduction

- ▶ Asexual reproduction allows rapid multiplication of organisms well suited to their environment.
- ▶ Vegetative reproduction involves the modification of a vegetative organ—usually the stem—for reproduction. Stolons, runners, tubers, rhizomes, bulbs, corms, and suckers are means by which plants may reproduce vegetatively.
- ▶ Some plant species produce seeds asexually by apomixis.
- ▶ Agriculturalists use natural and artificial techniques of asexual reproduction to reproduce particularly desirable plants.
- ▶ Horticulturists often graft different plants together to take advantage of favorable properties of both stock and scion. Review Figure 38.18
- ▶ Tissue culture techniques, based on the totipotency of many plant cells, are used to propagate plants asexually, to produce virus-free clones of crop plants, and to manipulate plants by recombinant DNA technology.

For Discussion

1. For a crop plant that reproduces both sexually and asexually, which method of reproduction might the farmer prefer?
2. Thompson seedless grapes are produced by vines that are triploid. Think about the consequences of this chromosomal condition for meiosis in the flowers. Why are these grapes seedless? Describe the role played by the flower in fruit formation when no seeds are being formed. How do you suppose Thompson seedless grapes are propagated?
3. Poinsettias are popular ornamental plants that typically bloom just before Christmas. Their flowering is photoperiodically controlled. Are they long-day or short-day plants? Explain.
4. You plan to induce the flowering of a crop of long-day plants in the field by using artificial light. Is it necessary to keep the lights on continuously from sundown until the point at which the critical day length is reached?

39

Plant Responses to Environmental Challenges

^pr?v" " If you are attacked, it makes sense to

M call for help. Plants do this, too. When caterpillars

WF begin to chew on the leaves of corn, cotton, or some other plant species, the plants synthesize and release chemical signals into the atmosphere. These substances attract other insects that feed on the caterpillars.

Herbivores aren't the only challenges plants face, however. The environment teems with plant pathogens. We know of more than a hundred diseases that can kill a tomato plant, each of them caused by a different pathogen (including various bacteria, fungi, protists, and viruses). Like animals, plants have a variety of defenses against pathogens. And, like the defenses of our own bodies, these mechanisms are not perfect, but they keep the plant world in competitive balance with its pathogens.

Environmental challenges to plants aren't limited to herbivores and pathogens. Some physical conditions pose substantial problems for plants and thus limit the places where different kinds of plants can live. The most challenging physical environments include ones that are very dry (deserts), that are water-saturated, that are dangerously salty, that contain high concentrations of toxic substances such as heavy metals, and that are very hot or very cold.

This chapter focuses on how plants meet the myriad challenges presented by their biological and physical environments. We begin by examining interactions between plants and pathogens and go on to consider interactions between plants and herbivores. Then we discuss the adaptations of some types of plants to their physical environments.

Plant-Pathogen Interactions

Plants and pathogens have evolved together in a continuing "arms race." Pathogens have evolved mechanisms by which to attack plants, and plants have evolved defenses against them. Each set of mechanisms uses information from the other. The pathogen's enzymes break down the plant's cell walls, for example, and the breakdown products signal to the plant that it is under attack. In turn, the plant's defenses alert the pathogen that it is under attack.

Calling In an Air Strike

As this caterpillar of a corn earworm moth (*Helicoverpa zed*) munches on a cotton boll, it is triggering a series of reactions in the plant that may end in the attraction of other insects that will attack the caterpillar.

What determines the outcome of a battle between a plant and a pathogen? The key to success for the plant is to respond to the information about the pathogen quickly and massively. Plants use both mechanical and chemical defenses in this effort.

Plants seal off infected parts to limit damage

Tissues such as epidermis or cork protect the outer surfaces of plants, and these tissues are generally covered by cutin, suberin, or waxes. This protection is comparable to the nonspecific defenses of animals. When pathogens pass these barriers, other nonspecific plant defenses are activated.

The defense systems of plants and animals differ. Animals generally repair tissues that have been damaged by pathogens, but plants do not. Instead, they seal off and sacrifice the damaged tissue so that the rest of the plant does not become infected. This approach works because most plants, unlike most animals, are modular and can replace damaged parts by growing new ones.

One of a plant cell's first defensive responses is the rapid deposition of additional polysaccharides to the cell wall, reinforcing this barrier to invasion by the pathogen (Figure 39.1). These polysaccharides block the plasmodesmata, limiting the ability of viral pathogens to move from cell to cell. They also serve as a base upon which lignin may be laid down. Lignin enhances the mechanical barrier, and the toxicity of lignin building blocks makes the cell inhospitable to some pathogens.

680 CHAPTER THIRTY-NINE

Pathogen molecules

Q Some molecules from the pathogen are recognized directly.

Pathogen

^Some pathogenic enzymes attack the cell wall...

Defensive molecules

.and the breakdown products are recognized by a membrane receptor.

Plants also produce several types of pathogenesis-related proteins, or PR proteins. Some are enzymes that break down the cell walls of pathogens. These enzymes destroy some of the invading cells, and in some cases the breakdown products of the pathogen's cell walls serve as chemical signals that trigger further defensive responses. Other PR proteins may serve as alarm signals to plant cells that have not yet been attacked. In general, PR proteins appear not to be rapid-response weapons; rather, they act more slowly, perhaps after other mechanisms have blunted the pathogen's attack.

I Polysaccharides strengthen the cell wall.

39. 7 Signaling between Plants and Pathogens

Chemical interactions between plants and pathogens are highly coevolved. Plants produce molecules such as sugars that attract pathogens. But the presence of a pathogen stimulates the plant to produce defensive molecules that can work in many different ways.

Plants have potent chemical defenses against pathogens

When infected by certain fungi and bacteria, plants produce a variety of defensive compounds, among which are small molecules called phytoalexins and larger proteins called pathogenesis-related proteins (see Figure 39.1).

Phytoalexins are toxic to many fungi and bacteria. (Most are phenolics or terpenes, compounds that are also used to protect plants against herbivores; see Table 39.1.) They are produced by infected cells and their immediate neighbors within hours of the onset of infection. Enzymes from a pathogenic fungus can cause plant cell walls to release hormones called oligosaccharins (see Chapter 37), which trigger phytoalexin production. Because their antimicrobial activity is nonspecific, phytoalexins can

destroy many species of fungi and bacteria in addition to the one that originally triggered their production. Physical injuries, viral infections, and chemical compounds produced in response to damage by herbivores can also induce the production of phytoalexins.

The hypersensitive response is a localized containment strategy

Plants that are resistant to fungal, bacterial, or viral diseases generally owe this resistance to what is known as the hypersensitive response. Cells around the site of microbial infection die, preventing the spread of the pathogen by depriving it of nutrients. Some of the cells produce phytoalexins and other chemicals before they die. The dead tissue, called a necrotic lesion, contains and isolates what is left of the microbial invasion (Figure 39.2). The rest of the plant remains free of the infecting microbe.

One of the chemicals produced during the hypersensitive response is a close relative of aspirin. Since ancient times, people in Asia, Europe, and the Americas have used willow (*Salix*) leaves and bark to relieve pain and fever. The active ingredient in willow is salicylic acid, the same substance from which aspirin is derived:

Salicylic acid

OH

It now appears that all plants contain at least some salicylic acid. This compound plays a hormonal role in the plants' own defenses, often leading to a long-lasting effect that makes them resistant to later attacks by pathogens.

Systemic acquired resistance is a form of long-term "immunity"

Systemic acquired resistance is a general increase in the resistance of the entire plant to a wide range of pathogen species. It is not limited to the pathogen that originally triggered it or to the site of the original infection.

39.2 The Aftermath of a Hypersensitive Response

The necrotic spots on these leaves are a response to the fungus that causes strawberry blight.

The systemic acquired resistance that sometimes follows the hypersensitive response is accompanied by the synthesis of PR proteins. Treatment of plants with salicylic acid or aspirin leads to the production of PR proteins and to a resistance to pathogens. Salicylic acid treatment provides substantial protection against tobacco mosaic virus (a well-studied plant pathogen) and some other viruses.

Salicylic acid also serves as a hormone for disease resistance. In some cases, microbial infection in one part of a plant leads to the export of salicylic acid to other parts of the plant, where it causes the production of PR proteins before the infection can spread. The PR proteins then limit the extent of the infection. Infected plant parts also produce the closely related methyl salicylate (also known as oil of winter-green). This volatile substance travels to other plant parts through the air. It may be that methyl salicylate can also trigger the production of PR proteins in neighboring plants that have not yet been infected.

Some plant genes match up with pathogen genes

Many plants use the hypersensitive response and systemic acquired resistance as nonspecific defenses against various pathogens. However, the triggering of these responses resides in a highly specific mechanism, called gene-for-gene resistance. In gene-for-gene resistance, the ability of a plant to defend itself against a specific strain of

PLANT RESPONSES TO ENVIRONMENTAL CHALLENGES 681

a pathogen depends on the plant's having a particular allele of a gene that corresponds to a particular allele of a gene in the pathogen (Figure 39.3). Let's see how this matching works.

Plants have a large number of R genes (resistance genes), and many pathogens have sets of Avr genes (avirulence genes). Dominant R alleles favor resistance, and dominant Avr alleles make a pathogen less effective. If a particular plant has the dominant allele of an R gene and a pathogen strain infecting it has the dominant allele of the corresponding Avr gene, the plant will be resistant to that strain. This is true even when none of the other R-Avr pairs features corresponding dominant alleles. (This effect, one R-Avr pair overruling the others, is an example of epistasis, which was discussed in Chapter 10.)

The mechanism of gene-for-gene resistance is not completely understood. There are thousands of specific R genes among the plants, and their products have different functions. The Avr genes in pathogens are simply genes that cause the pathogen to produce a substance that elicits a defensive response in the plant. Most gene-for-gene interactions trigger the hypersensitive response.

Not all biological threats to plants come from microorganisms and viruses that cause diseases. Many animals, from

inchworms to elephants, eat plants.

Plants and Herbivores: Benefits and Losses

Herbivores—animals that eat plants—depend on plants for energy and nutrients. Plants have many defense mechanisms that protect them against herbivores, as we will see. First, let's consider how herbivores can have a positive effect on the plants they eat.

Grazing increases the productivity of some plants

In grazing, a predator eats part of a plant, such as the leaves, without killing its prey, which then has the potential

to grow back (Figure 39.4). What are the consequences of grazing? Is it always detrimental to plants, or are they somehow

39.3 Gene-for-Gene Resistance

A single pair of corresponding dominant alleles promotes resistance even if all the other pairs are mismatches.

If, in any pair, the host and pathogen both contain a dominant allele, the plant will resist the pathogen...

... but if either "partner" lacks the dominant allele, this pair will not cause gene-for-gene resistance.

adapted to their place in the food chain? Certain plants and their predators evolved together, each acting as the agent of natural selection on the other (see Chapter 29). Because of this coevolution, grazing actually increases photo-synthetic production in some plant species.

Removing some leaves from a plant may increase the rate of photosynthesis of the remaining leaves. This phenomenon probably is the result of several factors. First, nitrogen obtained from the soil by the roots no longer needs to be divided among so many leaves. Second, the export of sugars and other photosynthetic products from the leaves may be enhanced because the demand for those products in the roots is undiminished, while the sources for such products—leaves—have been decreased. The remaining leaves may compensate by photosynthesizing more rapidly.

A third and particularly significant factor increasing photosynthesis, especially in grasses, is an increase in the availability of light to the younger, more active leaves or leaf parts. The removal of older or dead leaves by a grazer decreases the shading of younger leaves. Unlike most other plants, which grow from their shoot and leaf tips, grasses grow from the base of the shoot and leaf, so their growth is not cut short by grazing.

Mule deer and elk graze many plants, including one called scarlet gilia. Their grazing removes about 95 percent of the aboveground part of each plant (Figure 39.5), but each plant quickly regrows not one, but four, replacement stems. Grazed plants produce three times as many fruits by the end of the growing season as do ungrazed plants.

EXPERIMENT

Question: Is grazing by herbivores always detrimental to a plant?

A scarlet gilia was cropped to the point indicated.

The cropped plant grew four new stems and produced almost three times as many offspring...

...as did uncropped control plants.

Conclusion: Cropping can lead to increased growth.

39.4 Is Grazing Helpful or Harmful to Plants?

Grazing mammals such as this North American elk exist in virtually all of Earth's biomes, and the plants they feed on have evolved along with them.

39.5 Overcompensation for Being Eaten

Experiments confirm that some plants benefit from the effects of grazing.

Some grazed trees and shrubs continue to grow until much later in the season than do ungrazed but otherwise similar plants. This longer growing season results in part because the removal of apical buds by the grazers stimulates lateral buds to become active, producing a more heavily branched plant. Leaves on ungrazed plants may also die earlier in the growing season than leaves on grazed plants.

A plant may benefit from moderate herbivory by attracting animals that spread its pollen or that eat its fruit and thus

disperse its seeds. Nevertheless, resisting attack by herbivores is often to the advantage of a plant.

Some plants produce chemical defenses

Although a plant cannot flee its herbivorous enemies, it may be able to defend itself chemically. Many plants attract, resist, and inhibit other organisms by producing special chemicals known as secondary products. Primary products are substances, such as proteins, nucleic acids, carbohydrates, and lipids, that are produced and used by all living things. Although all organisms use the same kinds of primary products, plants can differ as radically in their secondary products as they do in their external appearance.

The more than 10,000 known secondary plant products range in molecular weight from about 70 to more than 400,000, but most are of low molecular weight. Some are produced by only a single species, while others are characteristic of an entire genus or even family. These compounds help plants compensate for being unable to move.

The effects of defensive secondary products on animals are diverse. Some secondary products act on the nervous systems of herbivorous insects, mollusks, or mammals. Others mimic the natural hormones of insects, causing some larvae to fail to develop into adults. Still others damage the digestive tracts of herbivores. Some secondary products are toxic to fungal pests. Humans make commercial use of many secondary plant products as fungicides, insecticides, rodenticides, and pharmaceuticals.

While many secondary products have protective functions, others are essential as attractants for pollinators and seed dispersers. Table 39.1 lists the major classes of defensive secondary plant products and their biological roles.

Let's look at a specific example of an insecticidal secondary product, canavanine.

Some secondary products play multiple roles

Canavanine is an amino acid that is not found in proteins, but is closely similar to the amino acid arginine, which is found in almost all proteins. Canavanine has two important roles in those plants that produce it in significant quantities. The first role is as a nitrogen-storing compound in seeds. The second, defensive role is based on the similarity of canavanine to arginine:

NH-

C = NH

C—OH

O

Arginine

H₂N—C

C—OH

H₂O

Canavanine

Many insect larvae that consume canavanine-containing plant tissue are poisoned. The canavanine is incorporated into the insect's proteins in some of the places where the DNA has coded for arginine because the enzyme that charges the tRNA specific for arginine fails to discriminate accurately between the two amino acids. The structure of canavanine is different enough from that of arginine that some of the resulting proteins end up with a modified tertiary structure and hence reduced biological activity. These defects in protein structure and function lead to developmental abnormalities that kill the insect.

A few insect larvae are able to eat canavanine-containing plant tissue and still develop normally. How can this be? In these larvae, the enzyme that charges the arginine tRNA discriminates correctly between arginine and canavanine. The canavanine they ingest is thus not incorporated into the proteins they form, and the larvae are not harmed.

Many defenses depend on extensive signaling

Plant defenses result from a series of signals. Insects feeding on tomato leaves damage the cells, leading to a chain of events including the formation of hormones and ending with the production of an insecticide. The signaling steps in the production of one defensive compound, shown in Figure 39.6, involve two hormones. Systemin is a polypeptide hormone—the first polypeptide hormone to be discovered in plants. Jasmonates are formed from the unsaturated fatty acid linolenic acid. The

final step in this series is the production of a protease inhibitor. The inhibitor, once in an insect's gut, interferes with the digestion of proteins and thus stunts the insect's growth.

Jasmonic acid (a jasmonate)

Jasmonates also take part in the "call for help" described at the beginning of this chapter. In that case, a substance re-

39.6 A Signaling Pathway for Synthesis of an Insecticide

The chain of events initiated by an insect's attack and leading to the production of a defensive chemical can consist of many steps. These steps may include the synthesis of one or two hormones, binding of receptors, gene activation, and, finally, synthesis of a poison.

leased by chewing caterpillars is the first signal, leading to the formation of jasmonates by the plant. The jasmonates, in turn, trigger the formation of the volatile compounds that attract the insects that prey on the caterpillars.

Gene splicing may confer resistance to insects

Wild and domesticated common beans (*Phaseolus vulgaris*) differ in their resistance to attack by two species of bean weevils. Some wild bean seeds are highly resistant to these insects, but no cultivated bean seeds show such resistance. Scientists discovered that all weevil-resistant bean seeds contain a specific seed protein, arcelin. This protein has never been found in cultivated bean seeds. Therefore, the scientists hypothesized that arcelin is responsible for the resistance of some seeds to predation by the weevils.

To rule out other differences between wild and cultivated beans as being responsible for the resistance, the scientists performed two series of experiments. In one series, they crossed cultivated and wild bean plants. All of the progeny seeds of such crosses that contained arcelin showed resistance to weevils. In the other series of experi-

ments, the scientists worked with artificial bean seeds made by removing the seed coats of cultivated beans and grinding the remainder of the seeds into flour. They added different concentrations of arcelin to different batches and molded the flour into artificial seeds. They then let weevils attack the artificial seeds. The more arcelin the artificial seeds contained, the more resistant they were to weevils.

In preliminary tests, arcelin in cooked beans was shown not to be harmful to rats—a first step toward determining whether arcelin is safe in food for humans. Agricultural scientists must sometimes choose between crop protection and appeal to humans. A plant with sturdy chemical defenses may taste bad, make us sick, or even kill us.

The development of crop plants that produce their own pesticides is an active area of research in agricultural biotechnology. Scientists are seeking to introduce genes for arcelin and other resistance-conferring proteins into agriculturally important crops such as beans. One of the most widely applied approaches is the engineering of several crops, such as tomato, corn, and cotton, to express the toxin genes from *Bacillus thuringiensis* discussed in Chapter 17.

Why don't plants poison themselves?

Why don't the chemicals that are so toxic to herbivores and microbes kill the plants that produce them? Plants that produce toxic secondary products generally use one of the following measures to protect themselves:

- ▶ The toxic material is isolated in a special compartment, such as the central vacuole.
- ▶ The toxic substance is produced only after the plant's cells have already been damaged.
- ▶ The plant uses modified enzymes or modified receptors that do not recognize the toxic substance.

The first method is the most common. Plants using this method store their poisons in vacuoles if they are water-soluble. If hydrophobic, the poisons are stored in laticifers (tubes containing a white, rubbery latex) or dissolved in waxes on the epidermal surface. This compartmentalized storage keeps the toxic substance away from the mitochondria, chloroplasts, and other parts of the plant's own metabolic machinery.

Some plants store the precursors of toxic substances in one compartment, such as the epidermis, and store the enzymes that convert the precursors to the active poison in another compartment, such as the mesophyll. These plants produce the toxic substance only after being damaged. When an herbivore chews part of the plant, the cells rupture, and the enzymes come in contact with the precursors, producing the toxic product. The only part of the plant that is damaged by the toxic material is that which was already damaged by the herbivore. Plants that respond to attack by producing cyanide—a strong inhibitor of cellular respiration in all organisms that respire—are among those that use this protective measure.

The third protective measure is used by the canavanine-producing plants described earlier. These plants produce a

39.7 Disarming a Plant's Defenses

This beetle is inactivating a milkweed's defense system by cutting its laticifer supply lines.

tRNA-charging enzyme for arginine that does not bind canavanine. However, as we have seen, some herbivores can evade being poisoned by canavanine in a similar manner, demonstrating that no plant defense is perfect.

The plant doesn't always win

Milkweeds such as *Asclepias syriaca* are latex-producing (laticiferous) plants. When damaged, a milkweed releases copious amounts of toxic latex from its laticifers. Latex has long been suspected to deter insects from eating the plant, because insects that feed on neighboring plants of other species do not attack laticiferous plants. This observed behavior is consistent with, but does not prove, the hypothesis that the latex keeps the insects at bay.

Stronger support for the hypothesis was obtained by studying field populations of *Labidomera clivicollis*, a beetle that is one of the few insects that feed on *A. syriaca*. These beetles show a remarkable prefeeding behavior: They cut a few veins in the leaves before settling down to dine (Figure 39.7). Cutting the veins, with their adjacent laticifers, causes massive latex leakage and interrupts the latex supply to a downstream portion of the leaf. The beetles then move to the relatively latex-free portion and eat their fill.

Does this behavior of the beetles negate the adaptive value of latex protection? Not entirely. There are still great numbers of potential insect pests that are effectively deterred by the latex. And evolution proceeds. Over time, milkweed plants producing higher concentrations of toxins may be selected by virtue of their ability to kill beetles that cut their laticifers.

Having discussed how plants defend themselves against other organisms, we now turn our attention to how plants adapt to environments where water is a problem.

Water Extremes: Dry Soils and Saturated Soils

Water is often in short supply in the terrestrial environment. Some terrestrial habitats, such as deserts, intensify

this challenge, and many plants that inhabit particularly dry areas have one or more adaptations that allow them to conserve water. Plants adapted to dry environments are called xerophytes.

Some plants evade drought

Some desert plants have no special structural adaptations for water conservation other than those found in almost all flowering plants. Instead, they have an alternative strategy. These desert annuals simply evade the periods of drought. They carry out their entire life cycle—from seed to seed—during a brief period in which rainfall has made the surrounding desert soil sufficiently moist (Figure 39.8).

Some leaves have special adaptations to dry environments

Plants that remain active during dry periods must have structural adaptations that enable them to survive. The secretion of a heavier cuticle over the leaf epidermis to retard water loss is a common adaptation to dry environments. An even more common adaptation is a dense covering of epidermal hairs. Some species have stomata only in sunken

39.8 Desert Annuals Evade Drought

Seeds of desert plants often lie dormant for long periods awaiting conditions appropriate for germination. When they do germinate, they grow and reproduce rapidly before the short wet season passes. During the long dry spells, only seeds remain alive.

39.9 Stomatal Crypts

Stomata in the leaves of some xerophytes are in sunken pits called stomatal crypts. The hairs covering these crypts trap moist air. (A section of the leaf's interior can be seen at the top of the photo.)

During dry periods, the thorny, leafless stems of an ocotillo appear almost dead.

When water is on hand, leaves develop rapidly and provide the plant with photosynthetic products.

39.10 Opportune Leaf Production

The ocotillo, a xerophyte that lives in the lower deserts of the southwestern United States and northern Mexico, produces leaves only when there is sufficient water for photosynthesis.

cavities below the leaf surface, which reduces the drying effects of air currents; often these stomatal cavities contain hairs as well (Figure 39.9).

Succulence—the possession of fleshy, water-storing leaves—is an adaptation to dry environments. Ice plants and their relatives have fleshy leaves in which water may be stored. Others, such as ocotillo, produce leaves only when water is abundant, shedding them as the soil dries out (Figure 39.10). Cacti and similar plants have spines rather than typical leaves, and photosynthesis is confined to the fleshy stems. The spines may reflect incident radiation, or they may dissipate heat. Corn and some related grasses have leaves that roll up during dry periods, thus reducing the leaf surface area through which water is lost. Some trees, such as eucalyptuses, that grow in arid regions have leaves that hang vertically at all times, thus evading the midday sun (Figure 39.11).

Xerophytic adaptations of leaves minimize water loss by the plant. However, such adaptations simultaneously minimize the uptake of carbon dioxide and thus limit photosynthesis. In consequence, most xerophytes grow slowly, but they utilize water more efficiently than do other plants; that is, they fix more grams of carbon by photosynthesis per gram of water lost to transpiration than other plants do.

Plants have other adaptations to a limited water supply

Roots may also be adapted to dry environments. The Atacama Desert in northern Chile often goes several years without measurable rainfall. The landscape there is almost barren of plant life, save for many surprisingly large

39.7 7 Shade at Midday

Because eucalyptus leaves hang vertically, their flat surfaces are not presented directly to the midday sun. This adaptation minimizes heating as well as water loss.

PLANT RESPONSES TO ENVIRONMENTAL CHALLENGES 687

mesquite trees (genus *Prosopis*; Figure 39.12). These trees obtain water through taproots that grow to great depths, reaching water supplies far underground, as well as from condensation on their leaves.

A more common adaptation of desert plants is a root system that grows rapidly during rainy seasons but dies back during dry periods. Cacti have shallow but extensive fibrous root systems that effectively intercept water at the surface of the soil following even light rains.

Xerophytes and other plants that receive inadequate water may accumulate the amino acid proline to substantial concentrations in their vacuoles. As a consequence, the osmotic potential and water potential of their cells become more negative; thus these plants tend to extract more water from the soil than do plants that lack this adaptation. Plants living in salty environments share this and several other adaptations with xerophytes, as we will see.

As we have seen, there are many ways in which some plants eke out an existence in terrestrial environments with very little water. What happens if there is too much water?

In water-saturated soils, oxygen is scarce

Some plants live in environments so wet that the diffusion of oxygen to their roots is severely limited. Since most plant roots require oxygen to support respiration and ATP production, most plants cannot tolerate this situation for long.

Pneumatophores are root extensions that grow out of the water, under which the rest of the roots are submerged.

39.13 Coming Up for Air

The roots of the mangroves in this tidal swamp obtain oxygen through pneumatophores.

39.12 Mining Water with Deep Taproots

Death Valley, California, is not as arid as the Chilean Atacama, but the mesquite must reach far down into the sand dunes for its water supply.

Some species, however, are adapted to life in a water-saturated habitat. Their roots grow slowly and hence do not penetrate deeply. Because the oxygen level is too low to support aerobic respiration, the roots carry on alcoholic fermentation (see Chapter 7), which provides ATP for the activities of the root system but explains why growth is slow.

The root systems of some plants adapted to swampy environments have pneumatophores, which are extensions that grow out of the water and up into the air (Figure 39.13). Pneumatophores have lenticels and contain spongy tissues that allow oxygen to diffuse through them, aerating the submerged parts of the root system. Cypresses and some mangroves are examples of plants with pneumatophores.

Submerged or partly submerged aquatic plants often have large air spaces in the leaf parenchyma and in the petioles. Tissue containing such air spaces is called aerenchyma (Figure 39.14). Aerenchyma stores oxygen produced by photosynthesis and permits its ready diffusion to parts of the plant where it is needed for cellular respiration.

Aerenchyma also imparts buoyancy. Furthermore, because it contains far fewer cells than most other plant tissue, respiratory metabolism in aerenchyma proceeds at a lower rate, and the need for oxygen is much reduced.

Thus far we have considered water supply—either too little or too much—as a factor limiting plant growth. Other substances also can make an environment inhospitable to plant growth. One of these is salt.

688 CHAPTER THIRTY-NINE

Aerenchyma channels are lined with cells that send projections into them.

Vascular bundle

Open channel

39.14 Aerenchyma Lets Oxygen Reach Submerged Tissues

The scanning electron micrograph, a cross section of a petiole of the yellow water lily, shows a vascular bundle and aerenchyma.

Too Much Salt: Saline Environments

Worldwide, no toxic substance restricts flowering plant growth more than salt (sodium chloride) does. Saline — salty — habitats support, at best, sparse vegetation. Saline habitats themselves are diverse, ranging from hot, dry, salty deserts to moist, cool, salty marshes. Along the seashore are saline environments created by ocean spray. The ocean itself is a saline environment, as are river estuaries, where fresh and salt water meet and mingle. The salinization of agricultural land is an increasing global problem. Even where crops are irrigated with fresh water, sodium ions from the water accumulate in the

soil to ever greater concentrations as the water evaporates.

Saline environments pose an osmotic problem for plants. Because of its high salt concentration, a saline environment has an unusually negative water potential. To obtain water from such an environment, a plant must have an even more negative water potential than that of a plant in a nonsaline environment; otherwise, it will lose water, wilt, and die. A second problem is the potential toxicity of high concentrations of certain ions, notably sodium and chloride.

The halophytes—plants adapted to saline habitats—belong to a wide variety of flowering plant groups. How can these plants cope with a highly saline environment?

Most halophytes accumulate salt

Most halophytes share one adaptation: They accumulate sodium and, usually, chloride ions, and transport these ions to the leaves. The accumulated ions are stored in the central vacuoles of leaf cells, away from more sensitive parts of the cells. Nonhalophytes accumulate relatively little sodium, even when placed in a saline environment; of the sodium

that is absorbed by their roots, very little is transported to the shoot. The increased salt concentration in the tissues of halophytes makes their water potential more negative, so they can take up water more easily from the saline environment.

In 1999, scientists reported the first success in causing overexpression of a gene in *Arabidopsis* that enables sodium uptake. This gene encodes a Na^+/H^+ antiport protein in the tonoplast (the membrane surrounding the central vacuole). By making the gene produce a greater than normal number of these antiport proteins, the scientists increased sodium transport in *Arabidopsis*, converting this nonhalophyte into a halophyte. Further research along this line may result in a great boost to agriculture in saline environments. Biologists in Israel and elsewhere have had some success in breeding crops that can be watered with seawater or diluted seawater.

Some halophytes have other adaptations to life in saline environments. Some, for example, have salt glands in their leaves. These glands excrete salt, which collects on the leaf surface until it is removed by rain or wind (Figure 39.15). This adaptation, which reduces the danger of poisoning by accumulated salt, is found both in some desert plants, such as tamarisk, and in some mangroves growing in seawater in the Tropics.

Salt glands can play multiple roles, as in the desert shrub *Atriplex halimus*. This shrub has glands that secrete salt into small bladders on the leaves, where, by increasing the gradient in water potential, the salt helps the leaves obtain water from the roots. At the same time, by making the water potential of the leaves more negative, the salt reduces the transpirational loss of water to the atmosphere.

The adaptations we have just discussed are specific to halophytes. Several other adaptations are shared by halophytes and xerophytes.

Halophytes and xerophytes have some similar adaptations

Many halophytes, like some xerophytes, accumulate the amino acid proline in their cell vacuoles, making the water

39.75 Secreting Salt

This salty mangrove has special salt glands that secrete salt, which appears here as crystals on the leaves.

potential of their tissues more negative. Unlike sodium, proline is relatively nontoxic.

Succulence is another adaptation that halophytes and xerophytes have in common, as might be expected, since saline environments, like dry ones, make water uptake difficult. Succulence characterizes many halophytes that occupy salt marshes. There the salt concentration in the soil solution may change throughout the day; while the tide is out, for instance, evaporation increases the salt concentration. Succulence may offer a reserve of water for the plant during the period of maximum salinity; when the salinity drops as the tide comes in, the leaf's store of water is replenished. Many succulents—both xerophytes and halophytes—use crassulacean acid metabolism (CAM) and have reversed stomatal cycles that enable them to conserve water by closing their stomata in the daytime (see Figure 35.11). Other general adaptations to a saline environment include high root-to-shoot ratios, sunken stomata, reduced leaf areas, and thick cuticles.

Salt is not the only toxic solute found in soils. Some heavy metal ions are more toxic than sodium at equivalent concentrations.

Habitats Laden with Heavy Metals

High concentrations of some heavy metal ions, such as aluminum, mercury, lead, and cadmium, poison most plants. Some geographic sites are naturally rich in heavy metals as a result of normal geological processes. Acid rain leads to the release of

toxic aluminum ions in the soil. Other human activities, notably the mining of metallic ores, leave localized areas—known as tailings—with substantial concentrations of heavy metals and low concentrations of nutrients. Such sites are hostile to most plants, and seeds falling on them generally do not produce adult plants.

Mine tailings rich in heavy metals, however, generally are not completely barren (Figure 39.16). They may support healthy plant populations that differ genetically from populations of the same species on the surrounding normal soils. How can these plants survive?

Initially, some plants were thought to tolerate heavy metals by excluding them: By not taking up the metal ions, it was believed, the plant avoided being poisoned. However, measurements have shown that tolerant plants growing on mine tailings do take up heavy metals, accumulating them to concentrations that would kill most plants. Thus the tolerant plants must have a mechanism for dealing with the heavy metals they take up. Such tolerant plants may be found to be useful agents for bioremediation, a decontamination process by which the heavy metal content of some contaminated soils is decreased by living organisms.

We know the mechanism of at least one case of tolerance to a heavy metal. The roots of a buckwheat grown in China secrete oxalic acid soon after they are exposed to aluminum concentrations high enough to inhibit root growth in other plants. Oxalic acid combines with aluminum ions, forming a complex that does not inhibit growth.

'si*&ttpt^^^&^^z%?^^^*^^^<^^

39.16 Life after Strip Mining

Although high concentrations of heavy metals kill most plants, grass is colonizing this eroded strip mine in North Park, Colorado.

From mine to mine, the heavy metals in the soil differ. In Wales and Scotland, bent grass (*Agrostis*) grows near many mines. Samples of bent grass from several such sites were tested for their ability to grow in various solutions, each containing only one heavy metal. In general, the plants tolerated a particular heavy metal—the one most abundant in their habitat—but were sensitive to others. That is, they tolerated only one or two heavy metals, rather than heavy metals as a group.

Tolerant plant populations can evolve and colonize an area surprisingly rapidly. The bent grass population around a particular copper mine in Wales is resistant to copper and is relatively abundant, even though the copper-rich soil dates from mining done only a century ago.

Hot and Cold Environments

Temperatures that are too high or too low can stress plants and even kill them. Plants differ in their sensitivity to heat and cold, but all plants have their limits.

Any temperature extreme can damage cellular membranes:

- High temperatures destabilize membranes and denature many proteins, especially some of the enzymes of photosynthesis.
- Low temperatures cause membranes to lose their fluidity and alter their permeabilities to solutes.
- Freezing temperatures may cause ice crystals to form, damaging cellular membranes.

690 CHAPTER THIRTY-NINE

Plants have ways of coping with high temperatures

Transpiration, the evaporative loss of water, can cool a plant, but it also increases the plant's need for water. Therefore, it is not surprising that many plants living in hot environments have adaptations similar to those of xerophytes. These adaptations include epidermal hairs and spines that radiate heat, modified leaf displays that intercept less direct sunlight, and others.

Plants respond within minutes to high temperatures by producing several kinds of heat shock proteins. Among these are

chaperonins (see Chapter 3), which help other proteins maintain their structures and avoid denaturation. Threshold temperatures for the production of heat shock proteins vary, but 40°C is sufficient to induce them in most plants. We have much to learn about the dozens of heat shock proteins, but we do know that some other types of stress also induce their formation. Among these are chilling and freezing.

Some plants are adapted to survival at low temperatures

Low temperatures above freezing injure many plants, including important crops such as rice, corn, and cotton. Many plant species can be modified to resist the effects of cold spells by a process called cold-hardening, which involves repeated exposure to cool, but not injurious, temperatures. The hardening process is a slow one, requiring many days. A key change that occurs during the hardening process is an increase in the relative fraction of unsaturated fatty acids in membranes. Unsaturated fatty acids solidify at lower temperatures than do saturated ones. Thus, the membranes retain their fluidity and function normally at cooler temperatures.

Low temperatures induce the formation of certain heat shock proteins that protect against chilling damage. There are also cases of "cross-protection" by heat shock proteins that are induced by one type of stress and that protect against other stresses. Tomatoes shocked by 2 days of high temperatures, for example, formed heat shock proteins and became resistant to chilling damage for the next 3 weeks.

If ice crystals form within cells, they can kill the cells by puncturing organelles and plasma membranes. Even outside cells, the growth of ice crystals can draw water from the cells and dehydrate them. Freezing-tolerant plants have a variety of adaptations to cope with these problems. A common one is the production of antifreeze proteins that inhibit the growth of ice crystals.

Plants have many effective mechanisms for coping with environmental challenges of many kinds. Their success is obvious—just look around you.

ra

Chapter Summary Plant-Pathogen Interactions

- ▶ Plants and pathogens evolve together. Review Figure 39.1
- ▶ Plants can strengthen their cell walls when attacked.
- ▶ Plant chemical defenses include PR proteins and phy-toalexins.
- ▶ In the hypersensitive response, cells produce phytoalexins and then die, trapping the pathogens in dead tissue.
- ▶ The hypersensitive response is often followed by systemic acquired resistance, in which the hormone salicylic acid activates further synthesis of PR proteins and triggers responses in other parts of the plant.
- ▶ The hypersensitive response is nonspecific. A more specific response, called gene-for-gene resistance, matches up alleles in a plant's resistance genes and a pathogen's avirulence genes. Review Figure 39.3

Plants and Herbivores: Benefits and Losses

- ▶ Grazing by herbivores increases the productivity of some plants. Review Figure 39.5
- ▶ Some plants produce secondary products that function as chemical defenses against herbivores. Review Table 39.1
- ▶ Various hormones, including systemin and jasmonates, participate in the pathways leading to the production of defensive chemicals. Review Figure 39.6
- ▶ To avoid poisoning themselves, plants may confine the toxic substances they produce to special compartments, or they may produce the substances only after cells have been damaged, or they may form enzymes and receptors that are not affected by the substances.

Water Extremes: Dry Soils and Saturated Soils

- ▶ Desert annuals evade drought by living only long enough to take advantage of the brief period during which the soil has enough moisture to support them.
- ▶ Some leaves have special adaptations to dry environments: a thickened cuticle, epidermal hairs, sunken stomata, fleshy leaves and stems, spines, and altered leaf display angles.
- ▶ Other adaptations to dry environments include long taproots and root systems that die back seasonally.
- ▶ The submerged roots of some plants form pneumatophores to allow oxygen uptake from the air. Aerenchyma in submerged plant parts stores and permits the diffusion of oxygen. Review Figure 39.14

Too Much Salt: Saline Environments

► A saline environment restricts the availability of water to plants. Halophytes are plants that are adapted to such environments.

► Most halophytes accumulate salt, and some have salt glands that excrete the salt to the leaf surface.

► Halophytes and xerophytes have some adaptations in common.

Habitats Laden with Heavy Metals

► Aluminum, mercury, lead, and cadmium are among the heavy metals that are toxic to plants at high concentrations.

► Rather than excluding heavy metals, tolerant plants deal with them after taking them up. A given plant's tolerance is limited to only one or two heavy metals.

Hot and Cold Environments

► High temperatures destabilize cell membranes and some proteins.

► Adaptations to elevated temperatures include the production of heat shock proteins.

► Low temperatures cause membranes to lose their fluidity.

PLANT RESPONSES TO ENVIRONMENTAL CHALLENGES 691

► Ice crystals can puncture organelles and plasma membranes.

► Adaptations to low temperatures and freezing include a change in membrane fatty acid composition and the production of antifreeze proteins.

For Discussion

1. We mentioned the possibility of designing crop plants that produce their own pesticides. Now chemical companies are designing crop plants capable of detoxifying

weed killers, so that crops grow after farmers have destroyed competing vegetation. Discuss the likely usefulness and possible drawbacks of such applications of recombinant DNA technology.

2. How might plant adaptations affect the evolution of herbivores? How might adaptations of herbivores affect plant evolution?

The stomata of the common oleander, *Nerium oleander*, are sunk in crypts in its leaves. Whether or not you know what an oleander is, you should be able to describe an important feature of its natural habitat; what is this feature?

Explain why halophytes often use the same mechanisms for coping with their challenging environments as xerophytes do for coping with theirs.

In ancient times, people used less sophisticated methods for mining than we use today. Thus ancient mines often yield substantial profits to modern-day miners who find and work them. On the basis of material in this chapter, how might you try to locate the site of an ancient mine?

Part Six

The Biology

of Animals

Physiology, Homeostasis, and Temperature Regulation

4fc r The camel is called the "ship of the

W[^]BP desert" because it can carry a large load across It 1 1 a hot desert without having to drink for days. / I i L Under similar conditions, a human sweats profusely to keep body temperature from rising, and can lose from 1 to 4 liters of water an hour. Without water, a human can become dangerously dehydrated in an hour. The dehydration causes the circulatory system and the thermoregulatory systems to fail, and body temperature begins to rise. As body temperature rises above 40°C, a person becomes dizzy and disoriented and gradually becomes delirious, loses consciousness, suffers brain damage, and dies. A person without water can die in the desert in only a few hours.

Why are camels better able to deal with desert conditions than we are? Several adaptations are important, but one of the most significant is that the camel's body temperature rises and falls more than ours does. Whereas humans try to keep their body temperatures close to 37°C by sweating, the camel allows its body temperature to rise to about 41°C over the course of the day. The camel's insulating coat of fur helps to slow its uptake of heat, but by tolerating the rise in its body temperature, it does not squander its body water for evaporative cooling.

When the air temperature falls at night, the camel passively unloads its accumulated heat to the environment. But now the situation reverses, and the camel allows its body temperature to fall. A human starts to produce heat by shivering when body temperature falls below about 36°C, but the camel's body temperature can fall below 34°C without stimulating shivering. The heat a camel stores in its body by allowing its body temperature to rise 7°C between sunup and sundown would require the evaporation of at least 5 liters of water to dissipate if the camel tried to maintain a constant body temperature. The camel has other adaptations, too. When it does reach water, it can drink about a third of its body weight to replace its losses!

The camel is an example of an animal that can live in an extreme environment. Physiology is the study of how organisms work—the study of the functions of all of the parts and processes of living systems. By studying the physiology of animals, we can understand how many species man-

Ships of the Desert

Camels conserve body water by allowing their body temperature to rise during the day rather than using evaporative cooling such as sweating and panting.

age to live in extreme environments. By studying the special adaptations of such species, we frequently gain new information about how the human body works.

Animal physiology is the focus of the next twelve chapters of this book. Each chapter will present a system of structures that provides essential functions for the animal body. A structure might be a single cell, or it might be a population of similar cells that make up a tissue, or it might be a collection of different kinds of tissues that make up an organ. Two or more interacting organs constitute an organ system that serves one or more physiological functions. Organs and organ systems function to maintain the various physical and chemical aspects of an animal's internal environment at optimal levels.

694 CHAPTER FORTY

In this chapter we set the stage for our study of animal physiology by presenting an overview of how cells are organized into tissues, tissues into organs, and organs into organ systems with different physiological functions. We discuss general principles of how organ systems are controlled and regulated to achieve constancy in the internal environment. Most of this chapter deals with one feature of the internal environment: temperature. We will see how temperature influences living systems, what adaptations animals have for dealing with temperature challenges, and finally, how mammals regulate body

temperature.

Homeostasis: Maintaining the Internal Environment

Single-celled organisms meet all their needs by direct exchanges with the external environment. Even the cells of some small, simple multicellular animals meet their needs in this way. Such animals are common in the sea. Seawater contains nutrients and salts, and provides a relatively unchanging physical environment. Most cells of a sponge or a jellyfish are in direct contact with seawater, or are close enough that they can receive nutrients and eliminate wastes without specialized organs to transport nutrients and wastes around their bodies. This lifestyle is quite limiting, however. No part of the animal's body can be more than a few cell layers thick, every cell must be able to take care of all its own needs, and the animal is limited to environments that provide for all of its cellular needs.

t

Skin separates the internal and external environments.

EXTERNAL ENVIRONMENT

Foods, salts, and water

The evolution of an internal environment, distinct from the external environment, made complex multicellular animals possible. The internal environment consists of extracellular fluids that bathe every cell of the body, supplying nutrients and receiving wastes. Its physical and chemical conditions can be kept at levels favorable to the cells. The cells are thereby protected from the external environment, making it possible for an animal to occupy habitats that would not support its cells if they were exposed to it directly. In complex multicellular organisms, it became possible for cells to become specialized for tasks that could contribute to maintaining specific aspects of the internal environment. Some cells became organized into tissues specialized to maintain the salt and water balance of the internal environment, others became specialized to provide nutrients, and still others to maintain appropriate levels of oxygen and carbon dioxide. Specialized tissues and organs form systems within the internal environment, each providing something all the cells of an animal need (Figure 40.1).

The composition of the internal environment is constantly being perturbed by the external environment and by the activities of cells themselves. The internal environment of a person in a desert, for example, will either increase in temperature or decrease in volume and change in composition because of water loss. Simultaneously, the activities of the person's cells will be taking nutrients from and contributing wastes to the internal environment. The activities of the specialized tissues and organs must continuously correct the physical and chemical composition of the internal environment so that it remains

conducive to life.

The maintenance of constant conditions in the internal environment is called homeostasis. Homeostasis is an essential feature of complex animals. If an organ fails to function properly, homeostasis is compromised, and as a result, cells become damaged and die. The damaged cells are not just those of the organ that functions improperly, but the cells of other organs as well. Loss of homeostasis is a serious problem that makes itself worse. To avoid loss of homeostasis, the activities of organs must be controlled and regulated in response to changes in both the external and the internal environments.

§j Fluids of the internal environment bathe all cells of the organism and differ in composition from the external environment.

A circulatory system moves materials to and from all parts of the internal environment.

Unabsorbed matter

Organic waste products, salts, and water

Some organs carry out the exchange of materials between the internal and external environments.

Cells of organs exchange materials with each other via the internal environment.

40.1 Maintaining Internal Stability While On the Go

Organ systems maintain a constant internal environment that provides for the needs of all cells of the body, making it possible for animals to travel among different and often highly variable external environments.

Control and regulation require information; hence the organ systems of information—the endocrine and nervous systems—must be included in our discussions of every physiological function. For that reason, we treat the endocrine and nervous systems early in this part of the book. Subsequent chapters deal with the systems responsible for controlling various aspects of the internal environment. Although each chapter will focus on different organs, those organs are all made of the same tissue types. What are these tissue types, and what are their general features?

Tissues, Organs, and Organ Systems

Cells are the basic building blocks of multicellular animals. When cells with the same characteristics or specializations are grouped together, they form a tissue. There are four basic types of tissues—epithelial, connective, muscle, and nervous—but there are variations on each basic type. An organ is usually made up of several different tissue types (Figure 40.2).

Epithelial tissues cover the body and line organs

Epithelial tissues are sheets of densely packed, tightly connected cells that cover inner and outer body surfaces. They line hollow organs of the body such as the gut, the lungs, the bladder, and the blood vessels. Some epithelial cells have se-

An organ is composed of tissues.

Within an organ, tissues are organized in specific ways.

cretory functions—for example, those that secrete milk, mucus, digestive enzymes, or sweat. Others have cilia and help substances move over surfaces or through tubes. Since epithelial cells create boundaries between the inside and the outside of the body and between body compartments, they frequently have absorptive and transport functions. Epithelial cells can also be receptors that provide information to the nervous system. Smell and taste receptors, for example, are epithelial cells that detect specific chemicals.

An epithelial tissue can be classified according to its structure and the appearance of its cells:

► A simple epithelium is a single layer of cells, such as that forming the tubules of the kidney (Figure 40.3a).

► A stratified epithelium consists of multiple layers of cells, as is the case with the skin (Figure 40.3b).

► A pseudostratified epithelium really consists of a single layer of cells, but because the cells are of different lengths, they give the appearance of multiple layers (Figure 40.3c).

The shapes of the cells making up an epithelium can be squamous (flattened), cuboidal, or columnar. Most cuboidal and columnar epithelia are involved in transport or secretory functions and have an abundance of organelles such as mitochondria and Golgi apparatus. Squamous epithelia, such as the outer layer of the skin, have fewer organelles; they frequently serve structural functions and as permeability boundaries. Epithelial tissues have distinct inner and outer surfaces. The outer surface faces the air, as in the case of the skin and lungs, or a fluid-filled organ cavity, such as the lumen of the gut. These outer surfaces are made up of the apical ends of the epithelial cells, which may have cilia or may be highly folded to increase their surface area. The inner surface of an epithelium consists of the basal ends of the epithelial cells, which rest on an extracellular matrix called a basal lamina (see Figure 4.30).

The skin and the lining of the gut are examples of epithelial tissues that receive much wear and tear. Accordingly, cells in these tissues have a high rate of cell division to replace cells that die and are shed. Dandruff consists of discarded skin cells, and the well-known Pap smear test for cancer of the female reproductive tract is based on examination of shed epithelial cells.

40.3 Epithelial Tissue

(a) A single layer of cuboidal cells forms a simple epithelium lining the collecting ducts of a human kidney, (b) Multiple layers of squamous cells form a stratified epithelium, (c) The columnar cells of this pseudostratified epithelium lining the respiratory tract give the appearance of multiple layers.

Columnar cells in pseudostratified epithelium

Connective tissues support and reinforce other tissues

In contrast to the densely packed epithelial tissues, connective tissues consist of dispersed populations of cells embedded in an extracellular matrix that they secrete. The composition and properties of the matrix differ among types of connective tissues.

An important component of the extracellular matrix is protein fibers secreted by the connective tissue cells. The dominant protein in the extracellular matrix is collagen, which is, in fact, the most abundant protein in the body (representing 25 percent of total body protein). Collagen fibers have high tensile strength. They give the dense connective tissue of skin, tendons, and ligaments resistance to stretch. Similarly, the collagen fibers of reticular connective tissue provide a netlike framework for organs, giving them shape and structural strength. Loose connective tissue fills spaces between organs and has a low density of collagen fibers.

Another type of protein fiber in the extracellular matrix of connective tissues is the stretchable protein elastin. It can be stretched to several times its resting length and then recoil. Fibers composed of elastin are most abundant in elastic

connective tissue, such as that in the walls of the lungs and the large arteries. Elastin fibers in the skin are responsible for its ability to snap back when stretched, and gradual loss of these fibers with age causes gradual loss of the resiliency of the skin.

Proteoglycans are extracellular proteins that give connective tissues resistance to compression. Proteoglycans are abundant in the extracellular matrix of the connective tissues lining joints.

Cartilage and bone are connective tissues that provide rigid structural support. In cartilage, a network of collagen fibers is embedded in a rather flexible matrix consisting of a protein-carbohydrate complex called chondroitin sulfate. The cells that form cartilage are called chondrocytes, and they exist in small cavities in the cartilage (Figure 40.4a). Cartilage forms the entire skeletal system of sharks and rays, which are therefore called cartilaginous fishes.

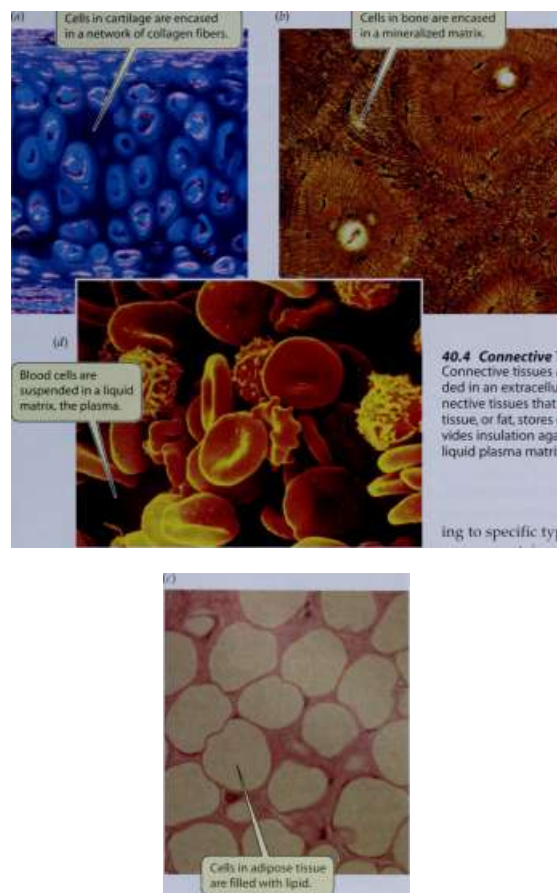

Cartilage forms the skeletons of the early developmental stages of more complex vertebrates, but it is gradually replaced by bone, a harder connective tissue (Figure 40.4b). Adult vertebrates retain cartilage as the support for flexible structures such as external ears, noses, and the windpipe. The extracellular matrix in bone also contains many collagen fibers, but it is hardened by the deposition of the mineral calcium phosphate. We will discuss bone in greater detail in Chapter 44.

Adipose tissue is a form of loose connective tissue that includes adipose cells, which form and store droplets of lipids (Figure 40.4c). Adipose tissue is a major source of stored energy, but it also serves to cushion organs, and layers of adipose tissue under the skin can provide a barrier to heat loss.

Blood is a connective tissue consisting of cells dispersed in an extensive extracellular matrix: the blood plasma (Figure 40.4d). The blood plasma is much more liquid than the extracellular matrices of the other connective tissues, but it too contains an abundance of proteins. One of those proteins, fibrinogen, serves a structural function when it is stimulated to polymerize and form a blood clot. Many of

Cells in cartilage are encased in a network of collagen fibers.

Cells in bone are encased in a mineralized matrix.

Blood cells are suspended in a liquid matrix, the plasma.

the proteins and cellular elements of the blood were presented in Chapter 19, and blood will be discussed again in Chapter 49.

Muscle tissues contract

Muscle tissues consist of elongated cells that can contract and cause movement. Muscle tissues are the most abundant tissues in the body, and they use most of the energy produced in the body. The contraction of muscle cells depends on intracellular protein filaments that can slide past each other. In Chapter 47, we will encounter three types of muscle tissues:

- Skeletal muscle connects bones to bones and is responsible for the body movements that constitute behavior.
- Smooth muscle is found in internal organs and is not under voluntary control; it performs functions such as moving food through the gut and constricting blood vessels.
- Cardiac muscle makes up the mass of the heart and pumps the blood.

Nervous tissues process information

There are two basic cell types in nervous tissues: neurons and glial cells. [Neurons, which are extremely diverse in size and form, generate electrochemical signals. Respond-

40.4 Connective Tissues

Connective tissues are of dispersed populations of cells embedded in an extracellular matrix, (a) Cartilage and (b) bone are connective tissues that provide rigid structural support, (c) Adipose tissue, or fat, stores energy, cushions the internal organs, and provides insulation against the cold, (d) Red and white blood cells in a liquid plasma matrix make up the connective tissue blood.

ing to specific types of stimuli, such as light, sound, pressure, or certain molecules, neurons generate sudden voltage changes across their plasma membranes. These nerve impulses can be conducted via long extensions of the neurons to other parts of the body, where they are communicated to other neurons, muscle cells, or secretory cells. Neurons are involved in controlling the activities of most organ systems to achieve homeostasis.

Glial cells do not generate or conduct electric signals, but they provide a variety of supporting functions for neurons. There are more glial cells than neurons in our nervous systems. We will detail and illustrate the properties of nervous

tissues in Chapters 44, 45, and 46.

Organs consist of multiple tissues

A discrete structure that carries out a specific function in the body is called an organ. Examples are the stomach, the heart,

the liver, or the kidney. Most organs include all four tissue types. The wall of the stomach is a good example (see Figure 40.2). The inner surface of the stomach that contacts food is lined with a simple epithelium. Some of the epithelial cells secrete mucus, enzymes, or stomach acid.

Beneath the epithelial lining is connective tissue. Within this connective tissue are nerves, glands (secretory epithelial cells), and blood vessels. Concentric layers of muscle tissue enable the stomach to contract to mix food with the digestive juices. A network of neurons between the muscle layers controls these movements and also partially controls the secretions of the stomach. Surrounding the stomach is a layer of connective tissue called the serosa.

An individual organ is usually part of an organ system—a group of organs that function together. The stomach is part of the digestive system, which also includes the food tube (esophagus), the small and large intestines, the pancreas, which secretes digestive enzymes, and the liver, which secretes bile. The major organ systems of mammals are outlined in Table 40.1.

^ Physiological Regulation and Homeostasis

Homeostasis depends on the ability to regulate the functions of the organs and organ systems to counteract influences that would change the physical or chemical composition of the internal environment. In this section we discuss the general properties of physiological regulatory systems, and then consider temperature regulation as a specific example.

Set points and feedback information are required for regulation

In addition to control mechanisms, regulation requires information. You can regulate the speed of a car only if you

know the speed at which you are traveling and the speed you wish to maintain. The desired speed is a set point, and the

reading on your speedometer is feedback information. When the set point and the feedback are compared, any difference between them is an error signal. Error signals suggest corrective actions, which you make by using the accelerator or brake (Figure 40.5).

Physiological regulation requires actions of cells, tissues, and organs, which are called effectors because they effect changes. Effectors are also referred to as controlled systems because their activities are controlled by commands coming from regulatory systems. Regulatory systems obtain, process, and integrate information and issue commands to the controlled systems. A fundamental way to analyze a regulatory system is to identify its source of feedback information.

Negative feedback is the most common type of feedback information in regulatory systems. The word "negative" indicates that this feedback information causes the effectors to reduce or reverse the process or influence that created the signal. In our car analogy, the recognition that you are going too fast is negative feedback if it causes you to slow down.

40.5 Control, Regulation, and Feedback

A driver uses information and control mechanisms to regulate the speed of the car.

Thermostats regulate temperature

The thermostat that is part of the heating-cooling system of a house is a regulatory system. It has upper and lower set points that you can adjust, and it receives feedback information from a sensor that measures room temperature. The circuitry of the thermostat converts differences between the set points and feedback information into signals that activate the controlled systems—the furnace and the air conditioner.

When room temperature rises above the upper set point, the thermostat activates the air conditioner to reduce the temperature; when room temperature falls below that upper set point, the air conditioner is turned off. If temperature falls below the lower set point, the furnace is activated, raising room temperature. The mechanism that senses room temperature provides negative feedback that is used to regulate both the air conditioner and the furnace. Negative feedback is a stabilizing influence in physiological regulatory systems. It contributes to homeostasis by stimulating actions that return a variable to its set point.

Is there any such thing as positive feedback in physiology? Although not as common as negative feedback, it does exist. Rather than returning a system to a set point, positive feedback amplifies a response. Examples of regulatory systems that use positive feedback are the responses that empty body cavities, such as urination, defecation, sneezing, and vomiting. Another example is sexual behavior, in which a little stimulation causes more behavior, which causes more stimulation, and so on.

Feedforward information is another feature of regulatory systems. The function of feedforward information is to change the set point. Seeing a deer ahead on the road when you are driving is an example of feedforward information (see Figure 40.5); this information takes precedence over the posted speed limit, and you change your set point to a slower speed. If you want the temperature of your house to be lower at night than during the day, you can add a clock to the thermostat to provide feedforward information about time of day.

These principles of control and regulation help organize our thinking about physiological systems. Once we understand how an organ or an organ system works, we can then ask how is it regulated. As an example, we will discuss in detail the system that regulates body temperature. But first, why is it necessary to regulate body temperature?

Temperature and Life

Over the face of Earth, temperatures vary enormously, from the boiling hot springs of Yellowstone National Park to the interior of Antarctica, where the temperature can fall below -80°C . Because heat always moves from a warmer to a cooler object, any change in the temperature of the environment causes a change in the temperature of an organism in that environment—unless the organism does something to regulate its temperature.

Living cells function over only a narrow range of temperatures. If cells cool to below 0°C , ice crystals damage their structures, possibly fatally. Some animals have adaptations such as antifreeze molecules in their blood that help them resist

freezing; others have adaptations that enable them to survive freezing. Generally, however, cells must remain above 0°C to stay alive.

700 CHAPTER FORTY

The upper temperature limit is less than 45°C for most cells. Some specialized algae can grow in hot springs at 70°C, and some archaea can live at near 100°C, but in general, proteins begin to denature and lose their function as temperatures approach 45°C. Most cellular functions are limited to the range between 0°C and 45°C, which are considered the thermal limits for life. A particular species, however, generally has much narrower limits.

Q_{10} is a measure of temperature sensitivity

Within the range 0° to 45°C / temperature changes create problems for animals. Most physiological processes, like the biochemical reactions that constitute them, are temperature-sensitive, going faster at higher temperatures (see Figure 6.26). The temperature sensitivity of a reaction or process can be described in terms of Q_{10} , a quotient calculated by dividing the rate of a process or reaction at a certain temperature, R_T , by the rate of that process or reaction at a temperature 10°C lower, R_{T-10} :

R_T

Q_k

Q_{10} can be measured for a simple enzymatic reaction or for a complex physiological process, such as the rate of oxygen consumption. If a reaction or process is not temperature-sensitive, it has a Q_{10} of 1. Most biological Q_{10} values are between 2 and 3, which means that reaction rates double or triple as temperature increases by 10°C (Figure 40.6).

Changes in temperature can be particularly disruptive to an animal's functioning because all the component reactions in the animal do not have the same Q_{10} . Individual reactions with different Q_{10} 's are linked together in complex networks that carry out physiological processes. Changes in temperature shift the rates of some reactions

The larger the Q_{10} , the faster the reaction rate rises in response to an increase in temperature.

more than those of others, thus disrupting the balance and integration that the processes require. For homeostasis, organisms must be able to compensate for or prevent changes in temperature.

An animal's sensitivity to temperature can change

The body temperature of some animals is tightly coupled to the environmental temperature. Think of a fish in a temperate-zone pond. As the temperature of the pond changes from 4°C in midwinter to 24°C in midsummer, the body temperature of the fish does the same (Figure 40.7). We can bring the fish into the laboratory in the summer and measure its metabolic rate (the sum total of the energy turnover of its cells, often measured by O_2 consumption). If we measure the metabolic rate at different water temperatures, we might plot our data as shown by the red line in Figure 40.7 and calculate a Q_{10} of 2. We predict from our graph that in winter, when the temperature is 4°C, the fish's metabolic rate will be only one-fourth of what it was in the summer. We then return the fish to its pond.

When we bring the fish back to the laboratory in the winter and repeat the measurements, we find, as the blue line shows, that its metabolic rate at 4°C is not as low as we predicted; rather, it is almost the same as it was at 24°C in the summer. If we repeat the measurement over a range of temperatures, we find that the fish's metabolic rate is always higher than the rate we predicted from the measurement we took at the same temperature in the summer. This difference is due to acclimatization, the process of physiological and biochemical change that an animal undergoes in response to seasonal changes in climate.

Seasonal acclimatization in the fish has produced metabolic compensation, which readjusts the biochemical machinery to counter the effects of temperature. What might account for such a change? Look again at Figure 6.26, which shows the different optimal temperatures of enzymes. If the fish can express similar enzymes that operate at different optimal temperatures, it can compensate metabolically by catalyzing reactions with one set of enzymes in summer and another set in winter. The end result is that metabolic functions are much less sensitive to long-term changes in temperature than they are to short-term thermal fluctuations.

Maintaining Optimal Body Temperature

Animals can be classified by how they respond to environmental temperatures.

- A homeotherm is an animal that maintains a constant body temperature.
- A poikilotherm is an animal whose body temperature changes when the temperature of its environment (the ambient temperature) changes.

This system of classification says something about the biology of the animals, but it presents problems. Should a fish in the deep ocean, where the temperature changes very little, be called a homeotherm? Should a hibernating mam-

EXPERIMENT

Question: How does a fish acclimatize to seasonal temperature changes?

METHOD Bring fish into the lab—in winter and summer—and measure its metabolic rate (O_2 consumption) at its natural pond temperature (it) and at other temperatures (•).

RESULTS

O_2
4°C
Winter pond temperature
14°C
24°C
Summer pond temperature

Conclusion: Between summer and winter a slow process of acclimatization compensates for seasonal temperature changes.

40.7 Metabolic Compensation

In its natural environment, a fish's metabolism readjusts, or acclimatizes, to compensate for seasonal changes in temperature. regulates its body temperature at a constant level some of the time.

Another set of terms classifies animals on the basis of the sources of heat that determine their body temperatures.

- Ectotherms depend largely on external sources of heat, such as solar radiation, to maintain their body temperatures above

the environmental temperature.

► Endotherms can regulate their body temperatures by producing heat metabolically or by mobilizing active mechanisms of heat loss.

Mammals and birds are endotherms; animals of all other species behave as ectotherms most of the time.

Ectotherms and endotherms respond differently in metabolic chambers

A small lizard is an example of an ectotherm. We can compare it with a mouse, which is an endotherm of the same body size. We can put each animal in a metabolic chamber and measure body temperatures and metabolic rates as we change the temperature of the chamber from 0°C to 35°C.

The results obtained from the two species differ. The body temperature of the lizard equilibrates with that of the chamber, whereas the body temperature of the mouse remains at 37°C (Figure 40.8#). The metabolic rate of the lizard decreases as the temperature decreases (Figure 40.8b). In contrast, the mouse's metabolic rate increases as chamber temperature falls below about 27°C (notice that you must read the graph right to left to see this). The lizard apparently cannot regulate its body temperature or metabolism independently of environmental temperature. The mouse, however, regulates its body temperature by in-

mal that allows its body temperature to drop to nearly the temperature of its environment be called a poikilotherm? The problem posed by the hibernator has been solved by creating a third category: the heterotherm, an animal that

creasing its metabolic rate, which increases its production of body heat.

Ectotherms and endotherms use behavior to regulate body temperature

We can test our laboratory conclusion that the lizard cannot regulate its body temperature. To do this, we release the lizard in its desert habitat and measure its temperature as it goes about its normal behavior in this environment, where temperature can change 40°C in a few hours (Figure 40.9).

Unlike what we observed in the metabolic chamber, the body temperature of the lizard is at times considerably different from the environmental temperature. At night, the temperature in the desert may drop close to freezing, but the temperature of the lizard remains stable at 16°C. No mystery here: The lizard spends the night in a burrow, where the soil temperature is a constant 16°C.

Early in the morning, soon after sunrise, the lizard emerges from its burrow. The air temperature is still cool, but the lizard's body temperature rises above 30°C in less than 30 minutes. The lizard achieves this by basking on a rock with maximum exposure to the sun. As its skin absorbs solar radiation, its body temperature rises considerably above the air temperature. By altering its exposure to the sun, the lizard maintains its body temperature around 35°C all morning.

By noon, the air temperature near the surface of the desert has risen to 50°C, but the lizard maintains its body temperature around 35°C by staying mostly in the shade and frequently in the branches of bushes, where there is a cooling breeze. As afternoon progresses, the air cools, and the lizard again spends more of its time in the sun and on hot rocks to maintain its body temperature around 35°C. The lizard returns to its burrow just before sunset, and its body temperature rapidly drops to 16°C.

Our conclusion must be that the lizard can regulate its body temperature quite well by behavioral mechanisms rather than by internal metabolic mechanisms. In our laboratory experiment, the lizard in the chamber could not use its thermoregulatory behavior, but in its natural environment it could move to different places to alter the heat exchange between its internal and external environments.

But behavioral thermoregulation is not the exclusive domain of ectotherms. It is also the first line of

40.9 An Ectotherm Uses Behavior to Regulate Its Body Temperature

The lizard's body temperature is dependent on environmental heat, but it can regulate its temperature by moving between different environments.

Sunrise

defense for endotherms. When the option is available, most animals select the thermal microenvironments that are best for them. They may change their posture, orient to the sun, move between sun and shade, and move between still air and moving air, as demonstrated by the lizard in our field experiment. Examples of more complex thermoregulatory behavior are nest construction and social behavior such as huddling. Humans select appropriate clothing and heat or cool their buildings. Behavioral thermoregulation is widespread in the animal kingdom (Figure 40.10).

Both ectotherms and endotherms control blood flow to the skin

Just as behavioral thermoregulation is not the exclusive domain of ectotherms, physiological thermoregulation is not the exclusive domain of endotherms. Both ectotherms and endotherms can alter the rate of heat exchange between their bodies

and their environments by controlling the flow of blood to the skin.

The skin is the interface between the internal and the external environment, and heat exchanges that alter body temperature occur across this interface. Heat exchange between the skin and the external environment occurs through four mechanisms: radiation, conduction, convection, and evaporation (Figure 40.11).

Heat exchange between the internal environment and the skin occurs largely through blood flow. For example, when a person's body temperature rises as a result of exercise, blood flow to the skin increases, and the skin surface becomes quite warm. The heat brought to the skin by the blood is lost to the environment, and this loss helps to bring the body temperature back to normal. In contrast, when a person is exposed to cold, the blood vessels supplying the skin constrict, decreasing blood flow and heat transport to the skin and reducing heat loss to the environment.

A lizard basks in the sun when air temperature is cold.

£] The lizard shuttles between sun and shade when air temperature is warm.

JJThe lizard avoids sun when air temperature is hot.

JJThe lizard returns to the constant temperature of its burrow at night.

(b)

The control of blood flow to the skin can be an important adaptation for an ectotherm like the marine iguana of the Galapagos archipelago. The Galapagos are volcanic islands that lie on the equator, but they are bathed by very cold oceanic currents. Marine iguanas are reptiles that bask on black lava rocks on shore and swim in the cold ocean, where they feed on algae. When the iguanas are feeding,

Evaporation of water from body surfaces or breathing passages cools the body.

Solar radiation

40.70 Endotherms Can Use Behavior to Thermoregulate

(a) Humans must put on many layers of insulating clothing to help their thermoregulatory mechanisms keep pace with the extreme cold of western Siberia. (f<) When air temperatures on the African savanna soar, an elephant may use a cool shower to thermoregulate.

they cool to the temperature of the sea, which makes them slower and more vulnerable to predators, and probably incapable of efficient digestion. They therefore alternate between feeding in the cold

— sea and basking in the sun

on the hot rocks. It is advantageous for iguanas to retain body heat as long as possible while swirruring and to warm up as fast as possible when basking. They adjust by changing their heart rate, and therefore their blood flow (Figure 40.12).

Some ectotherms produce heat

Some ectotherms raise their body temperatures by producing heat. For example, the powerful flight muscles of many insects must reach $35^{\circ}\text{--}40^{\circ}\text{C}$ before the insects can fly, and they must maintain these high temperatures during flight,

even at air temperatures around 0°C . Such insects produce the required heat by contracting their flight muscles in a manner analogous to shivering in mammals (Figure 40.13). The heat-producing ability of these insects can be quite remarkable. Probably the most impressive case is a species of scarab beetle that lives mostly underground in mountains north of Los Angeles, California. To mate, these beetles come above ground, and males fly in search of females. They un-

Objects in the environment exchange radiation with each other and with the sky. Warmer objects lose heat to cooler objects.

Heat is lost by convection /hen a stream of air (wind) is below body surface temperature.

Radiation energy exchange with environment

Conduction is the direct transfer of heat when objects of different temperatures come into contact.

40.11 Animals Exchange Heat with the Environment

An animal's body temperature is determined by the balance between internal heat production and the avenues of heat exchange with the environment: radiation, conduction, convection, and evaporation.

704 CHAPTER FORTY

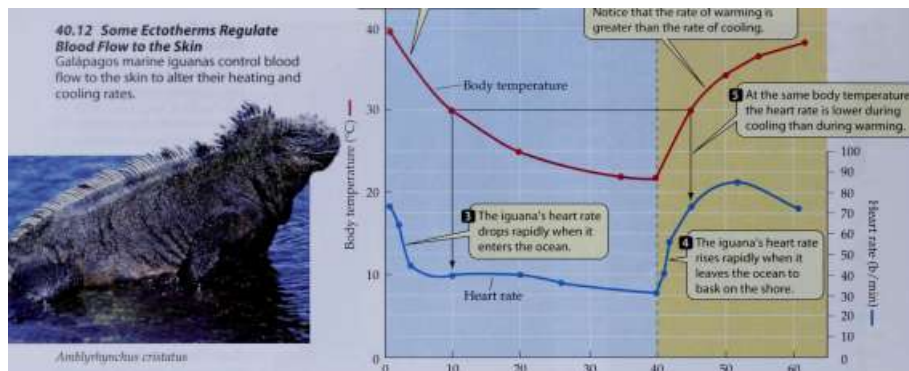

40.12 Some Ectotherms Regulate Blood Flow to the Skin

Galapagos marine iguanas control blood flow to the skin to alter their heating and cooling rates.

f

As soon as the iguana enters the ocean, it begins to cool.

When the iguana leaves the ocean to bask on the shore, it begins to warm. Notice that the rate of warming is greater than the rate of cooling.

Amblyrhynchus cristatus

undertake this mating ritual at night, in winter, and only during snowstorms.

Honeybees regulate temperature as a group. They live in large colonies consisting mostly of female worker bees that maintain the hive and rear the offspring of the single queen bee. During winter, honeybee workers combine their individual heat-producing abilities to regulate the temperature of the brood. They cluster around the brood and adjust their joint metabolic heat production and density of clustering so that the brood temperature remains remarkably constant, at about 34°C, even as the outside air temperature drops below freezing.

Some reptiles use metabolic heat production to raise their body temperatures above the air temperature. The female Indian python protects her eggs by coiling her body around them. If the air temperature falls, she contracts the muscles of her body wall to generate heat. The python is able to maintain the temperature of her body—and therefore that of her eggs—above air temperature.

Some fish elevate body temperature by conserving metabolic heat

It is particularly difficult for fish to raise their body temperatures because blood pumped from their hearts goes to the gills to pick up oxygen, where it comes into close contact with cool water flowing over the thin gill membranes. The blood equilibrates with the outside water temperature before it travels through the rest of the body. Any heat transferred to the blood from active muscles is lost rapidly to the environment when the blood flows through the gills. It is thus surprising to find that some large, rapidly swimming fishes, such as bluefin tuna and great white sharks, can maintain temperature differences as great as 10°-15°C between their bodies and the surrounding water. The heat comes from their powerful swimming muscles, and the ability of these "hot" fish to conserve that heat is due to remarkable arrangements of their blood vessels.

30 40

Time (min)

In the usual ("cold") fish circulatory system, oxygenated blood from the gills collects in a large dorsal vessel, the aorta, which travels through the center of the fish, distributing blood to all organs and muscles (Figure 40.14a). "Hot" fish have a smaller central dorsal aorta. Most of their oxygenated blood is transported in large vessels just under the skin (Figure 40.14b). Hence the cold blood from the gills is kept close to the surface of the fish. Smaller vessels trans-

During pre-flight warm-up, flight muscles contract simultaneously. Pulling against one another, they produce heat but do not cause the wings to beat (similar to human shivering).

T

In the gills, blood is oxygenated and comes to the same temperature as water.

I Cold blood flows from the gills to the body in arteries just under the skin.

40.14 Comparing Cold and Hot Fish

(a) Most fish species are "cold fish," whose circulatory systems conduct cool, oxygenated blood from the gills through a large dorsal aorta to the rest of the body, (b) The blood vessel anatomy of "hot" fish species allows for heat exchange between the cold arterial blood entering the muscles and the departing venous blood, which has been warmed by the metabolism of the muscles.

porting this cold blood into the muscle mass run parallel to the vessels transporting warm blood from the muscle mass back toward the heart. Since the vessels carrying the cold blood into the muscle are in close contact with the vessels carrying warm blood away, heat flows from the warm to the cold blood and is therefore trapped in the muscle mass. Because heat is exchanged between blood vessels carrying blood in opposite directions, this adaptation is called a countercurrent heat exchanger. It keeps the heat within the muscle mass, enabling the fish to have an internal body temperature considerably above the water temperature. Why is it advantageous for the fish to be warm? Each 10°C rise in muscle temperature increases the fish's sustainable power output almost threefold!

Thermoregulation in Endotherms

As we saw in Figure 40.8, endotherms respond to changes in environmental temperature by changing their rates of heat production, measured as metabolic rate. Within a narrow range of environmental temperatures called the thermoneutral zone, the metabolic rate of endotherms is low and independent of temperature. The metabolic rate of a resting animal at a temperature within the thermoneutral zone is called the basal metabolic rate. It is usually measured on animals that are quiet but awake, and that are not

Countercurrent heat exchanger

I Arterial blood flowing into the muscles is warmed by venous blood flowing out of the muscles.

using energy for digestion, reproduction, or growth. A resting animal consumes energy at the basal metabolic rate just to carry out all of its minimal body functions.

The basal metabolic rate of an endotherm is about six times greater than the metabolic rate of an ectotherm of the same size and at the same body temperature (see Figure 40.8b). A gram of mouse tissue consumes energy at a much higher rate than does a gram of lizard tissue when both tissues are at 37°C. This difference results from basic changes in cell metabolism that accompanied the evolution of endotherms from their ectothermic ancestors.

Endotherms actively increase heat production or heat loss

The thermoneutral zone is bounded by a lower critical temperature and an upper critical temperature. Figure 40.15 describes the thermoregulatory responses of a mammal at temperatures outside its thermoneutral zone.

When the environmental temperature falls below the lower critical temperature, mammals can create heat for thermoregulation through shivering and nonshivering heat production. Birds use only shivering heat production. Shivering uses the contractile machinery of skeletal muscles to consume ATP without causing observable behavior. The muscles pull against each other so that little movement other than a tremor results. All the energy from the conversion of ATP to ADP in this process is released as heat. Shivering heat production is perhaps too narrow a term; energy

Q Within the thermoneutral zone, body temperature is regulated by altering heat loss through the skin.

Upper critical temperature

o Below the lower critical temperature, the animal produces metabolic heat to compensate for increased heat loss to the environment.

§) Above the upper critical temperature, the animal must expend energy to lose heat by panting or sweating, which makes its metabolic rate increase.

Vertebral column

Heart

expenditure due to increased muscle tone and increased body movements also contributes to increased heat production in the cold.

Most nonshivering heat production occurs in specialized adipose tissue called brown fat (Figure 40.16). This tissue looks brown because of its abundant mitochondria and rich blood supply. In brown fat cells, a protein called thermogenin uncouples proton movement from ATP production, allowing protons to leak across the inner mitochondrial membrane rather than having to pass through the ATP synthase protein and generate ATP (review the discussion of respiration in Chapter 7). As a result, metabolic fuels are consumed without producing ATP, but heat is still released. Brown fat is especially abundant in newborn infants of many mammalian species, in some adult mammals that are small and acclimatized to cold, and in mammals that hibernate.

Decreasing heat loss is important for life in the cold

Outside the thermoneutral zone, maintaining a constant body temperature requires the expenditure of energy.

mammals, but almost no reptiles or amphibians, live in very cold habitats. What adaptations besides endothermy characterize species that live in the cold?

The most important adaptations of endotherms to cold environments are those that reduce heat loss to the environment. Since most heat is lost from the body surface, many cold-climate species have a smaller surface area than their warm-climate cousins, even when their body masses are the same. Rounder body shapes and shorter appendages reduce the surface area-to-volume ratios of some cold-climate species; compare, for example, the San Joaquin kit fox and the arctic fox (Figure 40.17).

Another means of decreasing heat loss is to increase thermal insulation. Animals adapted to cold have much thicker layers of fur, feathers, or fat than do their warm-climate relatives. The fur of an arctic fox or a northern sled dog provides such good thermal insulation that those animals don't even begin to shiver until the air temperature drops as low as -20°C to -30°C .

Fur and feathers are good insulators because they trap a layer of still, warm air close to the skin surface. If that air is displaced by water, insulation is drastically reduced. In many species, oil secretions spread through fur or feathers by grooming are critical for resisting wetting and maintain-

Brown fat occurs in specific anatomical locations.

40.76 Brown Fat

In many mammals, specialized brown fat tissue produces heat.

40.17 Adaptations to Hot and Cold Climates

(a) The San Joaquin kit fox, a desert dweller, has a large surface area for its body. The large ears serve as heat exchangers, passing heat from the fox's blood to the surrounding air. (f>) The thick fur of the arctic fox provides insulation in the frigid winter. Its ears and extremities are relatively smaller than those of the kit fox.

ing a high level of insulation.

Humans change their thermal insulation by putting on or taking off clothes. How do other animals do it? We have already discussed one example, the ectothermic marine iguana, which controls blood flow to its skin. Increasing or decreasing blood flow to the skin is an important thermoregulatory adaptation for endotherms as well. In a hot environment, your skin feels hot because there is a high rate of blood flow through it, but when you sit in an overly airconditioned theater, your hands, feet, and other body surfaces feel cold as blood flow to those areas decreases.

Evaporation of water is an effective way to lose heat

For highly insulated arctic animals, and for many large mammals in all climates, getting rid of excess heat can be a serious problem, especially during exercise. Arctic species usually have an area on the body surface, such as the abdomen, that has only a thin layer of fur and can act as a window for heat loss. Large mammals, such as elephants, rhinoceroses, and water buffalo, have little or no fur and seek places where they can wallow in water when the air

temperature is too high. Having water in contact with the skin greatly increases heat loss because water has a much greater capacity for absorbing heat than air does.

A gram of water absorbs about 580 calories of heat when it evaporates. Water is heavy, however, so animals do not carry an excess supply of it. Furthermore, hot environments tend to be arid places where water is a scarce resource. Therefore, evaporation of water by sweating or panting is usually a last resort for animals adapted to hot environments (recall the camels at the beginning of this chapter).

Sweating and panting are active processes that require the expenditure of metabolic energy. That's why the metabolic rate increases when the upper critical temperature is exceeded (see Figure 40.15). A sweating or panting animal is producing heat in the process of dissipating heat, which can be a losing battle. Animals can survive in environments that are below their lower critical temperature much better than they can in environments above their upper critical temperature.

The Vertebrate Thermostat

The thermoregulatory mechanisms and adaptations we have discussed are the controlled systems for the regulation of body temperature. These controlled systems must receive commands from a regulatory system that integrates information relevant to the regulation of body temperature. Such a regulatory system can be thought of as a thermostat. All animals that thermoregulate, both vertebrate and invertebrate, must have regulatory systems, but here we will focus on the vertebrate thermostat.

Where is the vertebrate thermostat? Its major integrative center is at the bottom of the brain in a structure called the hypothalamus. If you slide your tongue back as far as possible along the roof of your mouth, it will be just a few centimeters below your hypothalamus. The hypothalamus is a part of many regulatory systems, so we will refer to it again in the chapters to come. If the hypothalamus of a mammal's brain is damaged, the animal loses its ability to regulate its body temperature, which then rises in warm environments and falls in cold ones.

The vertebrate thermostat uses feedback information

What information does the vertebrate thermostat use? In many species, the temperature of the hypothalamus itself is the major source of feedback information to the thermostat. Cooling the hypothalamus causes fish and reptiles to seek a warmer environment, and heating the hypothalamus causes them to seek a cooler environment. In mammals, cooling the hypothalamus can stimulate constriction of the blood vessels supplying the skin and increase metabolic heat production. Because it activates these thermoregulatory responses, cooling the hypothalamus causes the body temperature to rise. Conversely, warming the hypothalamus stimulates dilation of blood vessels supplying the skin and sweating or panting, and the overall body temperature falls (Figure 40.18).

...and the animal's body temperature fell.

0.5 Time (hours)

>nclusion: The ground squirrel's hypothalamus acts as a thermostat.

The hypothalamus appears to generate a set point like a setting on the thermostat of a house. When the temperature of the hypothalamus exceeds or drops below that set point, thermoregulatory responses (the controlled system) are activated to reverse the direction of temperature change. Hence, hypothalamic temperature is a negative feedback signal.

Heating and cooling the hypothalamus show that an animal has separate set points for activating different thermoregulatory responses. If the hypothalamus of a mammal is cooled, the vessels supplying blood to the skin constrict at a specific hypothalamic temperature. A slightly lower hypothalamic temperature initiates shivering. If the hypothalamic temperature is then raised, shivering ceases; then blood vessels supplying the skin dilate; and at still higher hypothalamic temperatures, panting starts. We can describe the characteristics of hypothalamic control of each thermoregulatory response. For example, if we measure metabolic heat production while heating and cooling the hypothalamus (see Figure 40.18), we can describe the results graphically (Figure 40.19). Within a certain range of hypothalamic temperatures, metabolic heat production remains

low and constant, but cooling the hypothalamus below a certain level—a set point—stimulates increased metabolic heat production. The increase in heat production is proportional to how much the hypothalamus is cooled below the set point. This regulatory system is much more sophisticated than a simple on-off thermostat like the one in a house.

The vertebrate thermoregulatory system integrates other sources of information in addition to hypothalamic temperature. It uses information about the temperature of the environment as registered by temperature sensors in the skin. Changes in environmental temperature shift the hypothalamic set points for thermoregulatory responses. As Figure 40.19 shows, in a warm environment you might have to cool the hypothalamus of a mammal to stimulate it to shiver, but in a cold environment you would have to warm the hypothalamus of the same animal to stop it from shivering. The set point for the metabolic heat production response is higher when the skin is cold and lower when the skin is warm.

The temperature of the skin can be considered feedforward information that adjusts the hypothalamic set point. Many other factors also shift hypothalamic set points for responses. Set points are higher during wakefulness than during sleep, and they are higher during the active part of the daily cycle than during the inactive part, even if the animal is awake at both times.

40.18 The Hypothalamus Regulates Body Temperature

The observation that damage to the hypothalamus disrupts thermoregulation led to the finding that hypothalamus acts as a thermostat in the vertebrate body.

EXPERIMENT

Question: How does the mammalian thermoregulatory system integrate temperature information from the environment?

METHOD

RESULTS

Heat and cool the hypothalamus and measure metabolic rate (see Figure 40.18) at different environmental (ambient) temperatures.

Responses at 5°C ambient temperature

Q Cooling the hypothalamus below a certain level—a set point—stimulates increased metabolic heat production.

Ej The increase in heat production is proportional to how much the hypothalamus is cooled below the set point.

Within a certain range of hypothalamic temperatures, metabolic heat production remains low and constant.

37 Normal

Temperature of hypothalamus

Conclusion: Mammals have different set points for the metabolic heat production response to hypothalamic temperature at different environmental temperatures.

Fevers help the body fight infections

A fever is a rise in body temperature in response to substances called pyrogens that are derived from bacteria or viruses that invade the body. We respond to many infectious illnesses by getting a fever. Growing evidence suggests that fevers are adaptive responses that help the body fight disease-causing organisms.

The presence of a pyrogen in the body causes a rise in the hypothalamic set point for the heat production response. As a result, you shiver, put on a sweater, or crawl under a blanket, and your body temperature rises until it matches the new set point. At the higher body temperature you no longer feel cold, and you may not feel hot, but someone touching your forehead will say that you are "burning up." If you take an aspirin, it lowers your set point to normal. Now you feel hot, take off clothes, and even sweat until your elevated body temperature returns to normal.

Why do we take aspirin for fevers and "feeling crummy"? The pyrogens entering the body are attacked by cells of the immune system called macrophages (see Chapter 19). One of the things the macrophages do is to release chemicals called interleukins, which sound the alarm to other cells of the immune system throughout the body and trigger responses that contribute to feeling crummy. The interleukins also raise the hypothalamic set point for metabolic heat production. Among the intracellular signals trig-

40.19 Adjustable Set Points

Mammals have different set points for the metabolic heat production response to hypothalamic temperature at different environmental temperatures. Other factors, such as being asleep or awake, the time of day, or the presence of a fever, can also affect the set point.

regulated by interleukins are prostaglandins. Aspirin is a potent inhibitor of prostaglandin synthesis, thus explaining how this miracle drug reduces fever and makes us feel better.

Evidence suggests that moderate fevers help the body fight an infection. Some interesting studies were done on lizards that were given access to a heat lamp. These animals kept their body temperatures at about 38°C by adjusting their position with respect to the lamp. After they were injected with disease-causing bacteria, they spent more time close to the lamp and raised their body temperatures to 40°C and higher—they gave themselves fevers. To find out if the fever helped the lizards fight the bacteria, groups of lizards were given equal inoculations of bacteria, but were then placed in different incubators at 34°, 36°, 38°, 40°, and 42°C, respectively. All of the lizards at 34°C and 36°C died, about 25 percent at 38°C survived, and about 75 percent at 40°C and 42°C survived. Apparently fever helped the lizards fight the disease organisms.

However, extreme fevers (for example, 40°C) can be dangerous to humans and must be reduced. Even more modest fevers can be dangerous to people who have weakened hearts or those who are seriously ill. A fetus can be endangered when a pregnant woman has a fever. Fever-re-

ducing drugs may be important in such cases.

Animals can save energy by turning down the thermostat

Hypothermia is the condition in which body temperature is below normal. It can result from a natural turning down of the thermostat, or from traumatic events such as starvation (lack of metabolic fuel), exposure, serious illness, or treatment by anesthesia. Many species of birds and mammals use regulated hypothermia as a means of surviving periods of cold and food scarcity. Some become hypothermic on a daily basis. Hummingbirds, for example, are very small endotherms and have a high metabolic rate. They could exhaust their metabolic reserves just getting through a single day without food. Hummingbirds and other small endotherms can extend the period over which they can survive without food by dropping their body temperature during the portion of day when they would normally be inactive. This adaptive hypothermia is called daily torpor. Body temperature can drop 10°-20°C during daily torpor, resulting in an enormous saving of metabolic energy.

710 CHAPTER FORTY

I During more than half the year, a ground squirrel regulates its body temperature near 37°C.

Q During

I winter months, bouts of hibernation are interrupted by brief returns to normal body temperature.

Onset of hibernation

40.20 A Ground Squirrel Enters Repeated Bouts of Hibernation during Winter

At the beginning of each bout of hibernation, the ground squirrel's metabolic rate and body temperature fall. Its body temperature may come into equilibrium with the temperature of its nest and stay at that level for days. The bout is ended by a rise in metabolic heat production that returns body temperature to a normal level.

Regulated hypothermia can also last for days or even weeks, with drops to very low temperatures; this phenomenon is called hibernation (Figure 40.20). During the deep sleep of hibernation, the body's thermostat is turned down to an extremely low level to maximize energy conservation. Arousal from hibernation occurs when the hypothalamic set point returns to a normal level.

Many hibernators maintain body temperatures close to the freezing point during hibernation. The metabolic rate needed to sustain an animal in hibernation may be only one-fiftieth its basal metabolic rate, an enormous saving of metabolic energy. Many species of mammals, such as bats, bears, and ground squirrels, hibernate, but only one species of bird, the poorwill, has been shown to hibernate. The ability of hibernators to reduce their thermoregulatory set points so dramatically probably evolved as an extension of

Onset of arousal

Reentry

the set point decrease that accompanies sleep even in non-hibernating species of mammals and birds.

Chapter Summary

Homeostasis: Maintaining the Internal Environment

► The internal environment consists of the extracellular fluids. Organs and organ systems have specialized functions to keep certain aspects of the internal environment in a constant state. Review Figure 40.1

► Homeostasis is the maintenance of constancy in the internal environment. Homeostasis depends on the ability to control and regulate the functions of organs and organ systems.

Tissues, Organs, and Organ Systems

► Cells that have a similar structure and function make up a tissue. There are four general types of tissues: epithelial, connective, muscle, and nervous. Review Figure 40.2

► Epithelial tissues are sheets of tightly connected cells that cover the body surfaces and line hollow organs. Review Figure 40.3

► Connective tissues support and reinforce other tissues. They generally consist of dispersed cells in an extracellular matrix. Examples are cartilage, bone, blood, and adipose tissue. Review Figure 40.4

► Muscle tissues contract. There are three types: skeletal, cardiac, and smooth.

PHYSIOLOGY, HOMEOSTASIS, AND TEMPERATURE REGULATION 71 1

► There are two types of cells in nervous tissues: Neurons generate and transmit electrochemical signals, and glial cells provide supporting functions for neurons.

► Organs consist of multiple tissue types, and organs make up organ systems. Review Table 40.1

Physiological Regulation and Homeostasis

► Regulatory systems have set points and respond to feedback information. Negative feedback corrects deviations from the set point, positive feedback amplifies responses, and feedforward information changes the set point. Review Figure 40.5

Temperature and Life

► Living systems require a range of temperatures between the freezing point of water and the temperatures that denature proteins.

► Most biological processes and reactions are temperature-sensitive. Q_{10} is a measure of temperature sensitivity. Review Figure 40.6

► Animals that cannot avoid seasonal changes in body temperature have biochemical adaptations that compensate for those changes. These adaptations enable animals to acclimatize to seasonal changes. Review Figure 40.7

Maintaining Optimal Body Temperature

► Homeotherms maintain a fairly constant body temperature most of the time; poikilotherms do not. Endotherms produce metabolic heat to elevate body temperature; ectotherms depend mostly on environmental sources of heat. Review Figure 40.8

► Ectotherms and endotherms can regulate body temperature through behavior. Review Figure 40.9

► Heat exchange between a body and the environment is via radiation, conduction, convection, and evaporation. Review Figure 40.11

► Ectotherms and endotherms can control heat exchange with the environment by altering blood flow to the skin. Review Figure 40.12

► Some ectotherms, such as bees, nocturnal moths, and beetles, can produce metabolic heat to raise their body temperatures. Review Figure 40.13

► Some fish have circulatory systems that function as counter-current heat exchangers to conserve heat produced by muscle metabolism. Review Figure 40.14

Thermoregulation in Endotherms

► Endotherms have high basal metabolic rates. Over a range of environmental temperatures called the thermoneutral zone, the metabolic rate of resting endotherms remains at basal levels. Review Figure 40.15

► When the environmental temperature falls below a lower critical temperature, endotherms maintain their body temperatures through shivering and nonshivering metabolic heat production. Review Figure 40.16

► When the environmental temperature rises above an upper critical temperature, metabolic rate increases as a consequence of active evaporative water loss through sweating or panting.

► Endotherms that live in cold climates have adaptations that minimize heat loss, including a reduced surface area-to-volume ratio and increased insulation.

► Endotherms may dissipate excess heat generated by exercise or the environment via evaporation. The water loss involved in this process can be dangerous to endotherms in dry environments.

The Vertebrate Thermostat

► The vertebrate thermostat is located in the hypothalamus. It has set points for activating thermoregulatory responses. Hypothalamic temperature provides negative feedback information.

► Cooling the hypothalamus induces the constriction of blood vessels and increased metabolic heat production. Heating the hypothalamus induces the dilation of blood vessels and active evaporative water loss. Thermoregulatory behaviors are also induced by changes in hypothalamic temperature. Review Figure 40.18

► Changes in set point reflect the integration of information, such as environmental temperature and time of day, that is relevant to the regulation of body temperature. Review Figure 40.19

► Fever, which results from a rise in set point, helps the body fight infections.

► Adaptations in which set points are reduced to conserve energy include daily torpor and hibernation. Review Figure 40.20

For Discussion

1. In some sheets of epithelial tissue, the cells are joined together with dense extracellular proteins that form "tight junctions," which are extremely impermeable (see Chapter 5). In other epithelial sheets the cells are joined by filamentous extracellular proteins that are strong, but not as impermeable. What do you think are the functions of tight junctions, and where would you expect to find them? Where might you expect to find epithelial sheets with the leakier connections?
2. If the major adaptation of endotherms to cold climates is their insulation, how would you compare the cold adaptations of a polar bear and a seal?
3. Why is an environment above its upper critical temperature more dangerous to an endotherm than an environment below its lower critical temperature?
4. We discussed the vertebrate thermostat by describing experiments done on mammals. Lizards also have a temperature-sensitive hypothalamus. How would you design an experiment on a lizard to see if the temperature of its hypothalamus was important feedback information for its thermoregulation? How would you modify your experiment to see if the lizard also used information from temperature sensors in its skin?
5. If the hypothalamic temperature of a mammal is the feedback information for its thermostat, why does the hypothalamic temperature scarcely change when that animal moves between environments hot enough and cold enough to stimulate the animal to pant and to shiver, respectively?

41

Animal Hormones

^^ In shallow pools around the edge of Lake Tanganyika in east central Africa, brightly colored male cichlid fish stake out territories and vigorously defend them against neighboring males. These dominant males constantly patrol their territories and display their colorful sexual adornments for the benefit of females, who assemble in groups at the edge of the cichlid colony. The females are hard to see because they are inactive and protectively colored. When a female is ready to spawn, and is impressed by a male's territory and display, she enters his territory and lays her eggs in a spawning pit that the male has prepared. The male then fertilizes her

eggs-

At any one time, only about 10 percent of the males in the colony are displaying and holding territories. All the other males are small, nondescript, and nonaggressive like the females. If a dominant male is removed by a predator, however, the nondescript males fight over the vacated territory. The winner rapidly assumes the appearance and behavior of a dominant male: brightly colored, big, aggressive, and attractive to females.

What accounts for this dramatic change? Russell Fernald and his students at Stanford University have shown that soon after the nondescript male's victory, certain cells in his brain enlarge and secrete a chemical message. This message triggers cells in the pituitary gland, which is outside of the brain, to secrete chemical messages in turn. Although secreted in tiny quantities, these molecules enter the blood and are transported around the body. The responses of cells to these chemical messages produce the characteristics of a dominant male.

This change in the male cichlid is one example of how chemical messages, or hormones, can produce and coordinate anatomical, physiological, and behavioral changes in an animal. We explore many other examples in this chapter.

We look first at the nature of hormones and their evolution, and then examine some of their roles in the control of invertebrate life cycles. Most of this chapter is devoted to vertebrate hormones: their functions, control, and molecular mechanisms of action. We pay particular attention to the extensive interactions between the systems of neural and hormonal information. In the process, we discuss several human diseases involving hormonal dysfunction.

Dominant and Non-Dominant Male Cichlids

A dominant male cichlid [*Haplochromis burtoni*] displays bright colors that attract females to his spawning pit.

Hormones and Their Actions

In Chapter 40, we learned that control and regulation require information. This information is transmitted mostly as electric signals and as chemical signals. Electric signals are nerve impulses, a major focus of later chapters on the nervous system. Nerve impulses can be rapidly conducted over long distances to specific targets. Chemical signals are hormones, which are secreted by cells, diffuse locally in the extracellular fluid until they are picked up by the blood, and are distributed by the circulatory system.

Because the secretion, diffusion, and circulation of hormones is much slower than the transmission of nerve impulses, hormones are not useful for controlling rapid actions such as those involved in cichlid fighting. Hormone action is good for coordinating longer-term developmental processes, such as the transition of a nondescript cichlid into a dominant, territorial, breeding male. Hormones control many long-term physiological responses, such as the secretion of digestive enzymes by our guts and the reproductive cycles of many species.

A hormone is a chemical signal produced by certain cells of a multicellular organism and received by cells of the same organism. Cells that secrete hormones are called endocrine cells. To receive the hormonal message, a target cell must have appropriate receptors to which the hormone can bind. The binding of a hormone to its receptor activates mechanisms within the target cell that eventually lead to a response, which may be developmental, physiological, or behavioral. (In the case of the male cichlid, hormone release stimulates all three types of responses.)

Hormonal signaling systems can be distinguished according to the distance over which their messages operate. Some hormones only act on target cells close to their sites of release; others act on target cells at distant locations in the body. Some chemical messages, called pheromones, even exert their effects on other individuals.

Most hormones are distributed in the blood

The classic hormone is a chemical message secreted by cells in minute amounts and distributed throughout the body by the circulatory system (Figure 41.1a). Wherever such a hormone encounters a cell with a receptor to which it can bind, it triggers a response. The nature of the response depends on the responding cell. The same hormone can cause different responses in different types of cells.

Consider the hormone epinephrine. If you step off a curb without looking and a car screeches to a halt right next to you, you jump, your heart starts to thump, and a whole set of protective actions are set in motion. The jump and the initial heart thumping are driven by your nervous system, which can react very quickly. Simultaneously, the nervous system stimulates endocrine cells just above your kidneys (adrenal cells) to secrete epinephrine. Within seconds, epinephrine is diffusing into your blood and circulating around your body to activate the many components of the fight-or-flight response.

Epinephrine acts on the heart, blood vessels, liver, and fat cells. When it binds to its receptors in the heart, it causes the heart to beat faster and more strongly. It binds to receptors in the vessels that supply blood to your digestive tract, causing those vessels to constrict (digestion can wait!). Your heart is pumping more blood, and a greater percentage of that blood is going to the muscles needed for your escape. In the liver, epinephrine stimulates the breakdown of glycogen into glucose for a quick energy supply. In fatty tissue, it stimulates the breakdown of fats as another source of energy. These are just some of the many actions triggered by one hormone. They all contribute to increasing your chances of escaping a dangerous situation.

41.1 Chemical Signaling Systems

(a) The classic hormone is a secreted chemical message that is distributed throughout the body by the circulatory system. (b) An autocrine hormone influences the cell that releases it; paracrine hormones influence nearby cells, (c) Neurotransmitters (see Chapter 44) can be considered paracrine hormones.

Whether or not a cell responds to a hormone depends on whether it has receptors for that hormone, and how it responds depends on what kind of a cell it is. A single hormone can stimulate many different responses.

Some hormones act locally

Some hormones are released into the extracellular fluids in such tiny quantities, or they are so rapidly inactivated by degradative enzymes, or they are taken up so efficiently by local cells, that the circulation never has the chance to distribute them to distant target cells. Thus, these hormones act only locally. When a hormone affects cells near the secreting cell, it is said to have paracrine function (Figure 41.1b).

An example of a paracrine hormone is histamine, one of the mediators of inflammation. Histamine is released in damaged tissues by specialized cells called mast cells (see Chapter 19). When the skin is cut, the area around the cut becomes inflamed—red, hot, and swollen. Histamine causes this response by dilating the local blood vessels and making them more permeable ("leaky"), which allows

714 CHAPTER FORTY-ONE

blood plasma, including protective blood proteins and white blood cells, to move into the damaged tissue.

A major class of paracrine hormones consists of the various growth factors, which stimulate the growth and differentiation of cells. Growth factors were first discovered when scientists attempted to culture cells outside of the body- Even when given all sorts of nutrients and optimal conditions, the cells did not grow well unless blood plasma or a tissue extract was added to the medium. The components necessary for growth were found to be specific molecules present in very small quantities. At present, about 50 specific growth factors are known, along with a complex group of receptors. Some examples are:

► Nerve growth factor (NGF), which promotes the survival and growth of nerve cells.

- Epidermal growth factor (EGF), which stimulates many kinds of cells to divide
- Vascular endothelial growth factor, which stimulates the growth and branching of blood vessels

The nerve cells called neurons can also be considered paracrine cells. As we will see in Chapter 44, a neuron communicates with another cell by means of a chemical message called a neurotransmitter, which travels over a very small distance to the target cell (Figure 41.1c).

In cases in which receptors for the hormone are on the secreting cell itself, the hormone acts as an autocrine message (see Figure 41.1b). Growth factors are examples of local chemical messages that can also act as autocrine messages for the purpose of negative feedback. The autocrine response prevents the secretory cell from secreting too much of the hormone.

Hormones do not evolve as rapidly as their functions

Chemical signaling between cells exists even in single-celled organisms. Recall the life cycle of slime molds as described in Chapter 27. These protists lead solitary lives and reproduce by mitosis and fission as long as conditions are good. But when food and moisture become scarce, they secrete 3',5'-cyclic adenosine monophosphate (cAMP), which acts as a chemical signal for the individual cells to aggregate into a slug, form a fruiting structure, and release spores. Thus, in this protist, a chemical message passed between cells influences and coordinates behavior, development, and physiology.

The molecule responsible for this very primitive form of chemical communication between slime mold cells— cAMP—is involved in many hormonal signaling systems in multicellular animals. As you learned in Chapter 15, many molecular signals cause the production of cAMP within cells. This "second messenger" mediates a variety of responses within the cell via the phosphorylation of enzymes.

With the evolution of increasingly complex multicellular animals, more and more molecules acquired signaling functions. Also, as physiological systems changed through evolution, many existing molecular signals acquired new functions. As a result, the same chemical substances are used as

47.2 The Endocrine System of Humans

The endocrine system broadcasts chemical signals (hormones) that are received by cells with appropriate receptors. There are nine glands in the human endocrine system, but hormones are also secreted by tissues that are not part of discrete glands.

hormones in widely divergent species, but they may have completely different actions in different species.

The hormone thyroxine, for example, is found in animal species ranging from mollusks and tunicates (sea squirts) to humans. Its function is unknown in invertebrates, but it is produced in an organ that is involved in feeding. In frogs, thyroxine is essential for the metamorphosis from tadpole to adult. In mammals, thyroxine elevates cellular metabolism.

Prolactin is another example of a hormone that evolved different functions in different species. Prolactin stimulates milk production in female mammals after they give birth. In pigeons and doves, prolactin stimulates the production of crop milk, a substance secreted from the crop that is fed to the young. Prolactin causes amphibians to prepare for reproduction by seeking water. In fishes, such as salmon, that migrate between salt water and fresh water to breed, prolactin regulates the mechanisms that maintain osmotic balance with the changing environment. In all of these cases prolactin is involved in reproductive processes, but as those processes have changed through evolution, so has the information signaled by the hormone.

In summary, the structures of the molecules involved in chemical signaling are highly conserved—they have changed little throughout evolution—but their functions have changed dramatically.

Endocrine glands secrete hormones

Some endocrine cells are distributed as single cells within a tissue. Many hormones of the digestive tract, for example, are produced and secreted by isolated cells in the lining of the tract. As the contents of the digestive tract come into contact with these cells, they release their hormones, which

enter the blood and, like epinephrine, circulate throughout the body and activate cells that have appropriate receptors. Many hormones, however, are secreted by aggregations of endocrine cells that form secretory organs called endocrine glands.

Animals have two types of glands. Exocrine glands, such as sweat glands and salivary glands, release secretions that are not hormones through ducts that lead outside the body. Sweat gland ducts, for example, open onto the surface of the skin, and salivary gland ducts open into the mouth. Glands that secrete hormones and do not have ducts are called endocrine glands; they secrete their products directly into the extracellular fluid. Vertebrates have nine discrete endocrine glands, which collectively make up the endocrine system (Figure 41.2).

Hormonal Control of Molting and Development in Insects

Many hormones of invertebrate animals have multiple functions. In this chapter we cannot do justice to the diversity of hormones in the invertebrates, but we'll discuss two important aspects of the lives of many invertebrates that are controlled by hormonal mechanisms: molting and metamorphosis.

Hormones from the head control molting in insects

Because insects have rigid exoskeletons, their growth is episodic, punctuated with molts (shedding) of the exoskeleton (see Chapter 32). Each growth stage between two molts is called an instar. The British physiologist Sir Vincent Wigglesworth was a pioneer in the study of the hormonal control of growth and development in insects.

Wigglesworth conducted experiments on the bloodsucking bug *Rhodnius*, which undergoes incomplete metamorphosis. Upon hatching, *Rhodnius* is nearly a miniature version of an adult, but it lacks some adult features. *Rhodnius* molts five times before developing into a mature adult; a blood meal triggers each episode of molting and growth.

Rhodnius is a hardy experimental animal; it can live a long time even after it is decapitated. If decapitated about an hour after it has a blood meal, *Rhodnius* may live for up to a year, but it does not molt. If decapitated a week after its blood meal, it does molt (Figure 41.3, Experiment 1). These observations led Wigglesworth to the hypothesis that something diffusing slowly from the head controls molting.

The proof of this hypothesis came from a clever experiment in which Wigglesworth decapitated two *Rhodnius*: one that had just had its blood meal and another that had had its blood meal a week earlier. The two decapitated bodies

41.3 A Diffusible Substance Triggers Molting

The effect of time since the last blood meal on *Rhodnius* molting led Sir Vincent Wigglesworth to hypothesize that some substance was diffusing slowly through the insect's body. Further experiments showed that molting is indeed controlled by a substance— a hormone—diffusing from the head.

Conclusion: A diffusible substance from the head region is necessary for molt.

716 CHAPTER FORTY-ONE

were connected with a short piece of glass tubing—and they both molted (Figure 41.3, Experiment 2). Thus one or more substances from the bug fed a week earlier crossed through the glass tube and stimulated molting in the other bug.

We now know that two hormones working in sequence regulate molting:

- ▶ Cells in the brain produce brain hormone.
- ▶ Brain hormone is transported to and stored in a pair of structures attached to the brain, the corpora cardiaca (singular corpus car-diacum).
- ▶ After appropriate stimulation (which for *Rhodnius* is a blood meal) the corpora cardiaca release brain hormone, which diffuses to an endocrine gland, the prothoracic gland.
- ▶ Brain hormone stimulates the prothoracic gland to release the hormone ecdysone.
- ▶ Ecdysone diffuses to target tissues and stimulates molting.

The control of molting by brain hormone and ecdysone is a general mechanism in insects. The nervous system receives various types of information relevant in determining the optimal timing for growth and development. It makes sense, therefore, that the nervous system should control the endocrine gland that produces the hormone that orchestrates all the physiological processes involved in development and molting. Later in this chapter we will see similar links between the nervous system and endocrine glands in vertebrates.

Juvenile hormone controls development in insects

The *Rhodnius* decapitation experiments yielded a curious result: Regardless of the instar used, the decapitated bug always molted directly into an adult form. Additional experiments by Wigglesworth demonstrated that a hormone other than those responsible for molting determines whether a bug molts into another juvenile instar or into an adult.

Because the head of *Rhodnius* is long, it was possible to remove just the front part of the head, which contains the cells that secrete and release brain hormone, while leaving intact the rear part. That rear part contains two other endocrine structures called the corpora allata (singular corpus allatum). When fourth-instar bugs that had been fed one week earlier were partly decapitated, leaving the corpora allata intact, they molted into fifth instars, not into adults.

This experiment, was followed up by more experiments using glass tubes to connect individual bugs, allowing body fluid transfer between them. When an unfed, completely decapitated, fifth-instar bug was connected to a fourth-instar bug that had been fed and had only the front part of its head removed, both bugs molted into juvenile forms. A substance coming from the rear part of the head of the fourth-instar bug prevented the expected result that both bugs would molt into adult forms.

We now know that the substance is juvenile hormone and that it comes from the corpora allata. As long as juvenile

Secretory cells produce brain hormone.

Adult

41.4 Complete Metamorphosis

Butterflies and moths undergo complete metamorphosis, in which the feeding larvae (caterpillars) bear no resemblance to the reproductive adult. Three hormones control molting and metamorphosis in the silkworm moth *Hyalophora cecropia*.

juvenile hormone is present, *Rhodnius* molts into another juvenile instar. The corpora allata normally stop producing juvenile

The control of development by juvenile hormone is more complex in insects that, like butterflies, undergo complete metamorphosis. These animals undergo dramatic developmental changes between instars. The fertilized egg hatches into a larva, which feeds and molts several times, becoming bigger and bigger. Then it enters an inactive stage called a pupa. It undergoes major body reorganization as a pupa, and finally emerges as an adult.

In our perpetual war against insects, juvenile hormone is a new weapon. Synthetic forms of juvenile hormone can be distributed in the environment to prevent the development of juvenile insects into adults capable of reproduction. However, as you might expect from the fact that hormone structures are highly conserved, such a weapon is not without potentially serious side effects. First, it is not selective in its effects on insects and can affect species that are beneficial as well as those that are pests. Second, the synthetic juvenile hormone could have actions in vertebrates that are not yet known.

The diagram shows a sagittal section of the human brain. A red arrow points from the hypothalamus, located at the base of the brain, to the pituitary gland, which is situated just below it. A callout box points to the hypothalamus with the text: "The hypothalamus is the brain's master gland." The label "Hypothalamus" is also present at the bottom of the diagram.

The diagram illustrates the pituitary gland's location and components. The **Hypothalamus** is shown at the top, with a callout stating: "Hypothalamus produce the hormones that control the posterior pituitary". The **Pituitary stalk** connects the hypothalamus to the **Pituitary gland**. The gland is divided into the **Anterior pituitary** (adenohypophysis) and the **Posterior pituitary** (neurohypophysis). **Capillaries** are shown within the stalk. A red vessel labeled "flowing blood" is shown entering the anterior pituitary. A caption at the bottom states: "The hormones secreted by the..."

The list of chemical messages in the bodies of vertebrates is long and growing longer. To make the subject manageable, we focus mostly on the hormones of humans—how they function and how they are controlled. Table 41.1 presents an overview of the hormones of humans (most of which are found in all other mammals as well). Notice that the column listing the target

tissues of these hormones includes every organ system of the body.

We begin this survey with the pituitary gland because it plays a central role in the endocrine system. The pituitary is a link between the nervous system and many endocrine glands. It secretes some hormones that are actually produced by neurons in the brain, and under the influence of still other brain hormones, it produces a number of its own hormones, which control the activities of various endocrine glands throughout the body. For these reasons, the pituitary has been called "the master gland."

The pituitary develops from outpocketings of the mouth and brain

The pituitary gland sits in a depression at the bottom of the skull just over the back of the roof of the mouth (Figure 41.5). It is attached to the part of the brain called the hypothalamus, which is involved in many homeostatic regulatory systems (see Chapter 40).

The pituitary has two distinct parts that have different functions and separate origins during development. The anterior pituitary originates as an outpocketing of the embryonic mouth cavity, and the posterior pituitary originates as an outpocketing of the developing brain in the region that becomes the hypothalamus.

the posterior pituitary. The posterior pituitary releases two hormones, antidiuretic hormone and oxytocin. Both are small peptides synthesized in neurons in the hypothalamus.

718 CHAPTER FORTY-ONE

Hormones that are produced and released by neurons are called neurohormones. Antidiuretic hormone and oxytocin move down long extensions (axons) of the neurons that produce them, through the pituitary stalk into the posterior pituitary, where they are stored in the nerve endings (see Figure 41.5). How do they move down the axons? In the bodies of the neurons, these neurohormones are packaged into vesicles. Proteins called kinesins grab onto the vesicles and, powered by ATP, "walk" step by step down microtubules in the axons (see Figure 4.25).

The main action of antidiuretic hormone (ADH) is to increase the amount of water conserved by the kidneys. When ADH secretion is high, the kidneys resorb more water and produce only a small volume of highly concentrated urine. When ADH secretion is low, the kidneys produce a large volume of dilute urine.

The posterior pituitary increases its release of ADH whenever blood pressure falls or the blood becomes too salty. We will discuss the mechanism of ADH action in Chapter 51. ADH is also known as vasopressin because it

also causes the constriction of peripheral blood vessels as a means of elevating blood pressure.

When a woman is about to give birth, her posterior pituitary releases oxytocin, which stimulates the contractions of the muscles that push the baby out of her body. Oxytocin also brings about the flow of milk from the mother's breasts. The baby's suckling stimulates nerve cells in the mother, causing the secretion of oxytocin. Even the sight and sounds of her baby can cause a nursing mother to secrete oxytocin and release milk from her breasts.

the anterior pituitary. Four hormones released by the anterior pituitary (thyrotropin, adrenocorticotropin, luteinizing hormone, and follicle-stimulating hormone) control the activities of other endocrine glands and thus are called tropic hormones (see Figure 41.7). Each tropic hormone is produced by a different type of pituitary cell. We will say more about these tropic hormones when we describe their target

glands (thyroid, adrenal cortex, testes, and ovaries) later in this chapter and in the next.

The other hormones produced by the anterior pituitary influence tissues that are not endocrine glands. These hormones are growth hormone, prolactin, melanocyte-stimulating hormone, endorphins, and enkephalins.

Growth hormone (GH) consists of about 200 amino acids and acts on a wide variety of tissues to promote growth directly and indirectly. One of its important direct effects is to stimulate cells to take up amino acids. Growth hormone promotes growth indirectly by stimulating the liver to produce chemical messages that stimulate the growth of bone and cartilage. Thus, in some of its actions, growth hormone can also be considered a tropic hormone.

Overproduction of growth hormone in children causes gigantism, and underproduction causes dwarfism (Figure 41.6). Beginning in the late 1950s, children diagnosed as having a serious deficiency of growth hormone were treated

47.6 Effects of Abnormal Amounts of Growth Hormone

(a) Overproduction of growth hormone in childhood causes gigantism. This photo from 1939 shows a young man who is more than 8 feet tall standing next to his father, who is just under 6 feet tall, (b) Underproduction of growth hormone during childhood results in pituitary dwarfism. with human growth hormone extracted from human pituitaries in cadavers. The treatment was successful in stimulating substantial growth, but it could be made available to only small numbers of patients. A year's supply of human growth hormone for one individual required up to 50 pituitaries. In the mid-1980s, scientists using genetic engineering technology isolated the gene for human growth hormone and introduced it into bacteria, which produced enough of the hormone to make it widely available.

Preventing pituitary dwarfism is now feasible and affordable, but the availability of growth hormone raises new questions. Should every child at the lower end of the height charts be treated? Should a normal child whose parents think basketball stardom is assured if she is tall be given growth hormone? These types of questions are impossible to answer with scientific data alone.

Prolactin, another hormone produced by the anterior pituitary, stimulates the production and secretion of milk in female mammals. In some mammals, prolactin also functions as an important hormone during pregnancy. In human

males, prolactin plays a role along with other pituitary hormones in controlling the endocrine function of the testes.

Endorphins and enkephalins are the body's "natural opiates." In the brain, these molecules act as neurotransmitters in pathways that control pain. The significance of their release from the anterior pituitary is unknown. Interestingly, the production of endorphins and enkephalins in the pituitary is encoded by the same gene that encodes at least two other pituitary hormones. The gene actually encodes a large parent molecule called pro-opiomelanocortin. This large protein molecule is cleaved to produce several peptides, some of which have hormonal functions. Adrenocorticotropic hormone, melanocyte-stimulating hormone, endorphins, and enkephalins all result from the cleavage of pro-opiomelanocortin.

THE ANTERIOR PITUITARY IS CONTROLLED BY HYPOTHALAMIC

neurohormones Because the anterior pituitary produces tropic hormones that control other endocrine tissues, it acquired the designation "master gland." But we now

Anterior pituitary hormones leave gland in the blood.

47.7 Hormones from the Hypothalamus Control the Anterior Pituitary

Neurohormones produced in tiny quantities by cells in the hypothalamus are transported to the anterior pituitary through a system of portal blood vessels. These releasing and release-inhibiting hormones control the activities of anterior pituitary endocrine cells.

know that this "master" is under still higher control by the hypothalamus, and that their interaction integrates nervous system and endocrine system functions.

The hypothalamus receives information about conditions in the body and in the external environment through the nervous system. If the connection between the hypothalamus and the pituitary is experimentally cut, pituitary hormones are no longer released in response to changes in the environment or in the body. If pituitary cells are maintained in culture, extracts of hypothalamic tissue stimulate

ANIMAL HORMONES 721

some of those cells to release their hormones into the culture medium. Therefore, scientists hypothesized that secretions of the hypothalamic cells control the activities of anterior pituitary cells.

Although hypothalamic neurons do not extend into the anterior pituitary as they do into the posterior pituitary, a special set of portal blood vessels connects the hypothalamus and the anterior pituitary (Figure 41.7). It was thus proposed that secretions from nerve endings in the hypothalamus enter the blood and are conducted down the portal vessels to the anterior pituitary, where they cause the release of anterior pituitary hormones.

In the 1960s, two large teams of scientists, led by Roger Guillemin and Andrew Schally, initiated the search for the hypothalamic neurohormones. Because the amounts of such hormones in any individual mammal would be tiny, massive numbers of hypothalami from pigs and sheep were collected from slaughterhouses and shipped to laboratories in refrigerated trucks. One extraction effort began with the hypothalami from 270,000 sheep and yielded only 1 mg of purified thyrotropin-releasing hormone, or TRH, which was the first hypothalamic releasing (that is, release-stimulating) hormone isolated and characterized. Biochemical analysis of this pure sample revealed that TRH is a simple tripeptide consisting of glutamine, histidine, and proline. TRH causes certain anterior pituitary cells to release the tropic hormone thyrotropin, which in turn stimulates the activity of the thyroid gland.

Soon after discovering thyrotropin-releasing hormone, Guillemin's and Schally's teams identified gonadotropin-releasing hormone, which stimulates certain anterior pituitary cells to release the tropic hormones that control the activity of the gonads (the ovaries and the testes). For these discoveries, Guillemin and Schally received the 1972 Nobel prize in medicine. Many more hypothalamic neurohormones, including both releasing hormones and release-inhibiting hormones, are now known (Table 41.2).

47.8 Multiple Feedback Loops Control Hormone Secretion

Multiple feedback loops regulate the chain of command from hypothalamus to anterior pituitary to endocrine glands.

rior pituitary are also under negative feedback control by the hormones of the target glands they stimulate (Figure 41.8). For example, the hormone Cortisol, produced by the adrenal gland in response to adrenocorticotropin, returns to the pituitary in the circulating blood and inhibits further adrenocorticotropin release. Cortisol also acts as a negative feedback signal at the level of the hypothalamus, inhibiting the release of adrenocorticotropin-releasing hormone. In some cases a tropic hormone of the anterior pituitary also exerts negative feedback control on the hypothalamic cells producing the corresponding releasing hormone.

Thyroxine controls cell metabolism

The thyroid gland wraps around the front of the windpipe (trachea) and expands into a lobe on either side (see Figure 41.2). The thyroid gland produces the hormones thyroxine and calcitonin.

Thyroxine is synthesized in thyroid cells from two molecules of diiodotyrosine, which is the amino acid tyrosine with two atoms of iodine chemically bonded to it. Thus, a thyroxine molecule has four atoms of iodine, and is called

HO

OH

Thyroxine (T₄)

Thyroid cells also produce triiodothyronine, a version of thyroxine that has only three atoms of iodine and is called

II

HO

CH₂—CH—C—OH

NH₂ O

Triiodothyronine (T₃)

The thyroid usually makes and releases about four times as much T₄ as T₃. T₃ is the more active hormone in the cells of the body, but when T₄ is in circulation, it can be converted to T₃ by an enzyme. Therefore, when you read about thyroxine, keep in mind that the actions discussed are primarily due to T₃.

Thyroxine in mammals plays many roles in regulating cell metabolism. It elevates the metabolic rates of most cells and tissues and promotes the use of carbohydrates rather than fats for fuel. Exposure to cold for several days leads to an increased release of thyroxine, an increased conversion of T₄ to T₃, and an increase in basal metabolic rate. Thyroxine is especially crucial during development and growth, as it promotes amino acid uptake and protein synthesis by cells. Insufficient thyroxine in a human fetus or growing child greatly retards physical and mental growth, resulting in a condition known as cretinism.

The tropic hormone thyrotropin from the anterior pituitary activates the thyroid cells that produce thyroxine (Figure 41.9). TRH (thyrotropin-releasing hormone) produced in the hypothalamus and transported to the anterior pituitary through the portal blood vessels activates the thy-rotropin-producing pituitary cells. The brain uses environmental information such as temperature or day length to determine whether to increase or decrease the secretion of TRH. There is a very important negative feedback loop in this sequence of steps: Circulating thyroxine inhibits the response of the pituitary cells to TRH. Less thyrotropin is released when thyroxine levels are high, and more thyrotropin is released when thyroxine levels are low.

Thyroid dysfunction causes goiter

A goiter is an enlarged thyroid gland, which causes a pronounced bulge on the front and sides of the neck. Goiter can be associated with either hyperthyroidism (very high levels of thyroxine) or hypothyroidism (very low levels of thyroxine). The control diagram in Figure 41.9 helps explain how two very different conditions can result in the same symptom.

Hyperthyroid goiter results when the negative feedback mechanism fails to turn off the thyroid cells even though blood levels of thyroxine are high. The most common cause of hyperthyroidism is an autoimmune disease in which an antibody to the thyrotropin receptor is produced. This antibody can bind to the receptor and cause the thyroid cells to produce and release thyroxine. Even though blood levels of thyrotropin may be quite low because of the negative feed-

Thyroxine

47.9 Regulation of Thyroid Function in Response to Cold

Exposure to cold temperatures stimulates the hypothalamus to produce thyrotropin-releasing hormone, which stimulates anterior pituitary cells to secrete thyrotropin, which in turn stimulates the thyroid to release thyroxine.

back from thyroxine, the thyroid remains maximally stimulated, and it grows bigger. Hyperthyroid patients have high metabolic rates, are jumpy and nervous, usually feel hot, and may have a buildup of fat behind the eyeballs, causing their eyes to bulge.

Hypothyroid goiter results when there is not enough circulating thyroxine to turn off thyrotropin production. Its most common cause is a deficiency of dietary iodide, without which the thyroid gland cannot make thyroxine. Without sufficient thyroxine, thyrotropin levels remain high, so the thyroid continues to produce large amounts of nonfunctional thyroxine and becomes very large. The symptoms of hypothyroidism are low metabolism, intolerance of cold, and general physical and mental sluggishness.

Worldwide, goiter affects about 5 percent of the population. The addition of iodide to table salt has greatly reduced the incidence of the condition in industrialized nations, but goiter is still common in the less industrialized countries of the world.

Calcitonin reduces blood calcium

Another hormone released by the thyroid gland is calcitonin, although it is not produced by the same cells that produce thyroxine. Calcitonin helps reduce the levels of calcium circulating in the blood (Figure 41.10).

Bone is a huge repository of calcium in the body and is continually being remodeled. Cells called osteoclasts break down bone and release calcium; osteoblasts, on the other hand, use circulating calcium to deposit new bone. Calcitonin decreases the activity of osteoclasts and stimulates the activity of osteoblasts, thus shifting the

Calcitonin and parathormone help regulate blood calcium levels. Bone can be a source (site of production) or a sink (site of utilization or storage) for calcium.

724 CHAPTER FORTY-ONE

balance from adding calcium ions to the blood to removing them.

Calcitonin plays an important role in preventing bone loss in women during pregnancy. However, regulation of blood calcium levels is influenced more strongly by parathormone than it is by calcitonin.

Parathormone elevates blood calcium

The parathyroid glands are four tiny structures embedded on the surface of the thyroid gland. Their single hormone product is parathyroid hormone, or parathormone, a critical control in the regulation of blood calcium levels. Growth and remodeling of bone require calcium, and muscle contraction and nerve function are severely impaired if the blood calcium level rises or falls by as little as 30 percent of normal values.

A decrease in blood calcium triggers the release of parathormone, which stimulates osteoclasts to dissolve bone and release calcium to the blood (see Figure 41.10). Parathormone also prevents calcium in the blood from being lost in the urine by promoting calcium resorption by the kidneys. It also promotes the activation of vitamin D, which stimulates the digestive tract to absorb calcium from food.

Parathormone and calcitonin act antagonistically to regulate blood calcium levels: Parathormone elevates and calcitonin reduces. A similar antagonistic relationship is true of hormones of the pancreas, which regulate blood glucose levels.

Insulin and glucagon regulate blood glucose

Before the 1920s, diabetes mellitus was a fatal disease, characterized by weakness, lethargy, and body wasting. The disease was known to be connected somehow with the pancreas, a gland located just below the stomach, (see Figure 41.2), and with abnormal glucose metabolism, but the link was not clear.

Today we know that diabetes mellitus is caused by a lack of the hormone insulin, or by a lack of responsiveness of target tissues to that hormone. For patients in which the hormone is lacking, insulin replacement therapy is an extremely successful treatment. At present, more than 1.5 million people with diabetes in the United States lead almost normal lives through the use of manufactured insulin.

Insulin binds to a receptor on the plasma membranes of target cells, and this insulin-receptor complex allows glucose to enter the cell (see Figure 15.7). In the absence of insulin or insulin receptors, glucose accumulates in the blood

of glucose. As a result, the body of the untreated diabetic wastes away, and critical tissues and organs are damaged.

For centuries the prospects for a person with diabetes were bleak. A change in this outlook came almost overnight in 1921, when medical doctor Frederick Banting and medical student Charles Best of the University of Toronto discovered that they could reduce the symptoms of diabetes by injecting an extract they prepared from pancreatic tissue. The active component of the extract that Banting and Best prepared was found to be a small protein hormone—insulin—consisting of 51 amino acids.

Insulin is produced in clusters of endocrine cells in the pancreas. These clusters are called islets of Langerhans after the German medical student who discovered them. There are several types of cells in the islets:

- ▶ Beta (β) cells produce and secrete insulin.
- ▶ Alpha (α) cells produce and secrete the hormone glucagon, which has effects opposite those of insulin.
- ▶ Delta (δ) cells produce the hormone somatostatin.

The rest of the pancreas is an exocrine gland that produces enzymes and secretions that travel through ducts to the intestine, where they play roles in digestion.

After a meal, the concentration of glucose in the blood rises as glucose is absorbed from the food in the gut. This increase stimulates the pancreas to release insulin. Insulin stimulates cells to use glucose as fuel and to convert it into storage products such as glycogen and fat. When the gut contains no more food, the glucose concentration in the blood falls, and the pancreas stops releasing insulin. As a result, most cells of the body shift to using glycogen and fat rather than glucose for fuel. If the concentration of glucose in the blood falls below normal, the islet cells release glucagon, which stimulates the liver to convert glycogen back to glucose to resupply the blood. These effects will be discussed in greater detail in Chapter 50.

Somatostatin is a hormone of the brain and the gut

Somatostatin is released from the pancreas in response to rapid rises in glucose and amino acids in the blood. This hormone has paracrine functions within the islets: It inhibits the release of both insulin and glucagon. Its actions outside the pancreas slow the digestive activities of the gut. Pancreatic somatostatin extends the period of time during which nutrients are absorbed from the gut and used by the cells of the body. Somatostatin also acts as a hypothalamic neurohormone that inhibits the release of growth hormone

until it is lost in the urine. High levels of blood glucose and thyrotropin by the pituitary,

cause water to move from cells into the blood by osmosis, and the kidneys increase urine output to excrete excess fluid volume from the blood.*

Glucose uptake by most cells is impaired without insulin, so those cells must use fat and protein for fuel instead

The name diabetes refers to the copious production of urine. Mellitus (Greek for "honey") reflects the fact that the urine of an untreated diabetic is sweet.

The adrenal gland is two glands in one

An adrenal gland sits above each kidney just below the middle of your back. Functionally and anatomically, an adrenal gland consists of a gland within a gland (Figure 41.11). The core, called the adrenal medulla, produces the hormone epinephrine (also known as adrenaline) and, to a lesser degree, norepinephrine (or noradrenaline). Surrounding the medulla (as an apricot surrounds its pit) is the adrenal cortex.

Adrenal gland

The adrenal medulla

produces epinephrine and norepinephrine.

Kidney

adrenal cortex produces glucocorticoids (e.g., Cortisol), mineralocorticoids (e.g., aldosterone), and sex steroids e.g., testosterone).

41.11 The Adrenal Gland Has an Outer and an Inner Portion

An adrenal gland, consisting of an outer cortex and an inner medulla, sits on top of each kidney. The medulla and the cortex produce different hormones.

The adrenal cortex, which produces other hormones. The medulla develops from nervous system tissue and is under the control of the nervous system; the cortex is under hormonal control, largely by adrenocorticotropic (ACTH) from the anterior pituitary.

The adrenal medulla. The adrenal medulla produces epinephrine in response to stressful situations, arousing the body to action. As we saw earlier in this chapter, epinephrine increases heart rate, breathing rate, and blood pressure, and diverts blood flow to active skeletal muscles and away from the gut. These fight-or-flight reactions can be stimulated by physically threatening events, such as encountering a mugger, or by events that are mentally stressful, such as giving a public speech or taking a test. In situations of mental stress, many of the responses (such as increased heart and breathing rates) that would be useful for escaping physical danger are not useful, and can even be inconvenient or harmful.

Epinephrine and norepinephrine (a neurotransmitter involved in physiological regulation) bind to receptors on the surfaces of target cells. These receptors can be grouped into two general types, α -adrenergic and β -adrenergic receptors (each with at least two subtypes), which stimulate different actions within cells. Epinephrine acts equally on both types, but norepinephrine acts mostly on α -adrenergic receptors. Therefore, drugs called β -blockers, which selectively block β -adrenergic receptors, can reduce the fight-or-flight responses to epinephrine without disrupting the regulatory functions of norepinephrine.

The adrenal cortex. The cells of the adrenal cortex use cholesterol to produce three classes of steroid hormones. (Figure 41.12). Collectively, these classes of hormones are called the corticosteroids."

► The glucocorticoids influence blood glucose concentrations as well as other aspects of fat, protein, and carbohydrate metabolism.

► The mineralocorticoids influence the ionic balance of extracellular fluids.

► The sex steroids stimulate sexual development and reproductive activity.

The sex steroids are secreted in only negligible amounts by the adrenal cortex. They will be discussed in the next section, on gonadal hormones.

Side groups on the sterol backbone give different properties to the different corticosteroid hormones. This simplified outline of steroid biosynthesis leaves out many intermediate steps.

726 CHAPTER FORTY-ONE

(Aldosterone, the main mineralocorticoid, stimulates the kidney to conserve sodium. If the adrenal glands are removed from an animal, it must have sodium added to its diet, or its sodium will be depleted and it will die. One human patient with a nonfunctional adrenal gland compensated by salting her food heavily and, in addition, ate a 60-pound block of salt in the course of a year. - _

The main glucocorticoid, cortisol, is critical for mediating the body's response to stress. As we have seen, your immediate reaction to a frightening situation is stimulated by your nervous system and by the release of epinephrine. This fight-or-flight response ensures that your muscles will have enough oxygen and glucose to fuel your escape. You have a limited amount of blood glucose, however, and you need to conserve it for your muscles and your brain. Within minutes of the frightening stimulus, blood cortisol level rises. Cortisol stimulates cells not critical for your escape to decrease their use of blood glucose and shift instead to utilizing fats and proteins for energy. This is not a time to feel sick, have allergic reactions, or heal wounds, so cortisol also blocks immune system reactions. This is why cortisol is useful for reducing inflammations and allergies.

Cortisol release is controlled by ACTH from the anterior pituitary, which in turn is controlled by the hypothalamic adrenocorticotropic-releasing hormone. Because the cortisol response to a stressor has this chain of steps, each involving secretion, diffusion, circulation, and cell activation, it is much slower than the epinephrine response.

Turning off the cortisol response is as important as turning it on. A study of stress in rats showed that old rats could turn on their stress responses as effectively as young rats, but that they had lost the ability to turn them off as rapidly. As a result, they suffered from the well-known consequences of stress: ulcers, cardiovascular problems, strokes, impaired immune system function, and increased susceptibility to cancers and other diseases. Further research showed that turning off stress responses involves the long-loop negative feedback action of cortisol on cells in the brain, which causes a decrease in the release of an adrenocorticotropic-releasing hormone (see Figure 41.8). Repeated activation of this negative feedback mechanism leads to a gradual loss of cortisol-sensitive cells in the brain, and therefore a decreased ability to terminate stress responses.

The sex steroids are produced by the gonads

The gonads—the testes of the male and the ovaries of the female—produce hormones as well as gametes. Most of the gonadal hormones are steroids synthesized from cholesterol (see Figure 41.12). The male steroids are collectively called androgens, and the dominant one is testosterone. The female steroids are estrogens and progesterone. The dominant estrogen is estradiol.

The sex steroids have important developmental effects: They determine whether a fetus develops into a female or a male. (A fetus is the latter stage of an embryo; a human em-

bryo is called a fetus from the eighth week of pregnancy to the moment of birth.) After birth, the sex steroids control the maturation of the reproductive organs and the development and maintenance of secondary sexual characteristics, such as breasts and facial hair.

The sex steroids begin to exert effects in the human embryo in the seventh week of development. Until that time, the embryo has the potential to develop into either sex. In mammals and birds, the ultimate instructions for sex determination reside in the genes. In mammals, individuals that receive two X chromosomes normally become females, and individuals that receive an X and a Y chromosome normally become males (Figure 41.13). These genetic instructions are carried out through the production and action of the sex steroids, and the potential for error exists.

The presence of a Y chromosome normally causes the embryonic, undifferentiated gonads to begin producing androgens in the seventh week. In response to the androgens, the reproductive system develops into that of a male. If androgens are not produced at that time, female reproductive structures develop. In other words, androgens are required to trigger male development in humans. The opposite situation exists in birds: Male characteristics develop unless estrogens are present to trigger female development.

Occasionally the hormonal control of sexual development does not work perfectly, resulting in intersex individuals. The most extreme (but rare) case is a true hermaphrodite, who has both testes and ovaries. Pseudohermaphrodites have the gonads of one sex and the external sex organs of the other. For example, an XY fetus will develop testes, but if his tissues are insensitive to the androgens they produce because his androgen receptors do not function, the testes will remain within the abdomen, and the external sex organs and the secondary sexual characteristics of a female will develop.

Changes in control of sex steroid production initiate puberty

Sex steroids have dramatic effects at puberty —the time of sexual maturation in humans. Sex steroids are produced at low levels by the juvenile gonads, but their production increases rapidly at the beginning of puberty—around the age of 12 to 13 years. Why does this sudden increase occur? In the juvenile, as in the adult, the production of sex steroids by the ovaries and testes is controlled by the anterior pituitary tropic hormones luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which together are called the gonadotropins. The production of these tropic hormones is under the control of the hypothalamic gonadotropin-releasing hormone (GnRH). Prior to puberty, the gonads are capable of responding to gonadotropins, and the pituitary is capable of responding to GnRH. But prior to puberty the hypothalamus produces only very low levels of GnRH. Puberty is initiated by a reduction in the sensitivity of hypothalamic GnRH-producing cells to negative feedback from sex steroids and from gonadotropins. As a result, GnRH release increases, stimulating increased pro-

Under the influence of androgens, a penis and scrotum form.

Without the influence of androgens, female external organs develop.

41.13 The Development of Human Sex Organs

The sex organs of early human embryos are similar. Male sex steroids (androgens) promote the development of male sex organs. Without androgen action, female sex organs form, even in genetic males.

duction of gonadotropins and hence increased production of sex steroids.

In females, increasing levels of LH and FSH at puberty stimulate the ovaries to begin producing the female sex hormones. The increased circulating levels of these hormones initiate the development of the traits of a sexually mature woman: enlarged breasts, vagina, and uterus; broad hips; increased subcutaneous fat; pubic hair; and the initiation of the menstrual cycle.

In the male, an increasing level of LH stimulates groups of cells in the testes to synthesize androgens, which in turn initiate the profound physiological, anatomical, and psychological changes associated with adolescence. The voice deepens, hair begins to grow on the face and body, and the testes and penis grow. Androgens also help skeletal muscles grow, especially when they are exercised regularly.

Natural muscle development can be exaggerated by both men and women who want to increase their maximum

ANIMAL HORMONES 727

strength in athletic competition if they take synthetic androgens—called anabolic steroids. However, anabolic steroids have serious negative side effects. In women, their use causes the breasts and uterus to shrink, the clitoris to enlarge, menstruation to become irregular, facial and body hair to grow, and the voice to deepen. In men, the testes shrink, hair loss increases, the breasts enlarge, and sterility can result. You can understand the causes of some of these side effects by considering the negative feedback effects of sex steroids on the production of LH and FSH. Other side effects are even more serious. Continued use of anabolic steroids greatly increases the risk of heart disease, certain cancers, kidney damage, and personality disorders such as depression, mania, psychoses, and extreme aggression. Most official athletic organizations, including the International Olympic Committee, ban the use of anabolic steroids.

Melatonin is involved in biological rhythms and photoperiodicity

The pineal gland is situated between the cerebral hemispheres of the brain on a little stalk. It produces the hormone melatonin from the amino acid tryptophan. In various vertebrates, melatonin is involved in biological rhythms and photoperiodicity. Photoperiodicity is the phenomenon whereby seasonal changes in day length cause physiological changes in animals. Many species, for example, come into reproductive condition when the days begin to get longer (Figure 41.14). Humans are not photoperiodic, but melatonin in humans may play a role in entraining the daily rhythm of physiological and behavioral activities to the daily cycle of light and dark.

The release of melatonin by the pineal occurs in the dark and therefore marks the length of the night. Exposure to light inhibits the release of melatonin. The pineal of birds is directly sensitive to light, but in mammals, the light response is mediated through the eyes via a group of cells at the base of the brain, which generates a daily rhythm for many physiological functions of the body. We will learn more about this brain structure in Chapter 52.

The list of other hormones is long

We have discussed the major endocrine glands and the "classic" hormones in this chapter, but there are many hormones we have not mentioned. Examples include the hormones produced in the digestive tract that help organize the way the gut processes food (see Table 41.1 and Chapter 50). Even the heart has endocrine functions. When blood pressure rises and causes the walls of the heart to stretch, certain cells in the walls of the heart release atrial natriuretic hormone. This hormone

increases the excretion of sodium ions and water by the kidneys, thereby lowering blood volume and blood pressure. As we discuss the organ systems

47.74 The Release of Melatonin Regulates Seasonal Changes

(a) Melatonin is released in the dark and inhibited by light exposure. The duration of daily melatonin release thus changes as the day length (photoperiod) changes, inducing dramatic seasonal physiological changes in some animals, (b) In winter these Siberian hamsters are white and are non-reproductive. In summer they are mottled brown and breed.

of the body in the chapters that follow, we will frequently mention hormones that their tissues produce, or hormones that control their functions.

Mechanisms of Hormone Action

The hormones we have discussed are released in very small quantities, yet they can cause large responses in cells or tissues all over the body, and these responses can be quite specific in different cells. For example, we have discussed the many dramatic effects of testosterone, yet its concentration in the blood of adult human males is only about 30-100 ng/ml. How can hormones in such tiny quantities have such strong and selective actions?

The actions of hormones depend on receptors and signal transduction pathways

The selective action of hormones is explained by the fact that only cells with appropriate receptors respond to a hormone. Also, in different types of cells, the receptors for a particular hormone can be linked to different response mechanisms. There are numerous signal transduction pathways in cells (see Chapter 15), and therefore the response of a cell to a hormone depends both on the receptors and on the signal transduction pathways that exist in that cell. Epinephrine, for example, acts through four different receptors and several signal transduction pathways to induce a wide variety of responses in different tissues (Table 41.3).

The strength of hormone action frequently results from signal transduction cascades that amplify the original signal, as described in Chapter 15. An example is the response of liver cells to epinephrine (see Figure 15.17). A single molecule of epinephrine binding to its receptor on a liver cell can result in that liver cell releasing millions of molecules of glucose into the blood.

Hormone receptors are either on the cell surface or in the cell interior

Hormones can be classified as lipid-soluble or water-soluble, and that classification relates to where their receptors are. Lipid-soluble hormones, such as the steroid hormones and thyroxine, can diffuse through plasma membranes, and therefore their receptors are inside the cell, either in the cytoplasm or in the nucleus. In most cases, the complex formed by the lipid-soluble hormone and its receptor acts by altering gene expression in the cell, as described in Chapter 15.

Water-soluble hormones cannot readily pass through plasma membranes, and their receptors are on the cell surface. Water-soluble hormones include peptides such as the hypothalamic releasing hormones, proteins such as insulin and glucagon, and some other kinds of molecules, such as epinephrine and norepinephrine.

The cell surface receptors of water-soluble hormones are large glycoprotein complexes with three domains: a binding domain projecting beyond the outside of the plasma membrane, a transmembrane domain that anchors the receptor in the membrane, and a catalytic domain that extends into the

cytoplasm of the cell. The catalytic domain initiates cell responses by directly or indirectly activating protein kinases or protein phosphatases. In the direct pathway the catalytic domain changes its shape and becomes capable of phosphorylating tyrosine residues on protein kinases or phosphatases, thus changing their enzymatic activities. In the indirect pathway, the catalytic domain stimulates one of the several second messenger pathways that were described in Chapter 15.

Regulation of hormone receptors controls sensitivity of cells to hormones

We learned above that the release of hormones can be under feedback control, usually negative feedback control. Similarly, the abundance of receptors for a hormone can be under feedback control. In some cases, continuous high levels of a hormone can decrease the number of its receptors, in a process known as downregulation.

An example of downregulation is type II diabetes mellitus, also called insulin-independent diabetes, or sometimes adult-onset diabetes, because it occurs more frequently in adulthood than does type I diabetes mellitus, which is due to a lack of insulin and is usually diagnosed in childhood. Type II diabetes is distinguished by elevated levels of circulating insulin, but a loss of receptors. Although genetic factors are likely to be involved, a possible immediate cause of the disease is an overstimulation of pancreatic release of insulin by excessive carbohydrate intake, which leads to downregulation of the insulin receptors.

Upregulation of receptors is a positive feedback mechanism, and is less common. One example, however, is the monthly ovarian cycle of human females, whereby an ovum matures and is released. As we will learn in the next chapter, the maturation of the ovum and its associated cells is under the control of FSH. Early in this process, FSH causes the cells associated with the ovum to increase their production of FSH receptors. This upregulation of FSH receptors accelerates the maturation process stimulated by FSH.

Responses to hormones can vary greatly

So far in this chapter we have discussed two mechanisms for regulating physiological responses to hormones: controlling the amount of hormone released, and controlling the availability of receptors. Many other factors can influence physiological responses to hormones; therefore, it is valuable to be able to characterize these responses. One way is to construct a dose-response curve.

47.75 Dose-Response Curves Quantify Response to a Hormone

Between the threshold and maximum values, a dose-response curve frequently has a sigmoid or S shape. Anything that changes the responsiveness of a system—number of receptors in target cells, presence of enzymes and/or substrate, for example—affects the position of the curve.

To create such a curve, cells, tissues, organs, or even a whole animal are experimentally treated with different amounts of a hormone and the response is measured. The response is then plotted on the y axis of a graph, and the amount of the hormone used is plotted on the x axis (Figure 41.15). The resulting dose-response curve shows the threshold dose of the hormone necessary to get a response and the dose of the hormone that produces the maximum response. Between these two extreme values, the curve frequently has a sigmoid or S shape. The hormone dose that stimulates half the maximum response indicates the sensitivity of the cell, tissue, organ, or animal to the hormone.

Anything that changes the responsiveness of a system to a hormone is reflected in the dose-response curve. A change in the number of receptors in the responding cells, for example, can result in changes in threshold and in sensitivity. Changes in signaling pathways, rate-limiting enzymes, or the availability of substrates or cofactors can result in changes in the maximum response. Dose-response curves are valuable tools for studying the many factors that influence hormone-mediated processes.

Responses to hormones can also vary in their time course. Hormones are not simple on-off switches, and the time course over which it acts is an important characteristic of a hormone. This characteristic can be measured by the hormone's half-life in the blood. Soon after endocrine cells are stimulated to secrete their hormone, the hormone reaches its maximum concentration in the blood. By taking subsequent blood samples, researchers can determine how long it takes for the circulating hormone to drop to half of that maximum concentration.

The fight-or-flight response to epinephrine is relatively quick in its onset and termination, and the half-life of epinephrine in the blood is only 1 to 3 minutes. The actions of

The dose that stimulates half the maximum response indicates the organism's sensitivity to the hormone. At this dose, the hormone reaches its maximum response.

The minimum dose of hormone that elicits a response is called the threshold.

Changes in such factors as the number of receptors in the responding cells, rate-limiting enzymes, or the availability of substrate can change sensitivity and responsiveness of the system.

730 CHAPTER FORTY-ONE

other hormones, such as Cortisol or thyroxine, are expressed over much longer periods, and their half-lives are on the order of days.

Once a hormone has been released, its half-life is partially determined by processes of degradation and elimination. Hormones are enzymatically degraded in the liver, then they are removed from the blood in the kidney and excreted in the urine. The presence of hormones or their breakdown products in the urine is the reason that urine samples can provide important information in clinical tests. In addition, most hormones are taken up and degraded by the very cells on which they act, so that they are not available to continually activate receptors.

Another factor that influences the half-life of a hormone is its ability to leave the blood. Some hormones, such as epinephrine, circulate as free molecules, but many circulate bound to carrier proteins. The extent to which hormones are bound to carrier proteins limits their ability to diffuse out of the blood to reach their target cells, to be degraded in the liver, or to be excreted by the kidney.

For example, when the mineralocorticoid aldosterone is released, about 15 percent of it binds to carrier proteins, and its half-life is 25 minutes. In contrast, when thyroxine is released, almost 100 percent of it binds to carrier proteins, and thyroxine has a half-life of 6 days. This variation in the time course of hormone responsiveness allows hormone signaling systems to have temporal characteristics that match their functions.

Of course, the nature of the target cell response to a hormone is also a factor in determining the time course of hormone action. For a hormone that stimulates a developmental effect, the time course of hormone action can be months, years, and even a lifetime. A very good example of a long-term process regulated primarily by hormones is animal reproduction, the topic of the next chapter.

Chapter Summary

Hormones and Their Actions

- ▶ Endocrine cells secrete chemical messages called hormones, which bind to receptors on or in target cells.
- ▶ Most hormones diffuse through the extracellular fluids and are picked up by the blood, which distributes them throughout the body. Some hormones diffuse to targets near the site of secretion. Autocrine hormones influence the cell that secretes them; paracrine hormones influence nearby cells. Review Figure 41.1
- ▶ Hormones cause different responses in different target cells.
- ▶ The chemical structures of hormones have changed little through evolution, but their functions have changed dramatically.
- ▶ Hormones may be secreted by single cells or by cells organized into discrete endocrine glands. Review Figure 41.2

Hormonal Control of Molting and Development in Insects

- ▶ Insects must molt their exoskeletons to grow. Two diffusible substances, brain hormone and ecdysone, control molting. Review Figure 41.3
- ▶ Juvenile hormone, another diffusible substance, prevents maturation so that juvenile instars molt into bigger juvenile instars. When the level of juvenile hormone falls low enough, the juvenile molts into the adult form.
- ▶ Some insects, such as butterflies, go through complete metamorphosis. When juvenile hormone drops to a low level, the larval form becomes a pupa. Because no juvenile hormone is secreted during pupation, the pupa molts into an adult. Review Figure 41.4

Vertebrate Endocrine Systems

- ▶ Vertebrates have nine endocrine glands that secrete many hormones. Review Figure 41.2, Table 41.1
- ▶ The pituitary gland is divided into two parts. The anterior pituitary develops from embryonic mouth tissue; the posterior pituitary develops from the brain.
- ▶ The posterior pituitary secretes the neurohormones vasopressin and oxytocin. Review Figure 41.5
- ▶ The anterior pituitary secretes tropic hormones (thyrotropin, adrenocorticotropin, and two gonadotropins), as well as growth hormone, prolactin, melanocyte-stimulating hormone, endorphins, and enkephalins.
- ▶ The anterior pituitary is controlled by neurohormones produced by cells in the hypothalamus and transported through portal blood vessels to the anterior pituitary. Review Figure 41.7, Table 41.2
- ▶ Hormone release in the

hypothalamus/pituitary/endocrine gland axis is controlled by many feedback loops. Review Figure 41.8

- ▶ The thyroid gland is controlled by thyrotropin and secretes thyroxine, which controls cell metabolism. Goiter can be associated with too little or too much thyroxine. Review Figure 41.9
- ▶ The level of calcium in the blood is regulated by two hormones. Calcitonin, produced by the thyroid, lowers blood calcium. Parathormone, produced by the parathyroid glands, raises it. Review Figure 41.10
- ▶ The pancreas secretes three hormones. Insulin stimulates glucose uptake by cells and lowers blood glucose, glucagon raises blood glucose, and somatostatin slows the rate of nutrient absorption from the gut.
- ▶ The adrenal gland has two portions, one within the other. The hormones of the adrenal medulla, epinephrine and norepinephrine, stimulate the liver to supply glucose to the blood, as well as other fight-or-flight reactions. Review Figure 41.11

► The adrenal cortex produce three classes of corticosteroids: glucocorticoids, mineralocorticoids, and small amounts of sex steroids. Review Figure 41.12

► Aldosterone is a mineralocorticoid that stimulates the kidney to conserve sodium and to excrete potassium.

► Cortisol is a glucocorticoid that decreases glucose utilization by most cells.

► Sex hormones (androgens in males, estrogens and progesterone in females) are produced by the gonads in response to tropic hormones. Sex hormones control sexual development, secondary sexual characteristics, and reproductive functions. Review Figure 41.13

► The pineal hormone melatonin is involved in controlling biological rhythms and photoperiodism. Review Figure 41.14

Mechanisms of Hormone Action

► The responses of a cell to a hormone depend on what receptors it has and what signal transduction pathways those receptors activate. Review Table 41.3

ANIMAL HORMONES 731

► The receptors for water-soluble hormones are on the cell surface, and the receptors for lipid-soluble hormones are inside the cell.

► The sensitivity of a cell to hormones can be altered by up-or downregulation of the receptors in that cell.

► The sensitivity and time course of a response to a hormone depend on many factors, including receptor numbers, properties of signal transduction pathways, the actions of other hormones, binding of the hormone to carrier proteins, and elimination of the hormone through degradation and excretion.

► Important tools for characterizing hormone action are dose-response curves and measurements of half-life. Review Figure 41.15

For Discussion

1. Explain how both hyperthyroidism and hypothyroidism can cause goiter. Refer to the roles of the hypothalamus and the pituitary in your answer.
2. In the 1960s, women who showed signs of premature labor were sometimes treated with progestins (substances that have progesterone activity) to inhibit contractions. The female children of these women tended to be "tomboys." In recent years many of these offspring have claimed that they feel more male than female and have therefore undergone sex change operations. Can you suggest an explanation for this phenomenon? (Hint: Review Figure 41.12.)
3. Various side effects of anabolic steroid use were mentioned in this chapter. Some of these effects are due to the direct action of the steroid, but others are due to the negative feedback action of the steroid. Discuss an example of each and explain possible mechanisms.
4. The time course of hormone action can vary over a broad range. Compare the characteristics you would expect of a hormone signaling system that controls a short-term process, such as digestive functions, with the characteristics you would expect of a hormone signaling system that controls a long-term process, such as a developmental process.

Animal Reproduction

Natural selection has created some amazing and bizarre adaptations, but among the most unusual and diverse are the methods some animals use to reproduce. Just as "unmanned" submersibles are used in deep ocean exploration, some species of polychaete worms use "unwormed" submersibles to reproduce. The adults of these marine worms live in burrows on the ocean floor or in reefs. Predators make it dangerous for them to leave their burrows to seek a mate, and if they simply released their eggs and sperm at the mouth of the burrow, they would have a poor chance of successful fertilization. So both males and females develop specialized body segments that form at the worm's posterior end and become stuffed with sperm or eggs. These segments develop sensory organs but no mouth or gut, since they will not need to feed.

When the time is right—full moon for some species, new moon for others—these "sex-cell transporters" break loose from the main body of the worm, leave the burrow, swim up into the water column, swarm with more of their kind, and release their sperm or eggs. The sex-cell transporters die soon after they release their cargo. Union of sperm and eggs takes place in the water column, and fertilized eggs may drift a long way before they descend to the ocean floor and develop into adult worms. But in many places, the native people know when and where the sex-cell transporters will swarm, and people harvest them for food.

In this chapter you will learn how animals reproduce. We first examine asexual mechanisms of reproduction, in which only a single parent is involved, and then turn to sexual reproduction, which requires two parents. Sexually reproducing organisms produce haploid sex cells—sperm and eggs—through the process of meiosis. An egg and a sperm must unite through the process of fertilization to create a new diploid individual.

As we will see, much of the diversity in reproductive systems is in mechanisms for getting sperm and eggs together. This chapter, however, focuses the most attention on the anatomy, function, and endocrine control of the human re-

Feasting on Sex Cells

During the final quarter of November's moon, the people of Samoa and Fiji harvest the reproductive segments of the palolo worm, *Eunice viridis*. The adult worms release specialized reproductive vehicles into the ocean according to a precise cycle that native people have understood for centuries. The protein-rich worm segments are prepared by roasting or frying and are eaten as a delicacy.

productive system. This information will allow us to understand the technologies we use both to limit and to overcome infertility. We end the chapter with a discussion of sexual health and sexually transmitted diseases.

Asexual Reproduction

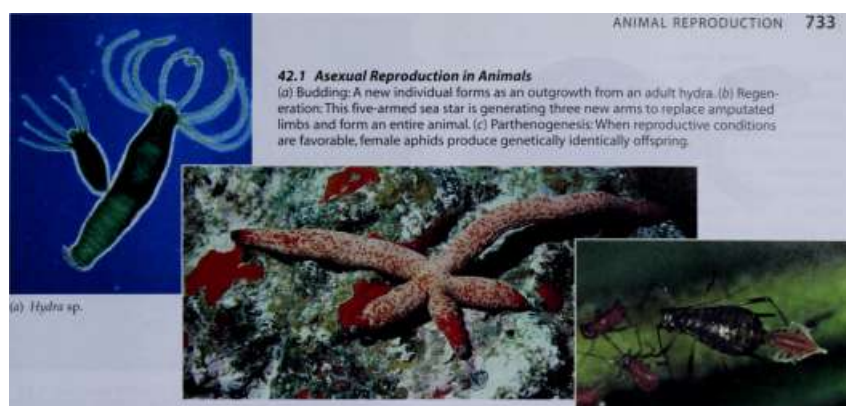

Sexual reproduction is a nearly universal trait of animals, although many species can reproduce asexually as well. Offspring produced asexually are genetically identical to one another and to their parents. Asexual reproduction is highly efficient because there is no mating. Mating requires energy, involves risks, and requires that resources be devoted to a large population of males, who do not produce offspring. Asexual populations can use resources efficiently because all individuals in the population can convert resources to offspring. However, asexual reproduction does not generate genetic diversity, and this can be a disadvantage in changing environments. As we learned in Chapter

ANIMAL REPRODUCTION

42.1 Asexual Reproduction in Animals

(a) Budding: A new individual forms as an outgrowth from an adult hydra, (b) Regen-eration: This five-armed sea star is generating three new arms to replace amputated limbs and form an entire animal, (c) Parthenogenesis: When reproductive conditions are favorable, female aphids produce genetically identical offspring.

(b) *Linckia* sp.

(c) *Macrosiphum rosae*

21, genetic diversity enables natural selection to shape adaptations in response to environmental change.

A variety of species, mostly invertebrates, reproduce asexually. They tend to be species that are sessile and cannot search for mates, or species that live in sparse populations and rarely encounter potential mates. Furthermore, asexually reproducing species are likely to be found in relatively constant environments, in which the potential for rapid evolutionary change is not as important as in more variable environments.

There are three common modes of asexual reproduction:

- ▶ Budding, in which new individuals form by mitotic cell division.
- ▶ Regeneration, in which a piece or section of an organism can generate an entire new individual.
- ▶ Parthenogenesis, in which individuals develop from unfertilized eggs.

Budding and regeneration produce new individuals by mitosis

Many simple multicellular animals produce offspring by budding; new individuals form as outgrowths of the bodies of older animals. These buds grow by mitotic cell division, and the cells differentiate before the buds break away from the parent (Figure 42.1a). The bud is genetically identical to the parent, and it may grow as large as the parent before it becomes independent.

Regeneration is usually thought of as the replacement of damaged tissues or lost limbs, but in some cases pieces of an organism can regenerate complete individuals. In a classic experiment demonstrating regeneration, a sponge is pushed through a cloth mesh, producing many little clusters of cells. Each cluster grows into a small but complete sponge. The ability of sponges to regenerate was used off the coast of Florida to restore the commercial bath-sponge

fishery, which was endangered by overfishing. Echinoderms also have remarkable abilities to regenerate. If sea stars are cut into pieces, each piece that includes a portion of the central disc grows into a new animal (Figure 42.1b).

Regeneration frequently results when an animal is broken by an outside force. A storm, for example, can cause a heavy surf that breaks colonial cnidarians such as corals. Pieces broken off the colony can regenerate into new colonies. In some species, the breakage occurs in the absence of external forces. Some species of segmented marine worms related to the ones we discussed at the beginning of this chapter develop segments with rudimentary heads bearing sensory organs, then break apart. Each fragmented segment forms a new worm.

Parthenogenesis is the development of unfertilized eggs

Not all eggs have to be fertilized to develop. A common mode of asexual reproduction in arthropods is the development of offspring from unfertilized eggs. This phenomenon, called parthenogenesis, also occurs in some species of fish, amphibians, and reptiles. Most species that reproduce parthenogenetically also engage in sexual reproduction or sexual behavior.

The aphids that can rapidly populate your rosebushes in the spring and summer reproduce parthenogenetically while conditions are favorable (Figure 42.1c). Some of the unfertilized eggs laid in spring and summer develop into male aphids, others into females. As conditions become less favorable, the aphids mate, and the females lay fertilized eggs. These eggs do not hatch until the following spring, and they yield only females.

In some species, parthenogenesis is part of the mechanism that determines sex. For example, in many hymenopterans (ants, and most species of bees and wasps), males develop from unfertilized eggs and are haploid.

42.2 Sexual Behavior May Be Required for Asexual Reproduction

(a) Parthenogenetic whiptail lizards are all female, but take turns acting the male role in reproductive behavior, (b) The stage of the ovarian cycle determines the role an individual plays.

Females develop from fertilized eggs and are diploid. Most females are sterile workers, but a select few become fertile queens. After a queen mates, she has a supply of sperm that she controls, enabling her to produce either fertilized or

unfertilized eggs. Thus the queen determines when and how much of the colony resources are expended on males. Parthenogenetic reproduction in some species requires sexual activity even though this activity does not fertilize eggs. The eggs of parthenogenetically reproducing ticks and mites, for example, develop only after the animals have mated, even though the eggs remain unfertilized. One case that has been investigated by David Crews and his students at the University of Texas is parthenogenetic reproduction in a species of whiptail lizard. There are no males in this species, but females act as males, engaging in all aspects of courtship display and mating, even though no sperm are produced or transferred (Figure 42.2). Whether a specific female acts as a female or as a male depends on her hormonal state at the time, but sexual activity is required to stimulate ovulation.

Sexual Reproduction

A large portion of the time and energy budgets of sexually reproducing animals goes into sexual behavior, which exposes them to predation, can result in physical damage, and detracts from other useful activities such as feeding, building secure living places, and caring for existing offspring. In spite of all of these disadvantages, there is an overwhelming evolutionary advantage to sexual reproduction: It produces genetic diversity.

Sexual reproduction requires the joining of two haploid sex cells to form a diploid individual. These haploid cells, or gametes, are produced through gametogenesis, a process that involves meiotic cell divisions. Two events in meiosis contribute to genetic diversity: crossing over of homologous chromosomes, and the independent assortment of chromo-

Acts as a female male female male

When its estrogen levels are high, a lizard acts as a female.

When its progesterone levels are high, a lizard acts as a male.

Time

somes. Both of these genetic phenomena were described in Chapter 10.

Mating behavior also contributes to genetic diversity in sexually reproducing species. The genetic variation in the gametes of a single individual and the genetic variation between any two parents produce an enormous potential for genetic variation between any two offspring of a sexually reproducing pair of individuals. This genetic diversity is the raw material for natural selection; thus evolutionary change in sexually reproducing animals can be quite rapid.

There are three fundamental phenomena of sexual reproduction in animals:

- Gametogenesis (making sex cells)
- Mating (getting sex cells together)
- Fertilization (getting sex cells to fuse)

There is not a great deal of diversity in gametogenesis when we compare different groups of animals. Processes of fertilization are also rather similar in widely different species. Therefore, although the discussion of gametogenesis that follows is primarily derived from information from mammals, the facts would not be terribly different if we focused on a different group of animals.

Mating, on the other hand, shows incredible evolutionary diversity. Our discussion of mating in this chapter will focus on a few specific examples as representative of the fascinating diversity that exists.

Eggs and sperm form through gametogenesis

Gametogenesis occurs in the primary sex organs, the gonads, which are testes (singular testis) in males and ovaries in females. The tiny gametes of males, called sperm, are motile and move by beating their flagella. The much larger female gametes are eggs, or ova (singular ovum), and are nonmotile (Figure 42.3).

Gametes are produced from germ cells, which have their origin in the earliest cell divisions of the embryo and remain distinct from the rest of the body. All the rest of the cells of the embryo are called somatic cells. Germ cells are sequestered in the body of the embryo until its gonads begin to form. The germ cells then migrate to the gonads, where they take up residence and proliferate by mitosis,

42.3 Gametes Differ in Size

Mammalian sperm (white) are much smaller than the mammalian egg (blue), as illustrated by this artificially colored micrograph of human fertilization.

42.4 Gametogenesis

(a) Diploid spermatogonia develop into haploid spermatids. Spermatids differentiate into sperm. (6) Diploid oogonia develop into haploid secondary oocytes, which mature into ova.

ANIMAL REPRODUCTION 735

producing oogonia (singular oogonium) in females and spermatogonia (singular spermatogonium) in males. Oogonia and spermatogonia, which are diploid, multiply by mitosis in turn, eventually producing primary oocytes and primary spermatocytes, which are still diploid cells.

Meiosis, the next step in gametogenesis, reduces the chromosomes to the haploid number, and these haploid cells mature into sperm and ova. (You may want to review the discussion of meiosis in Chapter 9 before reading further.) Although the steps of meiosis are very similar in males and females, there are some significant differences in gametogenesis.

spermatogenesis produces sperm. Primary spermatocytes undergo the first meiotic division to form secondary spermatocytes, which are haploid. The second meiotic division produces four haploid spermatids for each primary spermatocyte that entered meiosis. In mammals, these cells remain connected by cross-bridges of cytoplasm after each division (Figure 42 Aa).

The reason that mammalian spermatocytes remain in cytoplasmic contact throughout their development probably is the asymmetry of sex chromosomes in the males of

The first meiotic division produces a haploid secondary oocyte and a small, adjacent, nucleus-containing polar body.

The second meiotic division produces another polar body and the haploid egg (the first polar body may also divide at this time).

736 CHAPTER FORTY-TWO

most species. Half of the secondary spermatocytes receive an X chromosome, the other half a Y chromosome. The Y chromosome contains fewer genes than the X chromosome, and apparently some of the products of genes not included in the Y chromosome are essential for spermatocyte development. By remaining in cytoplasmic contact, all spermatocytes can share the gene products of the X chromosomes, even though only half of them have an X chromosome.

Just after being produced by meiosis, a spermatid bears little resemblance to a sperm. Through further differentiation, it will become compact, streamlined, and motile. We will look at the differentiation of human sperm in more detail below.

Oogenesis produces eggs. Oogonia, like spermatogonia, proliferate through mitosis. The resulting egg precursor cells differentiate into primary oocytes, which immediately enter prophase of the first meiotic division. In many species, including humans, the development of the oocyte is arrested at this point, and may remain so for days, months, or years. In contrast, there is no arrest in the development of male gametes; the process goes steadily to completion once the primary spermatocyte has differentiated. In the human female, as we will see, some primary oocytes may remain in arrested prophase I for 50 years!

During this prolonged prophase I, or shortly before it ends, the primary oocyte undergoes its major growth phase. It grows larger due to increased production of ribosomes, RNA, cytoplasmic organelles, and energy stores. At this time, the primary oocyte acquires all of the energy, raw materials, and RNA that the egg will need to survive its first cell divisions after fertilization. In fact, the nutrients in the egg will have to nourish the embryo until it is either nourished by the maternal system or can feed on its own.

When a primary oocyte resumes meiosis, its nucleus completes the first meiotic division near the surface of the cell. The daughter cells of this division receive grossly unequal shares of cytoplasm. This asymmetry represents another major difference from spermatogenesis, in which cell divisions apportion cytoplasm equally. The daughter cell that receives almost all of the cytoplasm becomes the secondary oocyte, and the one that receives almost none forms the first polar body (see Figure 42.4b).

The second meiotic division of the large secondary oocyte is also accompanied by an asymmetrical division of the cytoplasm. One daughter cell forms the large, haploid ootid, which eventually differentiates into a mature ovum, and the other forms the second polar body. Polar bodies degenerate, so the end result of oogenesis is that each primary oocyte produces only one mature egg. However, that egg is a very large, well-provisioned cell.

A second period of arrested development occurs after the first meiotic division forms the secondary oocyte. The egg may be expelled from the ovary in this condition. In many species, including humans, the second meiotic division is not completed

until the egg is fertilized by a sperm.

A single body can function as both male and female

Sexual reproduction requires both male and female haploid gametes. In most species, these gametes are produced by individuals that are either male or female. Species that have male and female members are called dioecious (from the Greek for "two houses"). In some species, a single individual may possess both female and male reproductive systems. Such species are called monoecious ("one house") or hermaphroditic.

Almost all invertebrate groups have hermaphroditic species. An earthworm is an example of a simultaneous hermaphrodite, meaning that it is both male and female at the same time. When two earthworms mate, they exchange sperm, and as a result, the eggs of each are fertilized (see Figure 31.24b). Some animals are sequential hermaphrodites, meaning that individuals function as a male or as a female at different times in their lives.

What is the selective advantage of hermaphroditism? Some simultaneous hermaphrodites have a low probability of meeting a potential mate. An example is a parasitic tapeworm. Even though it may be large and cause lots of trouble for its host, it may be the only tapeworm in the host. Tapeworms can fertilize their own eggs. Most simultaneous hermaphrodites must mate with another individual, but since each member of the population is both male and female, the probability of encountering a possible mate is double what it would be in monoecious species.

Sequential hermaphroditism can reduce the possibility of inbreeding among siblings by making them all the same sex at the same time and therefore incapable of mating with one another. In a species in which only a few males fertilize all females, sequential hermaphroditism can maximize reproductive success by making it possible for an individual to reproduce as a female until the opportunity arises for it to function successfully as a male.

Anatomical and behavioral adaptations bring eggs and sperm together

Sexual reproduction requires that two haploid gametes join together to form a diploid zygote. The purpose of mating behavior is to get eggs and sperm close enough together that this process—called fertilization—can occur. Many anatomical and behavioral adaptations have evolved to support mating. The simplest distinction in mating systems is whether fertilization occurs externally or internally.

EXTERNAL FERTILIZATION REQUIRES AN AQUATIC HABITAT. In an

aquatic environment, animals can simply release their gametes into the water. External fertilization is common among simple aquatic animals that are not very mobile (Figure 42.5). These animals produce huge numbers of gametes. A female oyster, for example, may produce 100 million eggs in a year, and the number of sperm produced by a male oyster is astronomical.

But numbers alone do not guarantee that gametes will meet. Timing is also important. The reproductive activities

A

42.5 External Fertilization Is Common in Aquatic Species

External fertilization requires an aqueous environment. These staghorn corals are all releasing sperm-egg bundles into the oceans of Ningaloo Reef, Australia.

of the males and females of a population must be synchronized. Seasonal breeders may use day length, changes in temperature, or changes in weather to time their production and release of gametes. Social stimulation is also important. Sexual activity on the part of one member of a population can stimulate others to engage in mating.

Behavior can play an important role in bringing gametes together even when fertilization is external. Many species travel great distances to congregate with potential mates and release their gametes at the same time in a suitable environment. Salmon are an extreme example, traveling hundreds of miles to spawn in the stream where they hatched.

INTERNAL FERTILIZATION ENABLES TERRESTRIAL LIFE. Sperm Can

move only through liquid, and delicate gametes released into air would dry out and die. Terrestrial animals avoid these problems by engaging in internal fertilization.

Animals have evolved an incredible diversity of behavioral and anatomical adaptations to get male gametes into the female reproductive tract. As we saw above, gametogenesis occurs in the primary sex organs, the gonads. All of the additional anatomical components of an animal's reproductive system are called accessory sex organs. An obvious accessory sex organ in the male is a tubular structure called the penis, which enables the male to deposit sperm in the female's accessory sex organ, the vagina (or, in some species, the cloaca, a cavity common to the digestive, urinary, and reproductive systems). Accessory sex organs include a variety of glands, tubules, ducts, and other structures.

Copulation is the physical joining of the male and female accessory sex organs. Transfer of sperm in internal fertilization can also be indirect. Males of some species of mites and scorpions (among the arthropods) and salamanders

ANIMAL REPRODUCTION 737

deposit spermatophores — containers filled with sperm—in the environment. When a female mite finds a spermatophore, she straddles it and opens a pair of plates in her abdomen so that the tip of the spermatophore enters her reproductive tract and allows the sperm to enter. Some female salamanders use the lips of their cloacae to scoop up the spermatophore.

Male squid and spiders play a more active role in spermatophore transfer. The male spider secretes a drop containing sperm onto a bit of web; then, with a special structure on his foreleg, he picks up the sperm-containing web and inserts it through the female's genital opening. Male squid use one special tentacle to pick up a spermatophore and insert it into the female's genital opening.

Most male insects copulate and transfer sperm to the female's vagina through a tubular penis. The genitalia — external sex organs—of insects often have species-specific shapes that match in a lock-and-key fashion. This mechanism ensures a tight, secure fit between the mating pair during the prolonged period of sperm transfer. The males of some insect species have elaborate structures on their penises that can scoop sperm deposited by other males out of the female's reproductive tract.

The evolution of vertebrate reproductive systems parallels the move to land

The earliest vertebrates evolved in aquatic environments. The closest living relatives of those earliest vertebrates are modern-day fishes. They remain exclusively aquatic animals, and most practice external fertilization. The most primitive of the fishes, the lampreys and hagfishes, broadcast their gametes into the environment, as do many aquatic invertebrates. In most fishes, however, fertilization is more selective: Mating behaviors bring females and males into close proximity at the time of gamete release.

In some sharks and rays, certain fins have evolved into structures that hold the male and female together and enable sperm to be transferred directly into the female reproductive tract. This internal fertilization in sharks and rays has made it possible for the females of some species to enclose fertilized eggs in protective egg cases before depositing them in the environment.

Amphibians were the first vertebrates to live in terrestrial environments. They dealt with the challenge of a dry environment by returning to water to reproduce, as most amphibians still do today. Exceptions are the terrestrial salamanders that use spermatophores to transfer sperm, as mentioned earlier. The spermatophore provides a protective, non-desiccating environment for the sperm. Other amphibians, like most fishes, rely on sexual behavior to bring eggs and sperm together. Frog mating behavior is characterized by amplexus, a behavior in which a male grasps a female around the middle with his forelegs and holds on until she releases her egg mass, at which time he releases his sperm (Figure 42.6).

Reptiles were the first vertebrate group to solve the problem of reproduction in the terrestrial environment.

738 CHAPTER FORTY-TWO

Agalychnis saltator

42.6 Getting Sperm and Eggs Together

Fertilization in frogs is external, but amplexus—a behavior in which the male holds the female with his forelegs until she releases her egg mass—helps guarantee that sperm and eggs will get together.

Their solution, the shelled egg, is shared by birds (Figure 42.7). But the shelled egg created a new problem for fertilization: Sperm cannot penetrate the shell, so they have to reach the egg before the shell forms. Hence the need for internal fertilization and the evolution of the necessary accessory sex organs.

Male snakes and lizards have paired hemipenes, which can be filled with blood and thereby extruded from the male's cloaca to form intromittent organs. Only one hemi-

(a) *Chelonia mydas*

42.7 The Shelled Egg

The shelled egg was a major evolutionary step that allowed reptiles and birds to reproduce in the terrestrial environment, (a) A female green sea turtle deposits her eggs in the sand, (b) Because the terrestrial environment offers no water to bring sperm and egg together, fertilization must take place internally, as with these penguins.

penis is inserted in the female's cloaca at a time. It is usually rough or spiny at the end to achieve a secure hold while sperm are transferred down a groove on its surface. Retractor muscles pull the hemipenis back into the male's body when mating is completed. Birds have erectile penises that channel sperm along a groove into the female cloaca.

All mammals use internal fertilization, but except for the monotremes, they have done away with the shelled egg. They keep the developing embryo in the female reproductive tract, at least through the early stages of development. Mammalian species differ enormously as to the developmental stage of the offspring at the time of birth.

Reproductive systems are distinguished by where the embryo develops

Two patterns of care and nurture of the embryo have evolved in animals: oviparity (egg bearing) and viviparity (live bearing). Oviparous animals lay eggs in the environment, and their embryos develop outside the mother's body. Oviparity is possible because eggs are stocked with abundant nutrients to supply the needs of the embryo.

Oviparous terrestrial animals such as insects, reptiles, and birds protect their eggs from desiccation with tough, waterproof membranes or shells. However, these egg coverings must be permeable to oxygen and carbon dioxide.

(b) *Aptenodytes patagonicus*

ANIMAL REPRODUCTION 739

Some oviparous animals engage in various forms of parental behavior to protect their eggs, but until the eggs hatch, the embryos depend entirely on the nutrients stored in the egg. The only oviparous mammalian species are the monotremes: the echidnas and the duck-billed platypus (see Figure 33.22).

Viviparous animals retain the embryo within the mother's body during its early developmental stages. Most mammals are viviparous. There are examples of viviparity in all other vertebrate groups except the crocodiles, turtles, and birds. Even some sharks retain fertilized eggs in their bodies and give birth to free-living offspring. But there is a big difference between viviparity in mammals and in other species. Mammals (except monotremes) have a specialized portion of the female reproductive tract, the uterus, that holds the embryo and enables it to derive nutrients from and deliver wastes to the maternal blood. In contrast, non-mammalian viviparous animals simply retain the fertilized eggs in the mother's body until they hatch. The embryos still receive their nutrition from the stores in the egg, so this reproductive adaptation is called ovoviviparity.

Among mammals there are various degrees of uterine adaptation. In marsupials, such as kangaroos and koalas, the uterus simply holds the embryo and has a limited capability for exchanging nutrients and wastes. Marsupials are born at a very early developmental stage, crawl into a pouch called a marsupium on the mother's belly, attach to a nipple, and complete development outside of the mother's uterus (see Figure 33.23). Mammals other than monotremes and marsupials are called eutherians. They are characterized by an intimate association of the blood supplies of mother and embryo in the walls of the uterus. We will now look at the reproductive system of eutherians in greater depth, using *Homo sapiens* as our model.

o Semen is ejaculated through the male copulatory organ, the penis.

The Human Reproductive System

So far we have seen a small sampling of the fascinating diversity of animal reproductive systems. In this section we describe the structures and functions of the male and female sex organs in eutherian mammals, specifically in human beings, and discuss hormonal regulation of both male and female systems.

Male sex organs produce and deliver semen

Semen is the product of the male reproductive system. Besides sperm, semen contains a complex mixture of fluids and molecules that support the sperm and facilitate fertilization. Sperm make up less than five percent of the volume of the semen.

Sperm are produced in the testes, the paired male gonads. In all mammals except bats, elephants, and marine mammals, the testes are located outside the body cavity in a pouch of skin, the scrotum (Figure 42.8). The optimal temperature for spermatogenesis in most mammals is slightly lower than the normal body temperature. The scrotum keeps the testes at this optimal temperature. Muscles in the scrotum contract in a cold environment, bringing the testes closer to the warmth of the body; in a hot environment they relax, suspending the testes farther from the body.

A testis consists of tightly coiled seminiferous tubules within which spermatogenesis takes place. Each tubule is lined with a stratified epithelium. Spermatogonia reside in the outer layers of this epithelium, and moving from these outer layers toward the lumen of the tubule, we find germ cells in successive stages of spermatogenesis (Figure 42.9). These germ cells are intimately associated with Sertoli cells, which protect them by providing a barrier between them and any noxious substances that might be circulating in the blood. Sertoli cells also provide nutrients for the developing sperm and are involved in the hormonal control

of spermatogenesis. Between the seminiferous tubules are clusters of Leydig cells, which produce male sex hormones.

With completion of the second meiotic division, each primary spermatocyte has given rise to four spermatids (see Figure 42.4a), which develop into sperm as they continue to migrate toward the lumen of the seminiferous tubule. The nucleus in what will become the head of the sperm becomes compact, and the surrounding cytoplasm is lost (see Figure 42.9). A flagellum, or tail, develops. The mitochondria, which will provide energy for tail motility, become condensed into a midpiece between the head and the tail. A cap, called an acrosome, forms over the nucleus in the head of the sperm. The acrosome contains enzymes that enable the sperm to digest a path through protective layers surrounding the egg. Fully differentiated sperm are shed into the lumen of the seminiferous tubule.

From the tubules, sperm move into a storage structure called the epididymis, where they mature and become motile. The epididymis connects to the urethra by a tube called the vas deferens (plural vasa deferentia). The urethra originates in the bladder, runs through the penis, and opens to the outside of the body at the tip of the penis. It serves as the common duct for the urinary and reproductive systems (see Figure 42.8).

The penis and the scrotum are the male genitalia. The shaft of the penis is covered with normal skin, but the tip, or glans penis, is covered with thinner, more sensitive skin that is especially responsive to sexual stimulation. A fold of skin called the foreskin covers the glans of the human penis.

The cultural practice of circumcision removes a portion of the foreskin.

Sexual arousal triggers responses in the the autonomic nervous system that result in the erection of the penis. The vessels carrying blood into the penis dilate, and this increased blood flow fills and swells shafts of spongy, erectile tissue located along the length of the penis. The enlargement of these blood-filled cavities compresses the vessels that normally carry blood out of the penis. As a result, the erectile tissue becomes more and more engorged with blood. The penis becomes hard and erect, facilitating its insertion into the female's vagina.*

The culmination of the male sex act propels semen through the vasa deferentia and the urethra in two steps, emission and ejaculation. During emission, rhythmic contractions of the smooth muscles of the ducts containing sperm and of the accessory glands move sperm and the various secretions into the urethra at the base of the penis. Ejaculation, which follows emission, is caused by contractions of other muscles at the base of the penis surrounding the urethra. The rigidity of the erect penis allows these contractions to force the gelatinous mass of semen through the urethra and out of the body.

Once a climax has been achieved, the autonomic nervous system switches signaling and causes the vessels leading

The male reproductive system is under hormonal control by the hypothalamus and the anterior pituitary.

into the penis to constrict. The resulting decrease in blood pressure in the erectile tissue relieves the compression of the blood vessels leaving the penis, and the erection declines.

The components of the semen other than sperm come from several accessory glands that contribute secretions to the urethra. A relatively small volume of fluid comes from the bulbourethral glands. This alkaline and mucoid secretion precedes other secretions; it neutralizes acidity in the urethra and lubricates the tip of the penis. About two-thirds of the volume of semen is seminal fluid, which comes from the seminal vesicles. Seminal fluid is thick because it contains mucus and protein. It also contains fructose, an energy source for the sperm, which are too small to carry much of their own fuel. Semen also carries a message for the female reproductive tract in the form of chemicals called prostaglandins. Prostaglandins stimulate rhythmic contractions in the female reproductive tract that help move the sperm up into the regions where fertilization can take place.

One-fourth to one-third of the volume of semen is a thin, milky fluid that comes from the prostate gland. Prostate fluid makes the uterine environment more hospitable to sperm. The prostate also secretes a clotting enzyme that works on the protein in seminal fluid to convert semen into a gelatinous mass. The prostate gland completely surrounds the urethra as it leaves the bladder. This gland tends to enlarge in men over 40 years of age, creating a condition known as benign prostate hyperplasia (BPH). A seriously enlarged prostate can block the urethra and make urination difficult. Unrelated to BPH, prostate cancer is the second most common cancer in men. It is relatively easy to diagnose, however, and is highly curable if detected early.

ANIMAL REPRODUCTION 741

Male sexual function is controlled by hormones

Spermatogenesis and maintenance of male secondary sexual characteristics depend on testosterone, which is produced by Leydig cells in the testes. In Chapter 41 we learned that increased production of testosterone at puberty is due to an increased release of gonadotropin-releasing hormone (GnRH) by the hypothalamus, which in turn stimulates cells in the anterior pituitary to increase their secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (Figure 42.10). Negative feedback loops help to regulate testis functions.

The Leydig cells are stimulated by LH to produce testosterone. The rise in the level of testosterone in the prepubertal male causes the development of secondary sexual characteristics and the pubertal growth spurt, promotes increased muscle mass, and stimulates growth and maturation of the testes. If a male is castrated (has his testes removed) before puberty, he will not develop a deep voice, typical patterns of body hair, or a muscular build, and his external genitalia will remain childlike. Continued production of testosterone after puberty is essential to maintain secondary sexual characteristics and to produce sperm. Spermatogenesis is controlled by the influence of FSH and testosterone on Sertoli cells in the seminiferous tubules.

Female sex organs produce eggs, receive sperm, and nurture the embryo

When an egg matures, it is released from the ovary directly into the body cavity. But the egg can't go far. Each ovary is enveloped by the undulating, fringed opening of an oviduct (also known as a fallopian tube), which sweeps the egg into the tube (Figure 42.11). Cilia lining the oviduct propel the egg slowly toward the uterus, or *zomb*, which is a muscular, thick-walled cavity shaped like an upside-down pear. The uterus is where the embryo develops if the egg is fertilized. At the bottom of the uterus is an opening called the cervix, which leads into the vagina. Sperm are ejaculated into the vagina during copulation, and the fetus passes through the vagina during birth.

Two sets of skin folds surround the opening of the vagina and the opening of the urethra, through which urine passes. The inner, more delicate folds are the labia minora (singular labium minus); the outer, thicker folds are the labia majora (singular labium majus). At the anterior tip of the labia minora is the clitoris, a small bulb of erectile tissue that is the anatomical homolog of the penis. The clitoris is highly sensitive and plays an important role in sexual response. The labia minora and the clitoris become engorged with blood in response to sexual stimulation.

The opening of an infant female's vagina is partly covered by a thin membrane, the hymen. Eventually the hymen becomes ruptured by vigorous physical activity or first sexual intercourse; it can sometimes make first intercourse difficult or painful for the female.

To fertilize an egg, sperm swim and are propelled by contractions of the female reproductive tract up from the vagina, through the cervix, the uterus, and most of the

742 CHAPTER FORTY-TWO

o Eggs are taken into the oviducts, where they travel to the uterus. Fertilization may occur in the upper regions of the oviduct, and development begins.

oviduct. The egg (actually a secondary oocyte in humans; see Figure 42. 4b) is fertilized in the upper region of the oviduct. Fertilization stimulates the completion of the second meiotic division, after which the haploid nuclei of the sperm and the egg can fuse to produce a diploid zygote nucleus. Still in the oviduct, the zygote undergoes its first few cell divisions to become a blastocyst. The blastocyst moves down the oviduct to the uterus, where it attaches itself to the epithelial lining, the endometrium. The endometrium and the cells of the uterine wall are stimulated by estrogen to proliferate and grow many new blood vessels in anticipation of receiving a blastocyst.

Once attached to the endometrium, the blastocyst burrows into it, a process called implantation, and forms a structure called the placenta. The placenta exchanges nutrients and waste products between the mother's blood and the baby's blood. If a blastocyst does not arrive in the uterus, the endometrium regresses or is sloughed off. Thus the female reproductive cycle actually consists of two linked cycles: an ovarian cycle that produces eggs and hormones, and a uterine cycle that creates an appropriate environment for the embryo should fertilization occur.

The ovarian cycle produces a mature egg

An ovarian cycle is about 28 days long in the human female,* but there is considerable variation among individu-

*Some mammals have ovarian cycles shorter than 28 days, others have longer ones. Rats and mice have ovarian cycles of about 4 days; many seasonally breeding mammals have only one ovarian cycle per year.

Labia Labia Vagina majora minora

als. During the first half of the cycle, at least one primary oocyte matures into a secondary oocyte (egg) and is expelled from the ovary. During the second half of the cycle, cells in the ovary that were associated with the maturing oocyte develop endocrine functions and then regress if the egg is not fertilized. The progression of these events is shown diagrammatically in Figure 42.12.

At birth, a human female has about a million primary oocytes in each ovary. By the time she reaches sexual maturity, she has only about 200,000; the rest have degenerated. During a woman's fertile years, her ovaries will go through about 450 ovarian cycles, and during each of these cycles one oocyte will mature and be released. At about 50 years of age, she reaches menopause, the end of fertility, and may have only a few oocytes left in each ovary. Throughout a woman's life, oocytes are degenerating, and no new ones are produced.

Each primary oocyte in the ovary is surrounded by a layer of follicle cells. An oocyte and its follicle cells constitute the functional unit of the ovary, the follicle. Between puberty and menopause, six to twelve follicles begin to mature each month. In each of these follicles, the oocyte enlarges and the surrounding cells proliferate. After about a week, one of these follicles is larger than the rest and continues to grow, while the others cease to develop and shrink. In the enlarged follicle, the follicle cells nurture the growing egg, supplying it with nutrients and with macro-molecules and proteins that it will use in early stages of development if it is fertilized.

After 2 weeks of follicular growth, ovulation occurs— the follicle ruptures, and the egg is released. Following ovulation, the follicle cells continue to proliferate and form a mass of endocrine tissue about the size of a marble. This

FTI ^ 42.12 The Ovarian Cycle

The ovarian cycle progresses from the development of a follicle to ovulation and finally to growth and degeneration of the corpus luteum. The micrograph shows a mature mammalian follicle; the oocyte is in the center.

If pregnancy does not occur, the corpus luteum degenerates.

| Primary oocytes are present in the ovary at birth.

I The remaining follicle cells form the corpus luteum, which produces progesterone and estrogen.

Ruptured follicle Egg

Ligament (holds ovary in place in body)

About once a month 6-12 primary oocytes begin to mature.

A primary oocyte and its surrounding cells constitute a follicle.

The developing oocyte is nourished by surrounding follicle cells.

Q After 1 week, usually only one primary oocyte (2n) continues to develop. A meiotic division just before ovulation creates the secondary oocyte (n).

structure, which remains in the ovary, is the corpus luteum (plural corpora lutea). It functions as an endocrine gland, producing estrogen and progesterone for about 2 weeks. It then degenerates unless the egg is fertilized.

The uterine cycle prepares an environment for the fertilized egg

The uterine cycle of human females parallels the ovarian cycle, and consists first of a buildup and then of a breakdown of the endometrium, or uterine lining (Figure 43.13). About 5 days into the ovarian cycle, the endometrium starts to grow in preparation for receiving a blastocyst. The uterus attains its maximum state of preparedness about 5 days after ovulation and remains in that state for another 9 days. If a blastocyst has not arrived by that time, the endometrium begins to break down, slough off, and flow from the body through the vagina—the process of menstruation (from menses, the Latin word for "months").

The uterine cycles of mammals other than humans do not include menstruation; instead, the uterine lining is re-sorbed. In

these species the most obvious correlate of the ovarian cycle is a state of sexual receptivity called estrus around the time of ovulation. When the female comes into estrus, or "heat," she actively solicits male attention and may be aggressive to other females. The human female is unusual among mammals in that she is potentially sexually receptive throughout her ovarian cycle and at all seasons of the year.

Hormones control and coordinate the ovarian and uterine cycles

The ovarian and uterine cycles of human females are coordinated and timed by the same hormones that initiate sexual maturation. Gonadotropins secreted by the anterior pituitary are the central elements of this control. Before puberty (that is, before about 11 years of age), the secretion of gonadotropins is low, and the ovaries are inactive. At puberty, the hypothalamus increases its release of gonadotropin-releasing hormone (GnRH), thus stimulating the anterior pituitary to secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

In response to FSH and LH, ovarian tissue grows and produces estrogen. The rise in estrogen causes the development of female secondary sexual characteristics, including growth of the uterus. Between puberty and menopause, interactions of gonadotropin-releasing hormone, gonadotropins, and sex steroids control the ovarian and uterine cycles.

Menstruation marks the beginning of the uterine and ovarian cycles (see Figure 42.13). A few days before menstruation begins, the anterior pituitary begins to increase its secretion of FSH and LH. In response, some follicles begin to mature in the ovaries, and follicle cells gradually increase production of estrogen. After about a week of growth, usually all but one of these follicles wither away. Occasionally more than one follicle continues to develop, making it possible for the woman to bear fraternal (nonidentical) twins.

744 CHAPTER FORTY-TWO

rn

42.13 The Uterine and Ovarian Cycles

During a woman's uterine and ovarian cycles there are coordinated changes in (a) gonadotropin release by the anterior pituitary, (b) the ovary, (c) the release of female sex steroids, and (d) the uterus. The cycles begin with the onset of menstruation; ovulation is at midcycle.

FSH and LH are under control of GnRH from the hypothalamus and the ovarian hormones estrogen and progesterone.

FSH stimulates the development of follicles; the LH surge causes ovulation and then the development of the corpus luteum.

Ovarian hormones stimulate the development of the endometrium in preparation for pregnancy.

The development of the uterine lining (the endometrium) is controlled by estrogen and progesterone.

42.14 Hormones Control the Ovarian and Uterine Cycles

The ovarian and uterine cycles are under a complex series of positive and negative feedback controls involving several hormones.

The follicle that is still growing secretes increasing amounts of estrogen, stimulating the endometrium to grow.

Estrogen exerts negative feedback control on gonadotropin release by the anterior pituitary during the first 12 days of the ovarian cycle. Then, on about day 12, estrogen exerts positive rather than negative feedback control on the pituitary (Figure 42.14). As a result, there is a surge of LH, and a lesser surge of FSH. The LH surge triggers the mature follicle to rupture and release its egg, and it stimulates follicle cells to develop into the corpus luteum and to secrete estrogen and progesterone.

Estrogen and especially progesterone secreted by the corpus luteum following ovulation are crucial to the continued growth and maintenance of the endometrium. In addition, these sex steroids exert negative feedback control on the pituitary, inhibiting gonadotropin release and thus preventing new follicles from beginning to mature.

If the egg is not fertilized, the corpus luteum degenerates on about day 26 of the cycle. Without the production of progesterone by the corpus luteum, the endometrium sloughs off, and menstruation occurs. The decrease in circulating steroids also releases the hypothalamus and pituitary

ANIMAL REPRODUCTION 745

from negative feedback control, so GnRH, FSH, and LH all increase. The increase in these hormones induces the next round of follicle development, and the ovarian cycle begins again.

If the egg is fertilized, and a blastocyst arrives in the uterus and implants itself in the endometrium, a new hormone comes into play. A layer of cells covering the blastocyst begins to secrete human chorionic gonadotropin (hCG). This gonadotropin, a molecular homolog of LH, keeps the corpus luteum functional. Because hCG is present only in the blood of pregnant women, the presence of this hormone is the basis for pregnancy testing.

These tissues derived from the blastocyst also begin to produce estrogen and progesterone, eventually replacing the corpus luteum as the most important source of these sex steroids. Continued high levels of estrogen and progesterone prevent the pituitary from secreting gonadotropins; thus the ovarian cycle ceases for the duration of the pregnancy. The same mechanism is exploited by birth control pills, which contain synthetic hormones resembling estrogen and progesterone that prevent the ovarian cycle (but not the uterine cycle) by exerting negative feedback control on the hypothalamus and pituitary.

Human Sexual Behavior

The organs of the male and female reproductive systems are similar in all eutherians. However, the hormonal and emotional biology of reproductive behavior in humans is more complex. The emotional and social complexities that have evolved to such a tremendous degree in humans have affected our reproductive lives, as have our extensive technological achievements. Here we discuss human sexual responses and technologies for both contraception (birth control) and enhanced fertility. The chapter closes with a discussion of sexually transmitted diseases.

Human sexual responses consist of four phases

The responses of both women and men to sexual stimulation consist of four phases: excitement, plateau, orgasm, and resolution. As sexual excitement begins in a woman, her heart rate and blood pressure rise, muscular tension increases, her breasts swell, and her nipples become erect. Her external genitals, including the sensitive clitoris, swell as they become filled with blood, and the walls of the vagina secrete lubricating fluid that facilitates copulation.

As a woman's sexual excitement increases, she enters the plateau phase. Her blood pressure and heart rate rise further, her breathing becomes rapid, and the clitoris begins to retract—the greater the excitement, the greater the retraction. The sensitivity that once focused in the clitoris spreads over the external genitals, and the clitoris itself becomes even more sensitive. Orgasm may last as long as a few minutes, and, unlike men, some women can experience several orgasms in rapid succession. During the resolution phase, blood drains from the genitals, and body physiology returns to close to normal.

In the male, as in the female, the excitement phase is marked by an increase in blood pressure, heart rate, and muscle tension. The penis fills with blood and becomes hard and erect. In the plateau phase, breathing becomes rapid, the diameter of the glans increases, and a clear lubricating fluid from the bulbourethral glands oozes from the penis. Pressure and friction against the nerve endings in the glans and in the skin along the shaft of the penis eventually trigger orgasm. Massive spasms of the muscles in the genital area and contractions in the accessory reproductive organs result in ejaculation.

Within a few minutes after ejaculation, the penis shrinks to its former size, and body physiology returns to resting conditions. The male sexual response includes a refractory period immediately after orgasm. During this period, which may last 20 minutes or more, a man cannot achieve a full erection or another orgasm, regardless of the intensity of sexual stimulation.

Humans use a variety of technologies to control fertility

People use many methods to control the number of their children and the time between their children's births. The only absolutely sure methods of preventing fertilization and pregnancy are complete abstinence from sexual activity or surgical removal of the gonads. Since those approaches are not acceptable to most people, they turn to a variety of other methods to prevent pregnancy or conception, which therefore are called methods of contraception.

Some methods of contraception are used by the woman, others by the man. They vary from means of blocking gametogenesis to means of blocking development of the embryo. Contraceptive methods vary enormously in their effectiveness and in their acceptability to those who use them. Here we review some of the most common methods and their relative failure rates (Table 42.1).

nontechnological approaches. An approach to contraception that does not involve physical or pharmacological technologies is to separate sperm and egg in time through the rhythm method. The couple avoids sex from day 10 to day 20 of the ovarian cycle, when the woman is most likely to be fertile. The cycle can be tracked by use of a calendar, supplemented by the basal body temperature method, which identifies the day of ovulation on the basis of the observation that a woman's body temperature drops on the day of ovulation and rises sharply on the day after. Changes in the stickiness of the cervical mucus also help identify the day of ovulation.

However, sperm deposited in the female reproductive tract may remain viable for up to 6 days. Similarly, the ovum remains viable for 2 to 3 days after ovulation. These facts, added to individual variation in the timing of ovulation, result in an annual failure rate of between 15 and 35 percent for the rhythm method. In other words, 15 to 35 percent of women using only the rhythm method for 1 year will become pregnant during that time.

Another approach is to try to separate sperm and egg in space through coitus interruptus —withdrawal of the penis before ejaculation. The annual failure rate of this method may be as high as 40 percent.

barrier methods. Techniques for placing a physical barrier between egg and sperm have been used for centuries. The condom is a sheath made of an impermeable material such as latex that can be fitted over the erect penis. A condom traps the semen so that sperm do not enter the vagina. Condoms also help prevent the spread of sexually transmitted diseases such as AIDS, syphilis, and gonorrhea. In theory, the use of a condom can be highly effective, with a failure rate near zero; in practice, the annual failure rate is about 15 percent, because of faulty technique. There is also a female condom, which can be used by the woman to create an impermeable lining of the vagina.

The diaphragm is a dome-shaped piece of rubber with a firm rim that fits over the woman's cervix and thus blocks sperm from entering the uterus. Smaller than the diaphragm is the cervical cap, which fits snugly just over the tip of the cervix. Both the diaphragm and the cervical cap are treated first with jelly or cream containing a spermicide —a chemical that kills or incapacitates sperm— and then inserted through the vagina before sexual intercourse. Annual failure rates are about the same as for condoms—about 15 percent.

Spermicidal foams, jellies, and creams can be used alone by placing them in the vagina with special applicators. Used in this way, they have an annual failure rate of 25 percent or more. Douching (flushing the vagina with liquid) after intercourse, in spite of popular belief, is almost useless as a method of birth control. Remember that sperm can reach the upper regions of the oviducts within 10 minutes after ejaculation.

15-35 10-40 3-20 3-25

The effectiveness of barrier methods can be greatly improved if different ones are used in combination. For example, if the man uses a condom and the woman a diaphragm, the failure rate is extremely low.

preventing ovulation. The widely used oral contraceptives, or birth control pills, work by preventing ovulation. Their mechanisms of action take advantage of the roles of estrogens and progesterone as negative feedback signals that work on both the hypothalamus and the pituitary to inhibit gonadotropin release. The most common pills contain low doses of synthetic estrogens and progesterones (progestins). By keeping the circulating levels of gonadotropins low, the birth control pill interferes with the maturation of follicles and ova. The ovarian cycle (but not the uterine cycle) is suspended. The negative side effects of oral contraceptives have been the topic of extensive discussion. These side effects include increased risk of blood clot formation, heart attack, stroke, and breast cancer. However, these side effects are associated mostly with pills containing higher hormone concentrations than are used in modern pills. For pills in use today, the risk of these side effects is low, except for women over 35 years old who smoke, for whom the risk is significantly greater. Risk of death from using "the pill" is less than the risk associated with a full-term pregnancy. The pill is the most effective method of contraception other than sterilization or perhaps combined barrier methods. Oral contraceptives have an annual failure rate of less than 1 percent.

The "mini-pill" is an oral contraceptive that contains very low doses of progestins. Although it may interfere with the normal maturation and release of ova, its principal mode of action is to alter the environment of the female reproductive tract so that it is not hospitable to sperm. Cervical mucus normally becomes watery at the time of ovulation, but low levels of progestin keep the mucus thick and sticky so that it blocks the passage of sperm.

Long-lasting injectable or implantable steroids are also used to block ovulation. DepoProvera is an injectable progestin that blocks normal pituitary function for several months. Another device, called Norplant, consists of thin, flexible tubes filled with progestin. Several of these tubes are inserted under the skin, where they continue to release progestin slowly for years.

preventing implantation. A highly effective method of contraception (with a failure rate varying from 1 percent to about 7 percent) is the intrauterine device, or IUD. The IUD is a small piece of plastic or copper that is inserted in the uterus. The IUD probably works by preventing implantation of the fertilized egg.

Another way of interfering with implantation is through the use of "morning-after pills/" which deliver high doses of steroids, primarily estrogens. By acting in several ways on the oviduct and the uterine lining, this treatment prevents implantation. Morning-after pills can be effective up to several days after intercourse.

A recent addition to birth control technology is a drug, RU-486, developed in France. RU-486 is not a contraceptive pill, but a contragestatiotml pill. It is a progesterone-like molecule that blocks progesterone receptors. It therefore interferes with the normal action of progesterone produced by the corpus luteum, which is necessary for the maintenance of the uterine lining in early pregnancy. If RU-486 is administered as a "morning-after pill", it prevents implantation. However, RU-486 can be effective even if taken at the time of the first missed menses after fertilization, after implantation has been initiated. After a few days of treatment with RU-486, the endometrium regresses and sloughs off along with the embryo, which is in very early stages of development.

sterilization. One virtually foolproof method of contraception is sterilization of either the man or the woman. Male sterilization by vasectomy is a simple operation that can be performed under a local anesthetic in a doctor's office (Figure 42.15a). After this minor surgery, the semen no longer contains sperm. Sperm production continues, but since the sperm cannot move out of the testes, they are destroyed by macrophages. Vasectomy does not affect a man's hormone levels or his sexual responses, and even the amount of semen he ejaculates is unchanged, because the sperm constitute so little of its volume.

In female sterilization, the aim is to prevent the egg from traveling to the uterus and to block sperm from reaching the egg. The most common method is tubal ligation —cutting and tying the oviducts (Figure 42.15b). Alternatively, the oviducts may be burned (cauterized) to seal them off, using a surgical technique called endoscopy. As in the male, these procedures do not alter reproductive hormones or sexual responses.

abortion. Once a fertilized egg has successfully implanted itself in the uterus, the termination of a pregnancy is called an abortion. A spontaneous abortion is the medical term for what is usually called a miscarriage. Miscarriages are common early in pregnancy; most of them occur because of an abnormality in the fetus or in the process of implantation. Abortions that are not spontaneous, but are the result of medical intervention, may be done either for therapeutic or for contraceptive purposes. A therapeutic abortion may be necessary to protect the health of the mother, or it may be performed because prenatal testing (which will be discussed in the following chapter) reveals that the fetus has a severe defect.

When performed in the first third of a pregnancy, a medical abortion carries less risk than a full-term pregnancy. The method is to dilate the cervix and then remove the

fetus and the endometrium by physical means. After the first 12 weeks of pregnancy, the risk associated with a medical abortion rises substantially.

controlling male fertility. You may ask why all the chemical approaches to controlling fertility apply to females and none have been devised to block male fertility. The control of male fertility is a difficult problem. First, since the production of sperm is a continuous, rather than a cyclical, event, it is not possible to block a particular step in a cyclical process. The ovarian cycle is vulnerable to manipulation because certain events must happen at certain times for ovulation and implantation to occur. Second, the suppression of spermatogenesis must be total to be effective, since it takes only a single sperm to fertilize an egg, and normally millions are produced. Such suppression requires powerful and continuous chemical intervention with associated side effects.

Reproductive technologies help solve problems of infertility

There are many reasons why a man and woman may not be able to have children. The man's rate of sperm production may be low, or his sperm may lack motility. The mucus in the woman's reproductive tract may be thick and not conducive to sperm moving up to the oviducts. Structural

748 CHAPTER FORTY-TWO

problems may also exist, such as a woman's oviducts being blocked by scar tissue or by endometriosis, a proliferation of endometrial cells outside of the uterus. In some cases, treatment with powerful chemicals to cure cancer damages the ability of the gonads to produce gametes.

Even a couple who are fully fertile and who want children may not want to take the risk of the natural process of fertilization if one or both parents are carriers for a genetic disease. A number of reproductive technologies have been developed to overcome these and other barriers to childbearing.

The oldest and simplest reproductive technology is artificial insemination, which involves placing sperm in the appropriate place in the female's reproductive tract for fertilization to occur. This technique is useful if the male's sperm count is low, if the sperm lack motility, or if problems in the female's reproductive tract prevent the normal movement of sperm up to and through the oviducts. Artificial insemination is used widely in the production of domesticated animals such as cattle.

More recent advances, called assisted reproductive technologies, or ART's, involve procedures that remove

unfertilized eggs from the ovary, combine them with sperm outside of the body, and then place fertilized eggs or egg/sperm

mixtures in the appropriate location in the female's reproductive tract for development to take place.

The first successful ART was in vitro fertilization (IVF). In IVF, the mother is treated with hormones that stimulate many follicles in her ovaries to mature. Eggs are harvested from these follicles, and sperm are collected from the father. Eggs and sperm are combined in a culture medium outside the body (in vitro), where fertilization takes place. The resulting embryos can then be injected into the mother's uterus in the blastocyst stage or kept frozen for implantation later. The first "test tube baby" resulting from IVF was born in 1978. Since that time, thousands of babies have been produced by this ART. IVF is useful when the woman's oviducts are blocked. It has a success rate of 20 to 25 percent.

A technique called gamete intrafallopian transfer (GIFT) can be used when only the entrance to the oviducts from the ovaries, or the upper segment of the oviducts, is blocked. In this procedure, harvested eggs and sperm are

'AIDS is widespread in other parts of the world, most notably in the southern part of the African continent, where some 9 million people are infected. The virus is also spreading rapidly in India and Southeast Asia.

Holding pipette

Egg Pipette injecting sperm

42.16 Intracytoplasmic Sperm Injection

In this procedure, sperm are injected directly into a mature egg cell. The fertilized egg can then be placed back in the female reproductive tract.

injected directly into the upper regions of the oviduct, where fertilization takes place, and the blastocyst enters the uterus via the normal route. GIFT has a success rate of about 30 percent.

ANIMAL REPRODUCTION 749

A major cause of failure of IVF and GIFT is the failure of sperm to gain access to the plasma membranes of eggs. To solve this problem, methods have been developed to inject a sperm cell directly into the cytoplasm of an egg. In intracytoplasmic sperm injection (ICSI), a harvested egg is held in place by suction applied to a polished glass pipette. A slender, sharp pipette is then used to penetrate the egg and inject a sperm (Figure 42.16). This ART was successful for the first time in 1992; now thousands of these procedures are performed in U.S. clinics each year, with a success rate of about 25 percent.

IVF coupled with sensitive techniques of genetic analysis, can eliminate the risk that parents who are carriers for genetic diseases will produce affected children. With in vitro fertilization, it is possible to take a cell from the blastocyst at the 4- or 8-cell stage without damaging its developmental potential. The sampled cell can then be subjected to molecular techniques to determine whether it carries the harmful gene. This information guarantees that only embryos that will not develop the genetic disease are implanted in the mother's uterus.

No cure. Symptoms can be alleviated. Antiviral drugs may lessen subsequent outbreaks

No cure for the virus. Warts can be removed surgically or by burning, freezing, or chemical treatment

No cure. Symptoms can be treated. A vaccine is available that can protect only if given before infection occurs

Antibiotics

The virus enters the bloodstream via cuts or abrasions, including minute ones in the genitalia. Spread primarily by intimate sexual contact, but can also be transmitted via contaminated needles

No cure. Treatments with a variety of medications can slow the course of the infection

750 CHAPTER FORTY-TWO

Sexual behavior transmits many disease organisms

Disease-causing organisms are parasites, and have a very limited ability to survive outside a host organism. Therefore, getting from host to host is a major evolutionary challenge for disease-causing organisms. One of the most intimate types of contact that hosts can have is copulation. It is not surprising, then, that many parasitic organisms have evolved to depend on sexual contact between their hosts as their means of transmission. These organisms are the causes of sexually transmitted diseases (commonly referred to as STD's), and they include viruses, bacteria, yeasts, and protozoans.

STD's have been with humans since ancient times, and they are one of the most serious public health problems today. Over 10 million new cases of STD's occur each year in the United States, and about two-thirds of these cases occur in people between the ages of 15 and 30. About half of the youth in this country will contract an STD before the age of 25.

A summary of the most common STD's is presented in Table 42.2 on the preceding page. The highly prevalent bacterially transmitted diseases chlamydia and gonorrhea are generally not fatal, but when untreated are a major cause of infertility and painful inflammatory diseases. Syphilis is transmitted by a spirochete and is fatal in about half of untreated cases. It is believed that syphilis was brought to the Old World from the New World by the crew of Christopher Columbus, who himself died of advanced syphilis 16 years after his first voyage to North America. AIDS, transmitted by a virus, is an STD of recent origin and currently has a high rate of mortality. The only device that is effective against the transmission of STD's is the condom.

Chapter Summary Asexual Reproduction

► Sexual reproduction is almost universal in animals, but some animals can reproduce asexually, producing offspring that are genetically identical to their parent and to one another. A disadvantage of asexual reproduction is that no genetic diversity is produced.

► Means of asexual reproduction include budding, regeneration, and parthenogenesis. Review Figures 42.1, 42.2

Sexual Reproduction

► Sexual reproduction consists of three basic steps: gametogenesis, mating, and fertilization. Gametogenesis and fertilization are similar in all animals, but mating includes a great variety of anatomical, physiological, and behavioral adaptations.

► In sexually reproducing species, genetic diversity is created by the recombination of genes during gametogenesis and by the independent assortment of chromosomes. Mating and fertilization also contribute to genetic diversity.

► Gametogenesis occurs in testes and ovaries. In spermatogenesis (the production of sperm) and oogenesis (the production of eggs), the primary germ cells proliferate mitotically, undergo meiosis, and mature into gametes. Review Figure 42.4

► Spermatogonia continue to proliferate by mitosis throughout the life span of the male. Each primary spermatocyte can produce four haploid sperm through the two divisions of meiosis. Review Figure 42.4a

► Primary oocytes immediately enter prophase of the first meiotic division, and in many species, including humans, their development is arrested at this point. Each oogonium produces only one egg through meiosis. Review Figure 42.4b

► Hermaphroditic species have both male and female reproductive systems in the same individual, either sequentially or simultaneously.

► Fertilization can occur externally, which is common in aquatic species, or internally, which is common in terrestrial species. Internal fertilization usually involves copulation.

► Internal fertilization is necessary for nonaquatic species. The shelled egg is an important adaptation to the desiccating terrestrial environment, but it must be fertilized before the shell forms. All mammals except monotremes retain the embryo internally and have done away with shelled eggs.

► Animals can be classified as oviparous or viviparous depending on whether the early stages of development occur outside or inside the mother's body.

The Human Reproductive System

► Males produce and deliver semen into the female reproductive tract. Semen consists of sperm suspended in a fluid that nourishes them and facilitates fertilization.

► Sperm are produced in the seminiferous tubules of the testes, mature in the epididymis, and are delivered to the urethra through the vasa deferentia. Other components of semen are produced in the seminal vesicles, prostate gland, and bulbourethral glands. All components of the semen join in the urethra at the base of the penis and are ejaculated through the erect penis by muscle contractions at the culmination of copulation. Review Figures 42.8, 42.9

► Spermatogenesis depends on testosterone secreted by Leydig cells in the testes, which are under control of luteinizing hormone from the pituitary. Spermatogenesis is also controlled by follicle-stimulating hormone from the pituitary. Hypothalamic gonadotropin-releasing hormone controls pituitary secretion of LH and FSH. The production of these hormones by the hypothalamus and pituitary is controlled by negative feedback from testosterone and another hormone produced by the testes, inhibin. Review Figure 42.10

► Eggs (ova) mature in the female's ovaries and are released into the oviducts, which deliver the eggs to the uterus. Sperm deposited in the vagina during copulation move up through the cervix into the uterus, some continuing up through the oviducts. Review Figure 42.11

► Fertilization occurs in the upper regions of the oviducts. The zygote becomes a blastocyst through repeated cell divisions as it passes down the oviduct. Upon arrival in the uterus, the blastocyst implants itself in the endometrium, where a placenta forms and the embryo develops.

► The maturation and release of ova constitute an ovarian cycle under the control of the anterior pituitary hormones FSH and LH. In humans, this cycle takes about 28 days. Review Figures 42.12, 42.13

► The uterus also undergoes a cycle that prepares it for receipt of a blastocyst. If no blastocyst is implanted, the lining of the uterus deteriorates and sloughs off, which is the process of menstruation. Review Figure 42.13

► Both the ovarian and the uterine cycles are under the control of hypothalamic and pituitary hormones, which in turn are under the feedback control of estrogen and progesterone. Review Figure 42.14

ANIMAL REPRODUCTION 751

Human Sexual Behavior

► Human sexual responses consist of four phases: excitement, plateau, orgasm, and resolution. In addition, males have a refractory period during which renewed excitement is not possible.

► Methods to prevent pregnancy include abstention from copulation or the use of technologies that decrease the probability of fertilization. Review Table 42.1

► Barrier methods of contraception, such as condoms, diaphragms, and spermicidal substances, block the passage of sperm in the female reproductive tract or weaken and kill them.

► Methods to prevent ovulation, such as birth control pills and other hormonal treatments, interfere with the ovarian cycle so that mature, fertile ova are not produced and released.

► Males and females can be sterilized by surgical blockage of the vasa deferentia (vasectomy) or oviducts (tubal ligation). Review Figure 42.15

► Methods to prevent implantation of a blastocyst include intrauterine devices, excess doses of steroids, and a progesterone receptor blocker. After implantation, the termination of a pregnancy is called an abortion.

► Assisted reproductive technologies have been developed to increase fertility. ARTs include in vitro fertilization and gamete intrafallopian transfer.

► Sexually transmitted diseases result from the transmission of disease-causing organisms through sexual behavior. Many STD's are curable if treated early, but can have serious long-term consequences if not treated. Review Table 42.2

For Discussion

1. In the very deep ocean, there are species of fish in which the male is very much smaller than the female and actually lives attached to her body. In terms of the selective pressures that operate on sexual and asexual reproduction and in terms of the deep-sea environment, what factors do you think resulted in the evolution of this extreme sexual dimorphism?
2. What are two main differences between the immediate products of the first and second meiotic division in spermatogenesis and oogenesis? Why do these differences exist?
3. At the beginning of each ovarian cycle in humans, about six follicles begin to develop in response to rising levels of FSH, but after a week, only one follicle continues to develop, and the others wither away. Given the facts that follicles produce estrogen, estrogen stimulates follicle cells to produce FSH receptors, and estrogen exerts negative feedback on FSH production in the pituitary, how can you explain how one follicle gets "selected" to grow?
4. Compare the actions of LH and FSH in the ovaries and testes.
5. Ovarian and uterine events in the month following ovulation differ depending on whether fertilization occurs. Describe the differences and explain their hormonal controls.

The whale blows its nose out the top of its head—as in "thar she blows," the infamous whalers' cry. The spout coming out of the blowhole is the whale's exhalation coming out of its nasal passages. It is convenient for a marine mammal to be able to breathe out of the top of its head. Not much of its body has to come out of the water for it to breathe, and it can continue moving forward through the water while breathing. But in most mammals, the nose is on the front of the head. How did the whale's nose happen to get to the top of its head? This is an evolutionary question, but the answer is to be found in embryological development.

The vertebrate body varies enormously among species in form and function, yet its basic structural design is highly conserved. For example, the whale flipper, the bat wing, and the human arm all have the same bones. However, during development these bones assume different shapes and dimensions to adapt the forelimbs to their various functions: swimming, flying, and tool use.

Similarly, vertebrates all have the same bones in their heads, but through development, these bones grow differentially, and therefore the skull takes on different shapes. In both the whale and the human, the nasal passages are in the nasal bone, which in both is just above the bones of the upper jaw. In the human, that places the nasal bone just above the jaw on the front of the face. During development of the whale skull, however, the bones of the upper jaw grow enormously relative to the other bones of the skull, and project far forward to form the cavernous mouth. As a result of this differential forward growth of the jaw bone, the nasal bone ends up on the top of the skull rather than on the front. The answer to why the whale's nose is on the top of its head and how forelimbs become flippers is found in the processes of development that form and shape the components of the basic vertebrate body plan.

Starting from the organization of the fertilized egg, signaling cascades unfold

Thar She Blows!

The nasal passages of the whale *Orcinus orca* are on top of its head because of the extreme growth of its jaw bones during development.

that control the building of the body. Typically, molecules acting as transcription factors influence the temporal and spatial expression of still other genes that control the growth and differentiation of cells. Interactions between cells set up ever more complex signaling relationships that result in the structural and functional differences between species. The chemical and genetic nature of these signals is remarkably similar over widely different species, but the exciting story of development is how these signals are used in different patterns and combinations to produce what we see as different species.

In this chapter we trace the early stages of embryonic development. We begin with the events of fertilization, which can be taken as the starting point for the development of the organism. From there we see how the zygote is converted by rapid cell divisions into a mass of cells. These cells then change position relative to each other, establishing new contacts between different groups of cells. These contacts initiate sequences of changes in cell growth, cell movements, and cell differentiation from which emerge the overall body plan, the various tissues, and the rudimentary organs of the adult.

To appreciate both the diversity and the similarity in the development of different animals, we discuss these early developmental steps in four organisms studied extensively by developmental biologists: sea urchins (invertebrates) and frogs, chicks, and humans (all vertebrates).

Jelly layer Vitelline envelope Egg plasma (extracellular coat) (extracellular membrane matrix)

In the sperm head the nucleus is capped by an enzyme-filled acrosome.

These enzymes digest a path through the protective jelly coat of the egg.

Q An acrosomal process then forms and makes contact with the vitelline envelope...

...which has species-specific receptors for the protein bindin.

The acrosomal process membrane and egg membrane fuse.

Egg cytoplasm

43.1 The Acrosomal Reaction

The acrosomal reaction allows a sea urchin sperm to recognize an egg of the same species and pass through its protective layers.

Fertilization: Interactions of Sperm and Egg

Development in sexually reproducing animals begins with fertilization, the union of sperm and egg to create a single cell: a diploid zygote. Fertilization requires a complex series of events:

- ▶ The sperm and the egg must recognize each other.
- ▶ The sperm must be activated so that it is capable of gaining access to the plasma membrane of the egg.
- ▶ The plasma membranes of the sperm and the egg must fuse.
- ▶ The egg must block entry by additional sperm.
- ▶ In mammals, the egg nucleus must complete its final meiotic division.
- ▶ The egg and sperm nuclei must fuse to create the diploid nucleus of the zygote.

We will look at each of these steps in turn.

Recognition molecules assure specificity in sperm-egg interactions

Specific recognition molecules mediate interactions between sperm and eggs. These molecules assure that the activities of the sperm are directed toward eggs and not other cells, and they help prevent eggs from being fertilized by sperm from the wrong species. The latter function is particularly important in species that engage in external fertilization. The sea urchin is such a species, and its mechanisms of fertilization have been well studied.

ANIMAL DEVELOPMENT 753

The plasma membrane of the sea urchin egg is protected by a proteinaceous vitelline envelope, and surrounding that is a jelly coat. The sperm must get through these two protective layers before it can fuse with the plasma membrane of the egg. To accomplish this, the sperm has a membrane-enclosed structure called an acrosome containing enzymes and other proteins. The acrosome is located at the front end of the sperm head and covers the nucleus.

When the sperm makes contact with an egg of its own species, substances in the jelly coat trigger an acrosomal reaction, which begins with the release of acrosomal enzymes that digest the jelly coat. Next, an acrosomal process extends out of the head of the sperm. The acrosomal process forms from globular actin behind the acrosome, which polymerizes when the acrosomal membrane breaks down (Figure 43.1).

The acrosomal process extends through the jelly coat to make contact with the vitelline envelope. Herein lies another species

recognition mechanism: The acrosomal process is coated with a membrane-bound protein called bindin. Different species have different bindin molecules. The egg plasma membrane has species-specific bindin receptors that extend through the vitelline envelope. The reaction of acrosomal bindin with these receptors stimulates the egg membrane to form a fertilization cone that engulfs the sperm head, bringing it into the egg cytoplasm.

In animals that practice internal fertilization, mating behaviors help guarantee species specificity, but egg-sperm recognition mechanisms still exist. The mammalian egg is surrounded by a thick layer called the cumulus, which consists of follicle cells in a gelatinous matrix (Figure 43.2). Beneath the cumulus is a glycoprotein envelope called the zona pellucida, which is functionally similar to the vitelline envelope of sea urchin eggs. When sperm are first de-

754 CHAPTER FORTY-THREE

posited in the \ aguaa, they are not capable of mounting an acrosomal reaction, but after being in the female reproductive tract for a time, the sperm undergo capacitation. A capacitated sperm is capable of interacting with an egg and its barriers, probably because certain critical proteins on its surface have been altered to make them reactive.

Mammalian sperm have enzymes on their surface that help them digest a path through the cumulus. When they make contact with the zona pellucida, a species-specific glycoprotein in the zona binds to recognition molecules on the head of the sperm. This binding triggers the acrosomal reaction, releasing acrosomal enzymes that digest a path through the zona. Other egg plasma membrane proteins then bind to adhesive proteins on the sperm, facilitating the fusion of sperm and egg plasma membranes.

The importance of the zona pellucida and its binding molecules in protection against heterospecific interactions between sperm and eggs was revealed in experiments in which the zona was stripped from eggs before they were exposed to sperm in a culture dish. In these experiments, it was possible for hamster sperm to fertilize human eggs, creating a hamster-human hybrid zygote. The hybrid zygote did not survive its first cell division because of chromosomal incompatibilities, but the experiment demonstrated that the mammalian species recognition mechanism resides in the zona.

Sperm entry triggers blocks to polyspermy and activates the egg

The fusion of the sperm and egg plasma membranes and the entry of the sperm into the egg initiate a programmed sequence of events. The first responses to sperm entry are blocks to polyspermy —that is, mechanisms that prevent more than one sperm from entering the egg. If more than one sperm enters the egg, the resulting embryo probably will not survive.

Blocks to polyspermy have been studied intensively in sea urchin eggs, which can be fertilized in a dish of seawater. Within a tenth of a second after a sperm enters a sea urchin egg, there is an influx of sodium ions, which changes the electric potential across the egg's plasma membrane. This fast block to polyspermy prevents the fusion of other sperm with the egg plasma membrane (Figure 43.3).

The slow block to polyspermy takes about a minute (Figure 43.4). Before fertilization, the vitelline envelope is bonded to the plasma membrane. Just under the plasma membrane are cortical granules consisting of enzymes and other proteins. The sea urchin egg, like all animal cells, contains calcium that is sequestered in endoplasmic reticulum.

When a sperm enters, the sea urchin egg releases calcium from its endoplasmic reticulum into its own cytoplasm. This increase in cytoplasmic calcium causes the cortical granules to fuse with the plasma membrane. The cortical granule enzymes are released by exocytosis, breaking the bonds between the vitelline envelope and the plasma membrane. Water then flows

into the space between the vitelline envelope and the plasma membrane, raising the vitelline envelope to form the fertilization envelope.

lope. The enzymes also degrade unused sperm-binding molecules at the surface of the fertilization envelope and cause it to harden, preventing the passage of additional sperm.

In mammals, sperm entry does not seem to cause a rapid change in membrane potential, but it does trigger the phosphatidylinositol (PTI) signaling system (see Figure 15.13), resulting in several events. Calcium is released from the endoplasmic reticulum, and the egg's metabolism is activated. The pH of the cytoplasm increases, oxygen consumption rises, and protein synthesis increases.

In mammals, the nuclei of the sperm and the egg do not fuse until about 12 hours after the sperm nucleus is taken into the egg cytoplasm because the nucleus of the egg must still complete its second meiotic division (see Figure 42Ab). Sea urchin eggs have already completed the second meiotic division at the time of sperm entry, and the nuclei fuse within an hour to create the zygote.

The sperm and the egg make different contributions to the zygote

Nearly all of the cytoplasm of the zygote comes from the egg. This cytoplasm is well stocked with nutrients, ribosomes, and a variety of molecules, including mRNAs. Moreover, because the sperm mitochondria degenerate, all of the mitochondria in the zygote come from the egg. In addition to its haploid nucleus, the sperm makes one other important contribution to the zygote in some species: a centriole. This centriole becomes the centrosome of the zygote, which produces the mitotic spindles for subsequent cell divisions.

For a long time, it was assumed that the one thing that sperm and egg contributed equally to the zygote was their haploid nuclei. However, we now know that even though they are equivalent in terms of genetic material, mammalian sperm and eggs are not equivalent in terms of their roles in development. In the laboratory, it is possible to construct zygotes in which both haploid nuclei come from the mother or both come from the father. In neither case does development progress normally. Apparently, in mammals at least, certain genes involved in development are active only if they come from a sperm and others are active only if they come from an egg—a phenomenon that has been termed genomic imprinting.

43.4 The Slow Block to Polyspermy

Enzymes from the sea urchin egg's cortical granules trigger the slow block to polyspermy.

Fertilization causes rearrangements of egg cytoplasm

The entry of the sperm into the egg stimulates changes and rearrangements of the cytoplasm that establish the symmetry and the body axes of the embryo. The nutrients and molecules in the cytoplasm of the zygote are not homogeneously distributed, and are not divided equally among all daughter cells when cell divisions begin. This unequal division of cytoplasmic factors sets the stage for the unfolding series of signals that orchestrates the sequential steps of development: determination, differentiation, and morphogenesis (see Chapter 16).

The rearrangements of egg cytoplasm in some species of frogs can be easily observed because of pigments in the egg

Animal

cytoplasm. The nutrient molecules in an unfertilized frog egg are dense, and are therefore concentrated by gravity in the lower half of the egg, which is called the vegetal hemisphere. The haploid nucleus of the egg is located at the opposite end of the egg, in the animal hemisphere. The outermost (cortical) cytoplasm of the animal hemisphere is heavily pigmented, and the underlying cytoplasm has more diffuse pigmentation. The vegetal hemisphere is not pigmented.

Sperm always enter the frog egg in the animal hemisphere. When this occurs, the cortical cytoplasm rotates toward the site of sperm entry. This rotation exposes a band of diffusely pigmented cytoplasm on the side of the egg opposite the site of sperm entry. This band, called the gray crescent, will be the site of important developmental events (Figure 43.5).

The cytoplasmic rearrangements that create the gray crescent bring different regions of cytoplasm into contact on opposite sides of the egg. Therefore, bilateral symmetry is imposed on what was a radially symmetrical egg. Instead of just the up-down difference of the animal and vegetal hemispheres, the movement of the cytoplasm sets the stage for the creation

43.5 The Gray Crescent

Rearrangements of the cytoplasm of frog eggs after fertilization create the gray crescent.

756 CHAPTER FORTY-THREE

of the anterior-posterior and left-right axes. In the frog, the site of sperm entry will become the ventral (belly) region, and the gray crescent will become the dorsal (back) region of the embryo. Since the gray crescent also marks the posterior end of the embryo, these relationships specify the anterior-posterior and left-right axes as well.

The molecular mechanism of this critical first step in embryo formation is beginning to be understood. The sperm centriole rearranges the microtubules in the vegetal pole cytoplasm into a parallel array that presumably guides the movement of the cortical cytoplasm. Organelles and certain proteins from the vegetal hemisphere move to the gray crescent region even faster than the cortical cytoplasm rotates.

As a result of these movements of cytoplasm, proteins, and organelles, changes in the distribution of critical developmental signals occur. A protein kinase called GSK-3 and a protein called β -catenin become unevenly distributed in the cytoplasm of the frog zygote. β -catenin is produced from maternal mRNA found throughout the cytoplasm of the egg. Once the zygote becomes a multicellular embryo, β -catenin will act as a transcription factor in the nuclei of those cells where it is present. GSK-3, which is also present throughout the egg cytoplasm, causes the degradation of β -catenin. However, inhibitors of GSK-3 migrate along the vegetal microtubules and prevent GSK-3 from degrading β -catenin (Figure 43.6). As a result, there is a higher concentration of β -catenin on what will become the dorsal side of the embryo.

Evidence supports the hypothesis that β -catenin is a key player in the cell-cell signaling cascade that begins the formation of the embryo in the region of the gray crescent. But before there can be cell-cell signaling, there must be multiple cells.

Cleavage: Repackaging the Cytoplasm

At some point after fertilization is complete (the exact timing differs among species), a rapid series of cell divisions called cleavage takes place. Because the cytoplasm of the zygote is not homogeneous, these first cell divisions result in the differential distribution of nutrients and informational molecules among the cells of the early embryo. In most animals, cleavage proceeds with rapid DNA synthesis and mitosis, but no cell growth and little gene expression. The embryo becomes a ball of smaller and smaller cells. This ball forms a central cavity called a blastocoel (a process called blastulation), at which point it is called a blastula. The individual cells are called blastomeres.

Cleavage, and therefore the formation of the blastula, is influenced in different species by two major factors. First, in some species, massive amounts of nutrients, or yolk, are stored in the egg. The yolk influences the pattern of cell divisions by impeding the formation of cleavage furrows between the daughter cells. Second, proteins and mRNAs stored in the egg by the mother guide the formation of mitotic spindles and the timing of cell divisions.

The vesicles release GSK-inhibiting protein...

...so GSK-3 cannot degrade β -catenin on the dorsal side...

J ...but does degrade it on the ventral side.

Thus there is a higher β -catenin concentration in the dorsal cells of the early embryo.

43.6 Cytoplasmic Factors Set Up Signaling Cascades

Cytoplasmic movement changes the distributions of critical developmental signals. In the frog zygote, the interaction of the protein kinase GSK-3, its inhibitor, and the protein β -catenin are crucial in specifying the dorsal-ventral (back-belly) axis of the embryo.

The amount of yolk influences cleavage

When the yolk content of the egg is sparse, there is little interference with cleavage furrow formation, and all the daughter cells are of similar size; the sea urchin egg provides an example (Figure 43.7a). More yolk means more resistance to cleavage furrow formation; therefore, cell divisions progress more rapidly in the animal hemisphere than in the vegetal hemisphere, where the yolk is concentrated. As a result, the cells derived from the vegetal hemisphere are fewer and larger; the frog egg provides an example (Figure 43.7b).

In spite of this difference between sea urchin and frog eggs, the cleavage furrows completely divide the egg mass in both cases; thus these animals are said to have complete cleavage. In contrast, in an egg, such as the chicken egg, that contains a lot of yolk, the cleavage furrows do not penetrate the yolk. As a result, cleavage is incomplete, and the embryo forms as a disc of cells, called a blastodisc, on top of the yolk mass (Figure 43.7c). This type of cleavage, called incomplete cleavage, is common in fishes, reptiles, and birds.

Another type of incomplete cleavage, called superficial cleavage, occurs in insects such as the fruit fly (*Drosophila*).

The nuclei migrate to the periphery, and plasma membranes form between them.

43.7 Patterns of Cleavage in Four Model Organisms

Patterns of early embryonic development reflect differences in the way the egg cytoplasm is organized.

In the insect egg, the massive yolk is centrally located (Figure 43.7d). Early in development, cycles of mitosis occur without cytokinesis. Eventually the resulting nuclei migrate to the periphery of the egg, and after several more mitotic cycles, the plasma membrane of the egg grows inward, partitioning the nuclei off into individual cells.

The orientation of mitotic spindles influences the pattern of cleavage

The positions of the mitotic spindles during cleavage are not random; rather, they are determined by cytoplasmic factors. In turn, the orientation of the mitotic spindles determines the cleavage planes and, therefore, the arrangement of the daughter cells.

If the mitotic spindles of successive cell divisions form at right angles or parallel to the animal-vegetal axis of the zygote, the cleavage pattern is radial, as in the sea urchin and the frog (see Figure 43.7a and b). The orientations of successive mitotic spindles in mammals are also at right angles or

parallel to the animal-vegetal axis, but the sequence is different from that in sea urchins, resulting in a pattern called rotational cleavage. In mollusks, the successive mitotic spindles are not at right angles; the resulting pattern has a twist, and is called spiral cleavage. The coiling of snail shells is an expression of this form of cleavage.

Cleavage in mammals is unique

The early development of placental mammals is quite different from that of the other species we have discussed. The zygote of a placental mammal produces both an embryo and the elaborate extraembryonic structures that serve as the interface between the embryo and the maternal uterus. Cell divisions are slower and genes are expressed during cleavage in placental mammals. As a result, proteins encoded by the genes of the embryo play a role in cleavage. In other species, cleavage is directed almost entirely by molecules that were present in the egg.

As in other animals that have complete cleavage, the early cell divisions in a mammalian zygote produce a loosely associated ball of cells. However, at about the 8-cell stage, the behavior of the cells changes. They suddenly maximize their surface contact with each other, form tight junctions, and become a very compact mass of cells.

At the transition from the 16-cell to the 32-cell stage, the cells separate into two groups. The innermost cells form the inner cell mass that will become the embryo, while the outermost cells become an encompassing sac called the trophoblast, which will become part of the placenta. The trophoblast cells secrete fluid, thus creating a cavity with the inner cell mass at one end (Figure 43.8). At this stage, the mammalian embryo is called a blastocyst to distinguish it from the blastula of other animals.

When the blastocyst reaches the uterus, the trophoblast adheres to the uterine wall, beginning the process of implantation that embeds the embryo in the endometrium. In humans, implantation begins about the sixth day after fertilization. Implantation must not occur as the blastocyst moves down the oviduct to the uterus, or the result will be an ectopic or tubal pregnancy—a very dangerous condition. Early implantation is normally prevented by the zona pellucida, which remains around the cleaving ball of cells. At about the time the blastocyst reaches the uterus, it "hatches" from the zona pellucida, and implantation can occur.

Specific blastomeres generate specific tissues and organs

Cleavage in all species results in a repackaging of the cytoplasm of the egg into a large number of small cells surrounding a central cavity. Little cell differentiation has occurred during cleavage, and in most nonmammalian species none of the genome of the embryo has been expressed. Nevertheless, cells in different regions of the blastula possess different complements of the nutrients and informational molecules that were present in the egg.

The blastocoel prevents cells from different regions of the blastula from interacting, but that will soon change. During the next stage of development, the cells of the blastula will move around and come into new associations with one another, communicate instructions to one another, and begin to differentiate.

In many animals, the movements of the blastomeres are so regular and well orchestrated that it is possible to label a specific blastomere and identify the tissues and organs that form from its progeny. Such labeling experiments produce fate maps of the blastula (Figure 43.9).

Blastomeres become determined—committed to specific fates—at different times in different species. In some

43.10 Twinning in Humans

In humans, monozygotic (identical) twins result when groups of cells in the blastula become physically separated and both groups produce embryos.

species, such as roundworms and clams, blastomeres at the 8-cell stage are already determined. If one of these blastomeres is experimentally removed, a particular portion of the embryo will not form. This type of development has been called mosaic development because each blastomere seems to contribute a specific set of "tiles" to the final "mosaic" that is the adult animal. In contrast, other species, such as sea urchins, frogs, and vertebrates, have regulative development: The loss of some cells during cleavage does not affect the developing embryo because the remaining cells compensate for the loss.

If some blastomeres can change their fate to compensate for the loss of other cells during cleavage and blastula formation, are these cells capable of forming an entire embryo? To a certain extent they are. During cleavage or early blastula formation, if the blastomeres are physically separated into two groups, both groups can produce complete embryos (Figure 43.10). Since the two embryos come from the same zygote, they will be monozygotic twins —genetically identical. Non-identical twins occur when two separate eggs are fertilized by two separate sperm. Thus, while identical twins are always of the same sex, non-identical twins have a 50 percent chance of being the same sex.

Chorion

► The cells remaining on the outside become the outer germ layer, the ectoderm, and give rise to the epidermis and the nervous system.

► Other cells migrate between these two layers to become the middle germ layer, or mesoderm, which will contribute tissues to many organs, including bones, muscles, liver, heart, and blood vessels.

Some of the most challenging and interesting questions in animal development have concerned what directs the cell movements of gastrulation and what is responsible for the resulting patterns of cell differentiation and organ formation. In the past 20 years scientists have answered many of these questions at the molecular level. In the discussion that follows, we consider the similarities and differences of gastrulation in sea urchins, frogs, reptiles, birds, and mammals. We also review some of the exciting discoveries about the mechanisms underlying these phenomena.

Involution of the vegetal pole characterizes gastrulation in the sea urchin

The sea urchin blastula is a simple, hollow ball of cells that is only one cell layer thick. The end of the blastula stage is marked by a dramatic slowing of the rate of mitosis, and the beginning of gastrulation is marked by a flattening of the vegetal hemisphere (Figure 43.11). Some cells at the vegetal pole bulge into the blastocoel, break free, and migrate into the cavity. These cells become primary mes-

Gastrulation: Producing the Body Plan

The blastula is typically a fluid-filled ball of cells. How does this ball of cells become an embryo, made up of multiple tissue layers, with head and tail ends and dorsal and ventral sides? Gastrulation is the process by which layers of tissue, called germ layers, form and take specific positions relative to one another (Figure 43.9; Table 43.1). The resulting spatial relations between tissues make possible inductive interactions: exchanges of signals among tissues that trigger differentiation and organ formation.

During gastrulation, the animal body forms three germ layers:

► Some blastomeres move as a sheet to the inside of the embryo, creating an inner germ layer, the endoderm, which will

give rise to gut tissues.

43.1

Fates of Embryonic Germ Layers in Vertebrates"

GERM LAYER

FATE

Ectoderm Brain and nervous system; lens of eye; inner ear; lining of mouth and of nasal canal; epidermis of skin; hair and nails; sweat glands, oil glands, milk secretory glands

Mesoderm Skeletal system (bones, cartilage, notochord); gonads; muscle; outer coverings of internal organs; dermis of skin; circulatory system (heart, blood vessels, blood cells); kidneys

Endoderm Inner linings of gut; respiratory tract (including lungs); liver; pancreas; thyroid; urinary bladder

" The final structures are complex, containing cells from more than one germ layer. Interactions among tissues are usually important in determining the composition and structure of an organ.

enchyme cells—cells of the middle germ layer, the mesoderm. (The word "mesenchyme" means "a loosely organized group of cells," in contrast to cells formed into a tightly packed sheet.)

The flattening at the vegetal pole becomes an involution, as if someone were poking a finger into a hollow ball. The cells that involute become the endoderm and form the primitive gut, the archenteron. At the tip of the archenteron more cells break free, entering the blastocoel to form more mesoderm, the secondary mesenchyme.

The archenteron continues to move inward, partly because of changes in the shapes of its cells and partly because it is pulled by secondary mesenchyme cells. These cells, attached to the tip of the archenteron, send out extensions that adhere to the overlying ectoderm and contract. Where the archenteron eventually makes contact with the ectoderm, the mouth will form, and the blastopore, the opening created by the invagination of the vegetal pole, will become the anus of the animal.

What mechanisms control the various cell movements of sea urchin gastrulation? The immediate answer is that specific properties of particular cells change. For example, some vegetal cells migrate into the blastocoel to form the primary mesenchyme because they lose their attachments to neighboring cells. Once they bulge into the blastocoel, they move by extending long processes called filopodia along an extracellular matrix of proteins that is laid down by the ectodermal cells lining the blastocoel.

A deeper understanding of gastrulation requires that we discover the molecular mechanisms whereby certain cells

43.12 Vegetal Pole Cells Contain Essential Cytoplasmic Factors

If a sea urchin blastula is divided into animal pole and vegetal pole cells, only the vegetal pole cells have the capacity to develop normally. If a few vegetal pole cells are added to a mass of animal pole cells, normal development can occur.

of the blastula develop properties different from those of others. Cleavage divides up the cytoplasm of the egg in a very systematic way. The sea urchin blastula at the 64-cell stage can be viewed as consisting of tiers of cells. As in the frog blastula, the top is the animal pole and the bottom the vegetal pole. If different tiers of blastula cells are separated, they show different developmental potentials (Figure 43.12). Only cells from the vegetal pole are capable of initiating the development of a complete larva.

It has been proposed that transcriptional regulatory proteins are unevenly distributed in the egg cytoplasm and therefore end up in particular groups of cells as cleavage progresses. Possibly, transcription factors found in the lowest vegetal cells become active in early cleavage. Indeed, one of these factors appears to be P-catenin, the transcription factor that is differentially distributed in the frog zygote. The genes activated by β -catenin seem to produce proteins that set up a signaling cascade that initiates the processes of cell determination and differentiation. Let's turn now to gastrulation in the frog, in which a number of key signaling molecules have been identified.

Animal pole

f

Gastrulation in the frog begins at the gray crescent

Amphibian blastulas have considerable yolk and are more than one cell layer thick; therefore, gastrulation is more complex in the frog than in the sea urchin. Gastrulation begins when certain cells in the gray crescent region of the blastula change their shape and their cell adhesion properties. These are the cells that received high concentrations of β -catenin in their cytoplasm and therefore made certain proteins that cells in other parts of the blastula did not make. In some way, this pattern of gene expression causes the bodies of these cells to bulge into the blastocoel while they remain attached to the outer surface by slender necks. Because of their shape, these cells are called bottle cells.

As the bottle cells move into the interior of the blastula, they appear to pull other surface cells in after them (Figure 43.13). This process creates a lip over which a sheet of cells moves into the blastocoel. The first involuting cells are the prospective endoderm, and they form the primitive gut, the archenteron. These cells also bring into the blastocoel the cells that will form the mesoderm. The initial site of involution is called the dorsal lip of the blastopore, and it plays a central role in vertebrate development.

As gastrulation proceeds, cells from all over the surface of the blastula move toward the site of invagination. This movement of cells toward the blastopore is called epiboly. The dorsal lip of the amphibian blastopore widens and eventually forms a complete circle surrounding a plug of yolk-rich cells. As cells continue to move in through the blastopore, the archenteron grows and gradually displaces the blastocoel.

§J Involution creates the archenteron and destroys the blastocoel. The blastopore lip forms a circle, with cells moving to the interior all around the blastopore; the yolk plug is visible through the blastopore.

Spemann's research revealed that gastrulation and subsequent normal development in salamanders depended on cytoplasmic factors localized in the gray crescent.

the i ndoderm, mesoderm, and ectoderm have become "determined" such that they will differentiate into specific tissue typt
The discovery of determination, our next topic, is one of the ost exciting stories in animal development.

The dorsal lip of the blastopore organizes formation of tt embryo

Early in the 1900s, German biologist Hans Spemann was studying the develop, lent of salamander eggs. He was interested in finding out . ether nuclei remain totipotent — capable of directing the <_, -elopment of a complete embryo—during cleavage

and blastula formation. With great patience and dexterity, he formed a loop from a single human baby hair to constrict fertilized eggs.

When Spemann's loop bisected the gray crescent, the cells on both sides of the constriction developed into complete embryos (Figure 43.14, left). But when the gray crescent was on only one side of the constriction, only that side

gastrulated and developed into a complete embryo. The side lacking gray crescent material became a clump of undifferentiated cells Spemann called the "belly piece" (Figure 43.14, right). Spemann thus hypothesized that cytoplasmic factors contained in the region of the gray crescent are necessary for gastrulation and thus for the development of a normal organism.

To test his hypotheses, Spemann and his student Hilde Mangold conducted a series of delicate tissue transplantation experiments. They transplanted pieces of early gastrulas to various locations on other gastrulas. Guided by fate maps (see Figure 43.9), they were able to take a piece of ectoderm they knew would develop into epidermis and transplant it to a region that normally becomes nervous system, and vice versa (Figure 43.15).

When they did these transplants in early gastrulas, the transplanted pieces always developed into tissues that were appropriate for the location where they were placed. Donor presumptive epidermis (that is, cells destined to become skin in their original location) developed into host nervous system, and donor presumptive neural ectoderm developed into host skin. Thus, the fates of the transplanted cells had not been determined before the transplantation.

In late gastrulas, however, the same experiment yielded opposite results. Donor presumptive epidermis produced patches of skin cells in the host nervous system, and donor presumptive neural ectoderm produced neurons in the host skin. Something had occurred during gastrulation to determine the fates of the embryonic cells. In other words, as Spemann had hypothesized, the path of differentiation a cell would follow was determined during gastrulation.

Then Spemann and Mangold did an experiment that produced momentous results: they transplanted the dorsal lip of the blastopore. When this small piece of tissue was transplanted into the presumptive belly area of another gastrula, it stimulated a second site of gastrulation, and another whole embryo formed belly-to-belly with the original embryo. The dorsal lip of the blastula was apparently capable of inducing the formation of an embryo. Thus, Spemann and Mangold called the dorsal lip of the blastopore the primary embryonic organizer.

The primary embryonic organizer has been studied intensively, and we are beginning to understand the molecular mechanisms involved in its action. The distribution of β -catenin corresponds to the location of the primary embryonic organizer, so it is a candidate molecule for initiating organizer activity. Correlation is not enough, however. To prove that a molecule is an inductive signal, it has to be shown that it is both necessary and sufficient for the proposed effect. In other words, the effect should not occur where expected if the candidate molecule is eliminated (necessity), and the candidate molecule must be capable of inducing the effect where it would otherwise not occur (sufficiency).

The criteria of necessity and sufficiency have been satisfied for β -catenin. If β -catenin transcripts are depleted by injections of antisense RNA into the egg (see Chapter 17), gastrulation does not occur. If β -catenin is experimentally

43.15 Tissue Transplants Reveal the Process of Determination

Tissue transplant experiments by Spemann and Mangold revealed that cell fate becomes increasingly determined during gastrulation. Transplanting the dorsal lip of the blastopore resulted in a second initiation of gastrulation and the formation of a second embryo.

overexpressed in another region of the blastula, it can induce a second axis of embryo formation, as the dorsal lip did in the Spemann-Mangold transplantation experiments. Thus, P-catenin appears to be both necessary and sufficient for the formation of the primary embryonic organizer, but it is only one component of a complex signaling cascade that is still the subject of intense investigation.

Reptilian and avian gastrulation is an adaptation to yolky eggs

The eggs of reptiles and birds have a massive yolk content, and therefore the blastulas of these species develop as a disc of cells on top of the yolk. We will use the chicken egg

to show how gastrulation occurs in a flat disc of cells rather than in a ball of cells.

Cleavage in the chick results in a flat, circular layer of cells called the blastodisc. Between the blastodisc and the yolk mass is a fluid-filled space. Some cells from the blastodisc break free and move into this space. Other cells grow into this space from the posterior margin of the blastodisc. These cells come together to form a continuous layer called the hypoblast. The overlying cells are called the epiblast. Thus, the avian blastula is a flattened structure consisting of an upper epiblast and a lower hypoblast, which are joined at the margins of the blastodisc. The blastocoel is the fluid-filled space between the epiblast and hypoblast.

43.76 Gastrulation in Birds

Because of the large yolk mass in bird and reptile eggs, these embryos display a pattern of gastrulation very different from that of sea urchins and amphibians.

Gastrulation begins with a thickening of a posterior region of the epiblast caused by the movement of cells toward the midline and then forward along the midline (Figure 43.16). The result is a midline ridge called the primitive streak. A depression called the primitive groove forms along the length of the primitive streak. The primitive groove becomes the blastopore as cells migrate through it into the blastocoel to become endoderm and mesoderm.

In the avian embryo, no archenteron forms, but the prospective endoderm and mesoderm migrate forward to form gut and other structures. At the extreme forward end of the primitive groove is a thickening called Hensen's node, which is the equivalent of the dorsal lip of the amphibian blastopore. In fact, many signaling molecules that have been identified in the frog organizer are also expressed in Hensen's node. Cells passing over Hensen's node become determined to differentiate into the tissues and structures that make up the head and the dorsal midline of the embryo.

Mammals have no yolk, but retain the avian-reptilian gastrulation pattern

Mammals and birds both evolved from reptilian ancestors, so it is not surprising that they share patterns of early development, even though the eggs of placental mammals have no yolk. Earlier we described the development of the mammalian trophoblast and the inner cell mass, which is the equivalent of the avian epiblast. Keeping avian gastrulation in mind, think of the mammalian inner cell mass as sitting on top of an imaginary body of yolk (Figure 43.17).

As in avian development, the inner cell mass splits into an upper layer called the epiblast and a lower layer called the hypoblast with a fluid-filled cavity, or blastocoel, between them. The embryo will form from the epiblast, and the hypoblast will contribute to the extraembryonic membranes. The epiblast also contributes to the extraembryonic

%;£

membranes; specifically, it splits off an upper layer of cells that will form the amnion. The amnion will grow to surround the developing embryo as a sac filled with amniotic fluid.

Gastrulation occurs in the mammalian epiblast just as it does in the avian epiblast. A primitive groove forms, and epiblast cells migrate through the groove to become layers of endoderm and mesoderm. The cells migrating over Hensen's node become the cells that form dorsal structures such as the brain and spinal cord.

Neurulation: Initiating the Nervous System

Gastrulation produces an embryo with three germ layers that are positioned to influence one another through inductive tissue interactions. During the next phase of development, called organogenesis, many organs and organ systems develop simultaneously and in coordination with one another. An early process of organogenesis that is directly related to gastrulation is neurulation, the initiation of the nervous system. We will examine this event in the amphibian embryo, but it occurs in a similar fashion in reptiles, birds, and mammals. Many of the genes involved are highly conserved all the way from worms to humans.

The stage is set by the dorsal lip of the blastopore

The cells that pass through the dorsal lip of the blastopore and move anteriorly in the blastocoel during gastrulation are determined to become mesoderm. The dorsal mesoderm closest to the midline is further determined to become chordomesoderm, which forms a rod along the dorsal midline. This rod, called the notochord, gives structural support to the developing embryo. The notochord eventually will be replaced by the vertebral column, but after gastrulation it induces the overlying ectoderm to begin forming the nervous system. Neurulation involves the formation of an internal tube from an external sheet of cells. The first signs of neurulation are flattening and thickening of the ectoderm overlying the notochord; this thickened area forms the neural plate (Figure 43.18). The edges of the neural plate that run in an anterior-posterior direction continue to thicken to form ridges or folds. Between the folds a groove forms and deepens as the folds roll over it to converge on the midline. The folds fuse, forming a cylinder, the neural tube, and a continuous overlying layer of epidermal

43.18 Neurulation in the Frog

Continuing the sequence from Figures 43.9 and 43.13, these drawings outline the development of the frog's neural tube. The mid-sagittal section (fc>) shows the development of the notochord and its position relative to the neural tube.

At the start of neurulation:

The neural plate, which forms from ectoderm above the notochord, is well defined.

(a) Dorsal

ectoderm. The neural tube develops bulges at the anterior end, which become the major divisions of the brain; the rest of the tube becomes the spinal cord.

Failure of the neural tube to develop normally can result in serious birth defects. If the neural tube fails to close in a posterior region, the result is a condition known as spina bifida. If it fails to close at the anterior end, an infant can develop without a forebrain—a condition called anencephaly. Whereas several genetic factors have been identified that can cause neural tube defects, there are also environmental factors, including dietary ones. The incidence of neural tube defects used to be about 1 in 300 live births, but we now know that this incidence can be cut in half if pregnant women have an adequate amount of folic acid (a B vitamin) in their diets.

Body segmentation develops during neurulation

Like the fruit flies whose development we traced in Chapter 16, vertebrates have a body plan consisting of repeating segments that are modified during development. These segments are most evident as the repeating patterns of vertebrae, ribs, nerves, and muscles along the anterior-posterior axis.

As the neural tube forms, mesodermal tissues gather along the sides of the notochord to form separate blocks of cells called somites (Figure 43.19). The somites produce cells that will become vertebrae, ribs, and muscles of the trunk and limbs.

The nerves that connect the brain and spinal cord with tissues and organs throughout the body are also arranged segmentally. The somites help guide the organization of these peripheral nerves, but the nerves are not of mesodermal origin. When the neural tube closes, cells adjacent to the line of closure break loose and migrate inward between the epidermis and the somites and under the somites. These cells, called neural crest cells, give rise to a number of structures, including the peripheral nerves, which grow out to the body tissues and back into the spinal cord.

As development progresses, the segments of the body become different. Regions of the spinal cord differ, regions of the vertebral column differ in that some vertebrae grow ribs of various sizes and others do not, forelegs arise in the anterior part of the embryo, and hind legs arise in the posterior region. How does a somite in the anterior part of a mouse embryo "know" to produce forelegs rather than hind legs?

Central to the process of anterior-posterior determination and differentiation are homeotic genes (see Chapter 16). We have seen how these genes control body segmentation in *Drosophila*. In the mouse, four families of similar genes, called homeobox or Hox genes, control differentiation along the anterior-posterior body axis.

Each family of mammalian Hox genes resides on a different chromosome and consists of about 10 genes. What is remarkable is that the temporal and spatial expression of these genes follows the same pattern as their linear order on their chromosomes. As a result, different segments of

43.19 The Development of Body Segmentation

Repeating blocks of tissue called somites form on either side of the neural tube. Skin, muscle, and bone form from the somites.

the embryo receive different combinations of Hox gene products, which serve as transcription factors (Figure 43.20). What causes the linear, sequential expression of Hox genes is unclear.

Whereas Hox genes give cells information about their positional location on the anterior-posterior body axis, other genes give information about dorsal-ventral position. Tissues in each segment of the body differentiate according to their dorsal-ventral location. In the spinal cord, for example, sensory connections develop in the dorsal region and motor connections develop in the ventral region. In the somites, dorsal cells develop into skin and muscle and ventral cells develop into cartilage and bone.

An example of a gene that provides dorsal-ventral information in vertebrates is sonic hedgehog, which is expressed in the mammalian notochord and induces cells in the overlying neural tube to follow fates characteristic of ventral spinal cord cells. (As with the Hox genes, sonic hedgehog is homologous to a *Drosophila* gene, which is known simply as hedgehog.)

A family of homeobox genes, the Pax genes, play many roles in nervous system and somite development. One of these genes, Pax3, is expressed in neural tube cells that develop into dorsal spinal cord structures. Sonic hedgehog represses the expression of Pax3, and their interaction is one

source of dorsal-ventral information for differentiation of the spinal cord.

With the development of body segmentation, the formation of organs and organ systems progresses rapidly. The development of an organ involves extensive inductive tissue interactions, which are a current focus of study for developmental biologists. In Chapter 16, you encountered the organogenesis of the vertebrate limb. In the next chapter you will learn about the development of the brain—another example of organogenesis.

Extraembryonic Membranes

The embryos of reptiles, birds, and mammals are surrounded by several extraembryonic membranes, which originate from the embryo but are not part of it. The ex-

5-Day embryo

traembryonic membranes play important roles in development, especially in mammals, in which they constitute the placenta that nourishes the embryo.

Four extraembryonic membranes form with contributions from all germ layers

We will use the chick to demonstrate how the extraembryonic membranes form from the germ layers created during gastrulation. The yolk sac is the first extraembryonic membrane to form, and it does so through extensions of the endodermal tissue of the hypoblast layer, which enclose the entire body of yolk in the egg (Figure 43.21, left). This yolk sac constricts at the top to create a tube that is continuous

43.21 The Extraembryonic Membranes

In birds, reptiles, and mammals, the embryo constructs four extraembryonic membranes. The yolk sac encloses the yolk, and the amnion and chorion enclose the embryo. Fluids secreted by the amnion fill the amniotic cavity, providing an aqueous environment for the embryo. The chorion, along with the allantois, mediates gas exchange between the embryo and its environment. The allantois stores the embryo's waste products.

Uterus

with the gut of the embryo. However, yolk does Fetus not pass through this tube. Yolk is digested by the endodermal cells of the yolk sac, and the nutrients are then transported to the embryo through blood \ essels lining the outer surface of the yolk sac.

Just as the endoderm grows out from the embryo to form the yolk sac, the ectoderm and mesoderm also extend beyond the limits of the embryo. These two layers of cells extend all along the inside of the eggshell, both over the embryo and below the yolk sac. Where they meet, they fuse, forming two membranes, the amnion and the chorion. The amnion, which is the inner membrane, surrounds the embryo, forming the amniotic cavity. The amnion secretes fluid into the cavity, providing an aqueous environment for the embryo. The outer membrane, the chorion, forms a continuous membrane just under the eggshell (Figure 43.21, right). It limits water loss from the egg and also mediates the exchange of respiratory gases between the embryo and the outside world.

The fourth membrane to form, the allantoic membrane, is another outgrowth of the embryonic endoderm. It forms the allantois, a sac for storage of metabolic wastes. The al-lantois, in combination with the chorion, is also involved in respiratory gas exchange.

Extraembryonic membranes in mammals form the placenta

In mammals, the first extraembryonic membrane to form is the trophoblast, which is already apparent by the fifth cell division (see Figure 43.8). When the blastocyst reaches the uterus and "hatches" out of its encapsulating zona pellucida, the trophoblast cells interact directly with the endometrium. Adhesion molecules expressed on the surfaces of these cells attach them to the uterine wall, and by excreting proteolytic enzymes, the trophoblast burrows into the endometrium, beginning the process of implantation (see Figure 43.17). Eventually, the entire trophoblast is within the wall of the uterus. The trophoblastic cells then send out numerous projections, or villi, to increase the surface area of contact with maternal blood.

Meanwhile, the hypoblast cells extend to form what in the bird would be the yolk sac. But there is no yolk in placental mammalian eggs, so the yolk sac contributes mesodermal tissues that interact with trophoblast tissues to form the chorion. The chorion, along with tissues of the uterine wall, produces the placenta, the organ of nutrition for the embryo (Figure 43.22).

At the same time the yolk sac is forming from the hypoblast, the epiblast produces the amnion, which grows to enclose the entire embryo in a fluid-filled amniotic cavity. The rupturing of the amnion and the loss of the amniotic fluid ("water breaking") herald the onset of labor in humans.

n allantois also develops in mammals, but its impor-

pends on how well nitrogenous wastes can be

tra; > d across the placenta. In humans the allantois is

43.22 The Mammalian Placenta

In most mammals, nutrients and wastes are exchanged between maternal and fetal blood in the placenta, which forms from the chorion and tissues of the uterine wall. The embryo is attached to the placenta by the umbilical cord, and embryonic blood vessels invade the placental tissue to form fingerlike villi. Maternal blood flows into the spaces surrounding the villi.

minor; in pigs it is important. In humans and other placental mammals, allantoic tissues contribute to the formation of the umbilical cord by which the embryo is attached to the chorionic placenta. It is through the blood vessels of the umbilical cord that nutrients and oxygen from the mother reach the developing fetus and wastes, including carbon dioxide and urea, are removed (see Figure 43.22).

The extraembryonic membranes provide means of detecting genetic diseases

Cells slough off of the embryo and float in the amniotic fluid that bathes it. Later in development, a small sample of the amniotic fluid may be withdrawn with a needle as the first step of a process called amniocentesis. Some of these cells can be cultured and used for biochemical and genetic analyses that can reveal the sex of the fetus, as well as genetic markers for diseases such as cystic fibrosis, Tay-Sachs disease, and Down syndrome.

If amniocentesis is performed, it is usually not until after the fourteenth week of pregnancy, and the tests require two weeks to complete. If abnormalities in the fetus are detected, termination of the pregnancy at that stage would put the mother's health at greater risk than would an earlier abortion. Therefore a newer technique, called chorionic villus sampling, is now in common use. In this test a small sample of the tissue from the surface of the chorion is taken (Figure 43.23). This test can be done as early as the eighth week of pregnancy, and the results are available in several days.

ANIMAL DEVELOPMENT 769

The sample can be used for biochemical analysis...

...or chromosomal analysis to determine sex of the fetus and presence of any chromosomal abnormalities.

Cervical canal Vagina

43.23 Chorionic Villus Sampling

Information about genetic defects can be obtained from chorionic tissues.

Human Pregnancy and Birth

Human pregnancy can be divided into three trimesters

Gestation, or pregnancy, in humans has a duration of about 266 days, or 9 months. In smaller mammals gestation is shorter—for example, 21 days in mice—and in larger mammals it is longer—for example, 330 days in horses and 600 days in elephants. To follow the temporal sequence of

events in human pregnancy, we can divide it into three trimesters of about 3 months each.

the first trimester. Implantation of the human blastocyst begins on about the sixth day after fertilization. After implantation, the placenta develops and the tissues and organs of the embryo begin to differentiate. The human heart begins to beat in week 4, and limbs form by week 8 (Figure 43.24a). Most organs have started to form by the end of the first trimester. By the end of the first trimester, the embryo looks like a miniature version of the adult, and is called a fetus.

Because the first trimester is a time of rapid cell division and differentiation, it is the period during which the embryo is most sensitive to radiation, drugs, and chemicals that can cause birth defects. An embryo can be damaged before the mother even knows she is pregnant.

Hormonal changes cause major and noticeable responses in the mother during the first trimester, even though the fetus at the end of that time is still so small that it would fit into a teaspoon. Soon after the blastocyst implants itself, it begins to secrete human chorionic gonadotropin (hCG), the hormone that stimulates the corpus luteum to continue producing estrogen and progesterone. The high levels of these hormones have negative feedback effects on the production and secretion of hypothalamic

and pituitary hormones (see Chapter 42). These dramatic hormonal shifts cause the well-known symptoms of pregnancy: morning sickness, mood swings, changes in the senses of taste and smell, and swelling of the breasts.

tion, shortness of breath, and swelling of the legs and ankles. Since the fourth week of pregnancy the heart of the fetus has been beating, and as the third trimester approaches its end, other internal organs mature. The digestive system begins to function, the liver stores glycogen, the kidneys produce urine, and the brain undergoes cycles of sleep and waking.

Parturition is triggered by hormonal and mechanical stimuli

Throughout pregnancy, the uterus periodically undergoes slow, weak, rhythmic contractions called Braxton Hicks contractions. These contractions become gradually stronger during the third trimester and are sometimes called false labor contractions. True labor contractions usually mark the beginning of childbirth, or parturition.

Many factors contribute to the onset of labor. Both hormonal and mechanical stimuli increase the contractility of the uterus. Progesterone inhibits and estrogen stimulates contractions of uterine muscle. Toward the end of the third trimester, the estrogen-progesterone ratio shifts in favor of estrogen. Oxytocin stimulates uterine contraction; its secretion by the pituitaries of both mother and fetus increases at the time of labor.

Mechanical stimuli come from the stretching of the uterus by the fully grown fetus and the pressure of the fetal head on the cervix. These mechanical stimuli increase the pituitary release of oxytocin, which in turn increases the activity of the uterine muscle, which causes even more pressure on the cervix. This positive feedback loop converts the weak, slow, rhythmic contractions of the uterus into stronger labor contractions (Figure 43.25).

the second trimester. During the second trimester the fetus grows rapidly to a weight of about 600 g, and the mother's abdomen enlarges considerably. The limbs of the fetus elongate, and the fingers, toes, and facial features become well formed. Fetal movements are first felt by the mother early in the second trimester, and they become progressively stronger and more coordinated. By the end of the second trimester, the fetus may suck its thumb (Figure 43.24fr).

The production of estrogen and progesterone by the placenta increases during the second trimester. As placental production of these hormones increases, the level of hCG decreases and the corpus luteum degenerates. Ovulation and menstruation are still inhibited by the steroids secreted by the placenta. Along with these hormonal changes, the unpleasant symptoms of early pregnancy usually disappear.

THE third trimester. The fetus and the mother continue to grow rapidly during the third trimester. As the fetus approaches its full size, pressure on the mother's internal organs can cause indigestion, constipation, frequent urina-

43.26 Delivery

A new person enters the world head first.

ANIMAL DEVELOPMENT 771

In the early stage of labor, the contractions of the uterus are 15 to 20 minutes apart, and each lasts 45 to 60 seconds. During this time, the contractions pull the cervix open until it is large enough to allow the baby to pass through. This stage of labor lasts an average of 12 to 15 hours in a first pregnancy and 8 hours or less in subsequent ones. Gradually the contractions become more frequent and more intense.

The second stage of labor, called delivery, begins when the cervix is fully dilated. The baby's head moves into the vagina and becomes visible from the outside (Figure 43.26). The usual head-down position of the baby at the time of delivery comes about when the fetus shifts its orientation during the seventh month. If the fetus fails to move into the head-down position, a different part of the fetus enters the vagina first, and the birth is more difficult.

Passage of the fetus through the vagina is assisted by the woman's bearing down with her abdominal and other muscles to help push the baby along. Once the head and shoulders of the baby clear the cervix, the rest of its body eases out rapidly, but it is still connected to the placenta in the mother by the umbilical cord. Delivery may take as little as a minute, or up to half an hour or more in a first pregnancy.

As soon as the baby clears the birth canal, it can start breathing and become independent of its mother's circulation. The umbilical cord may then be clamped and cut. The segment still attached to the baby dries up and sloughs off in a few days, leaving behind its distinctive signature, the belly button—more properly called the umbilicus. The detachment and expulsion of the placenta and fetal membranes takes from a few minutes to an hour, and may be accompanied by uterine contractions.

In humans, the completion of delivery is the start of many years of nurturing and care for the young organism. Many processes of development continue throughout childhood, and indeed, throughout life.

Chapter Summary

Fertilization: Interactions of Sperm and Egg

- Fertilization involves interactions between sperm and egg, including sperm activation, species-specific binding of sperm to the outer covering of the egg, the acrosomal reaction, digestion of a path through the outer covering of the egg, and fusion of sperm and egg plasma membranes. Review Figure 43.1
- The entry of the sperm into the egg triggers fast and slow blocks to polyspermy, which prevent additional sperm from entering the egg and, in mammals, signals the egg to complete meiosis and begin development. Review Figures 43.2, 43.3, 43.4
- Sperm and egg contribute differentially to the zygote. The sperm contributes a haploid nucleus and, in some species, a centriole. The egg contributes a haploid nucleus, nutrients, ribosomes, mitochondria, and informational molecules that will control the early stages of development.
- The cytoplasmic contents of the egg are not distributed homogeneously, and they are rearranged after fertilization to set up the major axes of the future embryo. Review Figures 43.5, 43.6

Cleavage: Repackaging the Cytoplasm

- In most animals, cleavage is a period of rapid cell division without cell growth or gene expression. During cleavage, the cytoplasm of the zygote is repackaged into smaller and smaller cells.
- The pattern of cleavage is influenced by the amount of yolk that impedes cleavage furrow formation and by the orientation of the mitotic spindles. The result of cleavage is a ball or mass of cells called a blastula. Review Figure 43.7
- Cleavage in mammals is unique in that cell divisions are much slower and genes are expressed early in the process. Cleavage results in an inner cell mass that becomes the embryo and an outer cell mass that becomes the trophoblast. The mammalian embryo at this stage is called a blastocyst. Review Figure 43.8
- Fate maps, which identify what tissues and organs will form from particular blastomeres, can be created for the blastula. Review Figure 43.9
- Some species undergo mosaic development, in which the fate of each cell is determined by the 8-cell stage. Other species, including vertebrates, undergo regulative development, in which cells are not determined so early and can change developmental fates. In these species, blastomeres separated at early stages can develop into complete embryos, which are then monozygotic, or identical, twins. Review Figure 43.10

Gastrulation: Producing the Body Plan

- Gastrulation involves massive cell movements that produce three primary germ layers and place cells from various regions of the blastula into new associations with one another. Review Table 43.1
- The initial step of sea urchin and amphibian gastrulation is inward movement of certain blastomeres. The site of inward movement becomes the blastopore. Cells that move into the blastula become the endoderm and mesoderm; cells remaining on the outside become the ectoderm. Cytoplasmic factors in the vegetal pole cells are essential to initiate development. Review Figure 43.11, 43.12
- Gastrulation in frogs is initiated when cells in the gray crescent move into the blastocoel. This inward migration creates the blastopore. The dorsal lip of the blastopore is a critical site for the determination of tissues. It has been called the primary embryonic organizer. Review Figures 43.13, 43.14, 43.15
- The anterior-posterior axis of the frog blastula appears to be determined by the distribution of the protein β -catenin, which activates a signaling cascade that induces the primary embryonic organizer.
- Gastrulation in reptiles and birds is different from that in sea urchins and frogs because the large amount of yolk in their eggs causes the blastula to form a flattened disc of cells. Review Figure 43.16
- Mammals have a pattern of gastrulation similar to that of birds, even though they have no yolk. Review Figure 43.17

Neurulation: Initiating the Nervous System

► Neurulation follows gastrulation. Cells that migrate over the dorsal lip of the blastopore are determined to be chordomesoderm, which forms the notochord. The notochord induces the overlying ectoderm to thicken, form parallel ridges, and fold in on itself to form a neural tube below the

772 CHAPTER FORTY-THREE

epidermal ectoderm. The nervous system develops from this neural tube. Review Figure 43.18

► The notochord and neural crest cells participate in the segmental organization of tissues called somites along the body axis. Rudimentary organs and organ systems form during this stage. Review Figure 43.19

► Four families of Hox genes determine the pattern of anterior-posterior differentiation along the body axis in mammals. Other genes, such as sonic hedgehog, contribute to dorsal-ventral differentiation. Review Figure 43.20

Extraembryonic Membranes

► The embryos of reptiles, birds, and mammals are protected and nurtured by four extraembryonic membranes. In birds and reptiles the yolk sac surrounds the yolk and provides nutrients to the embryo, the chorion lines the eggshell and participates in gas exchange, the amnion surrounds the embryo and encloses it in an aqueous environment, and the allantois stores metabolic wastes. Review Figure 43.21

► In mammals, the chorion and the trophoblast cells interact with the maternal uterus to form a placenta, which provides for nutrient and gas exchange. The amnion encloses the embryo in an aqueous environment. Review Figure 43.22

► Samples of amniotic fluid or pieces of chorion can be taken during pregnancy and analyzed for evidence of genetic disease. Review Figure 43.23

Human Pregnancy and Birth

► Pregnancy in humans can be divided into three trimesters. Early embryogenesis occurs in the first trimester; during this time, the embryo is vulnerable to damage that could lead to birth defects. Hormonal changes, including high hCG, estrogen, and progesterone levels, block further ovulation and menstruation and also cause symptoms of pregnancy.

► During the second and third trimesters the embryo grows, the limbs elongate, and organ systems mature.

► The onset of labor is due to many factors, both hormonal and mechanical, that increase contractility of uterine muscles. Oxytocin plays a major role in a positive feedback loop. Review Figure 43.25

► Birth is not the end of development, which continues throughout childhood and throughout life.

For Discussion

1. Knowing what you do about sperm-egg interactions at the time of fertilization, propose a line of research that could produce a new contraceptive method. What is the rationale for your method, and what problems will you have to overcome to make it successful?
2. If you found a protein that was localized to a small group of cells in the frog blastula, how would you determine if that protein played a role in development? Address the issues of sufficiency and necessity.
3. Find out what a chimeric mouse is and explain how it is produced.
4. During gastrulation in the chick, a gene called sonic hedgehog is expressed only on the left side of Hensen's node. What could be the significance of this expression pattern?
5. Much of the early work of describing animal development was done on sea urchins, amphibians, and chicks. Most recent work on the molecular mechanisms of animal development have been done on roundworms, fruit flies, zebrafish, and mice. Why do you think there has been a shift in the animal models used by developmental biologists?

Neurons and Nervous Systems

"On your mark." "Get set." Bang! 10.75 seconds later Marion Jones crossed the finish line 100 meters away, winning an Olympic gold medal. An amazing number of events took place in her nervous system during those 10.75 seconds. Cells in her ear converted the gunshot sound waves into bursts of electrical activity called nerve impulses, which traveled via nerve cells to a part of her brain that processes sound information. Cells from that part of the brain carried nerve impulses to another

part of the brain that commands and coordinates the movements of the body. Command cells controlling the muscles in her legs were triggered to fire bursts of nerve impulses. These cells carried the bursts of nerve impulses down the spinal cord to about the middle of her back region. There the connections were made to other command cells, sending nerve impulses to the muscles of Marion's legs and feet. Those muscles contracted and propelled her off the blocks. Each time a cell in this chain passed information to another cell, it released small packets of chemicals that stimulated the next cell to generate bursts of nerve impulses.

All of these events took about a tenth of a second. For the next 10.65 seconds, hundreds of thousands of nerve cells fired repeated bursts of nerve impulses in just the right patterns to cause the many muscles of Marion's legs, feet, arms, and torso to repeatedly contract and relax, powering the 80 or so strides it took her to reach the finish line. Each of the millions of cell-cell interactions that occurred involved a small release of chemicals from one cell and a receptor-mediated response from another cell. What amazing complexity and precision—yet running 100 meters is a simple task for the nervous system (although very few people will ever do it as fast as Marion Jones did).

The nervous system is the most complex system of the human body. As in other organs and organ systems, its basic building blocks are cells. In the nervous system, cells are arranged in networks and circuits that process information. Within those circuits resides not

On the Fast Track

Marion Jones can run fast because her nervous system processes sensory information and commands her muscles so quickly.

only the capacity to generate immediate responses to stimuli on the many sensory systems, but also the capacity to remember those stimuli and responses, to relate stimuli and responses to other experiences, and to learn from the information that is processed. Within the cells and connections of the nervous system reside our individual personalities, our egos, and our ability to love and to hate.

Understanding the human nervous system is probably the biggest challenge in all of biology. We start with the basic building blocks: nerve cells. This chapter describes the cells of nervous systems. It then details how nerve cells generate electric signals and conduct those signals from place to place. Finally, it explains how those signals are communicated from cell to cell and how receiving cells respond.

Nervous Systems: Cells and Functions

In multicellular animals, nerve cells, called neurons, are specialized to receive information, encircle it, and transmit it to other cells. Together with their specialized supportive cells, neurons make up nervous systems, whose functions can be described in terms of networks of interacting neurons.

Animals receive various kinds of information from both inside and outside their bodies. This information is re-

ceived and converted, or transduced, by sensory cells (also called receptor cells) into electric signals that can be transmitted and processed by neurons. To cause behavioral or phys-

Human

(Chordata)

In squid, more complex behaviors are served by collections of neurons in specialized ganglia..

44. 7 Nervous Systems Vary in Size and Complexity

As we compare animals that have increasingly complex sensory and behavioral abilities, we find information processing increasingly centralized in ganglia (collections of nerve cells) or in a brain.

biological responses, a nervous system communicates these signals to effectors, such as muscles and glands.

Nervous systems process information

A simple animal that remains fixed to its substrate, such as a sea anemone (a cnidarian), can process information with a simple network of neurons that does little more than provide direct lines of communication from sensory cells to effectors (Figure 44.1). The cnidarian's nerve net merely detects food or danger and causes its tentacles and body to extend or retract

More complex animals that move around the environment and hunt for food and mates need to process and integrate larger amounts of information. Even animals such as flatworms fit this description, and their increased need for information processing is met by clusters of neurons called ganglia. Ganglia serving different functions may be distributed around the body, as in the earthworm or the squid. Frequently one pair of ganglia is larger and more recentral than the others.

In vertebrates, most of the cells of the nervous system are found in the brain and the spinal cord, the site of most information processing, storage, and retrieval (see Figure 44.1). Therefore, the brain and spinal cord are called the central nervous system (CNS). Information is transmitted from sensory cells to the CNS and from the CNS to effectors via neurons that extend or reside outside of the brain and the spinal cord; these neurons and their supporting cells are called the peripheral nervous system.

Vertebrates have highly developed central nervous systems, but they vary greatly in behavioral complexity and physiological capabilities. Figure 44.2 shows the brains of

Alligator

Shark

A shark is an "eating machine" with little complex behavior. Its brain deals primarily with sensory and motor information.

44.2 Brains Vary in Size and Complexity

The brains of four vertebrate species—all of which may have a similar body mass—show immense differences.

(a) Generalized neuron anatomy

(b) Specialized neurons

Dendrites receive information from other neurons.

Neurons with bushy dendrites collect information from many other cells.

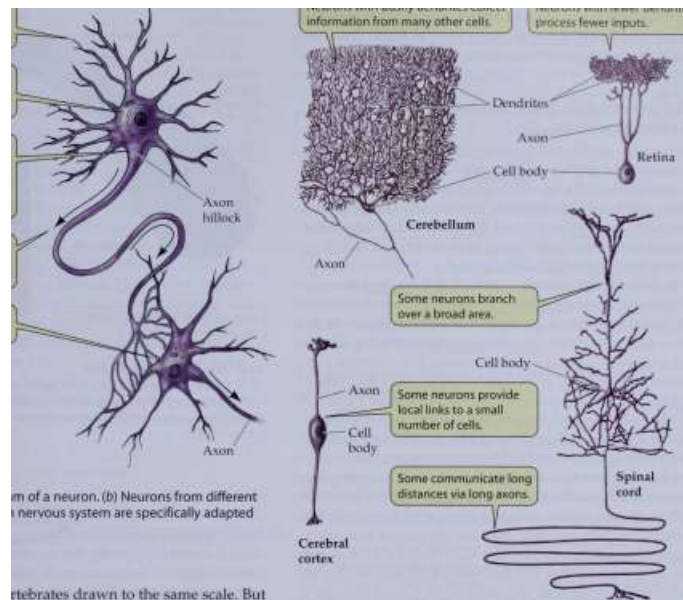

Neurons with fewer dendrites process fewer inputs.

The cell body contains the nucleus and most cell organelles.

The cell body integrates information collected by dendrites and initiates nerve impulses at the beginning of the axon.

The axon conducts nerve impulses away from the cell body.

Axon terminals synapse with a target cell.

44.3 Neurons

(a) A generalized diagram of a neuron, (b) Neurons from different parts of the mammalian nervous system are specifically adapted to their functions.

four similar-sized vertebrates drawn to the same scale. But even small nervous systems are remarkably complex. Consider the nervous systems of small spiders that have programmed within them the thousands of precise movements necessary to construct a beautiful web without prior experience.

Neurons are the functional units of nervous systems

Although nervous systems vary enormously in structure and function, neurons function similarly in animals as different as squids and humans. Their plasma membranes generate electric signals called nerve impulses or action potentials—conduct these signals from one location on a cell to the most distant reaches of that cell—a distance that can be more than a meter.

Most neurons have four regions—a cell body, dendrites, an axon, and axon terminals (Figure 44.3a)—but the variation among different types of neurons is considerable (Figure 44.3b). The cell body contains the nucleus and most of the cell's organelles. Many projections may sprout from the cell body. Most of these projections are bushlike dendrites (from the Greek dendron, "tree"), which bring information from other neurons or sensory cells to the cell body. In most neurons, one projection is much longer than the other—and

Cerebral cortex

is called the axon. Axons usually carry information away from the cell body. The length of the axon differs in different types of neurons—some axons are remarkably long, such as those that run from the spinal cord to the toes. The degree of branching of the dendrites can also be quite different among types of neurons.

Axon are the "telephone lines" of the nervous system. Information received by the dendrites can cause the cell body to generate a nerve impulse, which is then conducted along the axon to the cell that is its target. At the target cell—which can be another neuron, a muscle cell, or a gland cell—the axon divides into a spray of fine nerve endings. At the tip of each of these tiny nerve endings is a swelling called an axon terminal that comes very close to the target cell.

Where an axon terminal comes close to another cell, the membranes of both cells are modified to form a synapse. In most cases, a space or cleft only about 25 nm wide separates the two membranes at the synapse. A nerve impulse arriving at an axon terminal causes molecules called neurotransmitters stored in the axon terminal to be released. The released neurotransmitters diffuse across the synaptic cleft and bind to receptors on the plasma membrane of the target cell.

776 CHAPTER FORTY-FOUR

Thousands of synapses impinge on most individual neurons. A neuron generally receives information (synaptic inputs) from many sources before a single nerve impulse travels down its single axon to target cells. We will discuss synaptic transmission in more detail later in the chapter.

Glial cells are also important components of nervous systems

Neurons are not the only type of cell in the nervous system. In fact, there are more glial cells than neurons in the human brain. Like neurons, glial cells come in several forms and have a diversity of functions. Some glial cells physically support and orient the neurons and help them make the right contacts during their embryonic development. Other glial cells insulate axons.

In the peripheral nervous system, Schwann cells wrap around the axons of neurons, covering them with concentric layers

insulating plasma membrane (Figure 44.4). Other glial cells called oligodendrocytes perform a similar function in the central nervous system. The covering produced by Schwann cells and oligodendrocytes, called myelin, gives many parts of the nervous system a glistening white appearance. Later in the chapter we will see how the electrical insulation provided by myelin increases the speed with which axons can conduct nerve impulses.

Glial cells are well known for the many housekeeping functions they perform. Some glial cells supply neurons with nutrients; others consume foreign particles and cell debris. Glial cells also help maintain the proper ionic environment around neurons. Although they have no axons and do not generate or conduct nerve impulses, some glial cells communicate with one another electrically through a special type of contact called a gap junction, a connection that enables ions to flow between cells (see Chapter 5).

Glial cells called astrocytes (because they look like stars) contribute to the blood-brain barrier, which protects the brain from toxic chemicals in the blood. Blood vessels throughout the body are very permeable to many chemicals, including toxic ones, which would reach the brain if this special barrier did not exist. Astrocytes help form this barrier by surrounding the smallest and most permeable blood vessels in the brain.

Protection of the brain is crucial because, unlike other tissues of the body, the brain has a limited capacity to recover from damage by generating new neurons and new

neuronal connections. Throughout life, populations are, progressively

lost. Without the blood-brain barrier, the rate of neuron loss could be much greater. However, the barrier is not perfect. Since it consists of plasma membranes, it is permeable to fat-soluble substances. Anesthetics, alcohol, both of which have well-known effects on the brain, are fat-soluble chemicals.

Neurons function in networks

As we learn more about the properties of neurons, it is important to keep in mind that nervous systems depend on

(a)

Myelin-producing Schwann cell

Site and direction of myelin growth

Multiple layers of plasma membrane (myelin) insulate the axon.

44.4 Wrapping Up an Axon

(a) Schwann cells wrap axons with layers of myelin, a type of plasma membrane that provides electrical insulation. (b) A group of myelinated axons, seen in cross section through an electron microscope.

neurons working together. The simplest neuronal network consists of three cells: a sensory neuron connected to a motor neuron connected to a muscle cell. Most of the neuronal networks that carry out the functions of the human nervous system are much more complex and consist of many more neurons. The human brain contains between 10^9 and 10^{11} neurons. Most of these neurons receive information from a thousand or more synapses. Thus there may be as many as 10^{14} synapses in the human brain. Therein lies the incredible ability of the brain to process information.

This astronomical number of neurons and synapses is divided into thousands of distinct but interacting networks that function in parallel and accomplish the many different tasks of the nervous system. But before we can understand how even one of these circuits works, we must understand the properties of individual neurons.

Neurons: Generating and Conducting Nerve Impulses

In this section, we explore the electrical properties of cells. After reviewing some basic electrical concepts, we examine in detail the roles of ions, ion pumps, and ion channels in establishing and altering the electrical properties of neurons. These electrical changes generate action potentials, the language by which the nervous system processes and communicates information.

The interior of cells is electrically negative in comparison to the outside. The difference in voltage across the plasma membrane of a neuron is called its membrane potential. In an unstimulated neuron, this voltage difference is called

a resting potential!

Membrane potentials can be measured with electrodes. An electrode can be made from a glass pipette pulled to a very sharp tip and filled with a solution containing ions that conduct electric charge. Using such electrodes, we can record very tiny local electrical events that occur across plasma membranes. If a pair of electrodes is placed one on each side of the plasma membrane of a resting axon, they measure a voltage difference of about -70 mV—the resting potential (Figure 44.5).

The resting potential provides a means for neurons to respond to a stimulus. A neuron is sensitive to any chemical or physical factor that causes a change in the resting potential across a portion of its plasma membrane. The most extreme change in membrane potential is a nerve impulse, which is a sudden and rapid reversal in the voltage across a portion of the plasma membrane. For a brief moment—1 or 2 milliseconds—the inside of a part of the cell becomes more positive than the outside. Nerve impulses are also called action potentials, a name that conveys their contrast with the resting potential. An action potential can travel along the plasma membrane from one part of a neuron to its farthest extensions.

Simple electrical concepts underlie neuronal functions

To understand how resting potentials are created, how they are perturbed, and how action potentials are generated and conducted along plasma membranes, it is necessary to know a little about electricity, ions, and the special ion channel proteins in the plasma membranes of neurons.

Voltage (potential) is the tendency for electrically charged particles like electrons or ions to move between two points. Voltage is to the flow of electrically charged particles what pressure is to the flow of water. If the negative and the positive poles of a battery are connected by a copper wire, electrons flow from negative to positive because there is a voltage difference between them. This flow of electrons is an electric current, and it can be used to do work, just as a current of water can be used to do work such as turning a turbine.

Electric charges move across cell membranes not as electrons, but as charged ions. The major ions that carry electric charges across the plasma membranes of neurons are sodium (Na^+), chloride (Cl^-), potassium (K^+), and calcium (Ca^{2+}). It is also important to remember that ions with opposite charges attract each other. With these basics of bioelectricity in mind, we can ask how the resting potential of the neuronal plasma membrane is created, and how the flow of ions through membrane channels is turned on and off to generate action potentials.

Ion pumps and channels generate resting and action potentials

The plasma membranes of neurons, like those of all other cells, are lipid bilayers that are impermeable to ions. However, these impermeable lipid bilayers contain many protein molecules that serve as ion channels and ion pumps (see Chapter 5). Ion pumps and channels are responsible for resting and action potentials.

44.5 Measuring the Resting Potential

The difference in electric charge across the plasma membrane of a neuron can be measured using two electrodes, one inside and one outside the cell. In an unstimulated neuron, this difference is constant (about -60 mV), and is known as the resting potential.

*

778 CHAPTER FORTY-FOUR

Ion pumps use energy to move ions or other molecules against their concentration gradients. The major ion pump in neuronal membranes is the sodium-potassium pump. The action of this pump expels Na^+ ions from the cell, exchanging them for K^+ ions from outside the cell (Figure 44.6a). The sodium-potassium pump keeps the concentration of K^+ inside the cell greater than that of the external medium, and the concentration of Na^+ inside the cell less than that of the external medium. The concentration differences established by the pump mean that K^+ would diffuse out of the cell and Na^+ would diffuse in if the ions could cross the lipid bilayer.

Ion channels are pores formed by proteins in the lipid bilayer. These water-filled pores allow ions to pass through, but they cannot actively transport ions as ion pumps do (Figure 44.6b). They are generally selective; that is, some types of ions pass

through them more easily than others. Thus there are potassium channels, sodium channels, chloride channels, and calcium channels, and there are different kinds of each. Ions move through channels by diffusion, and therefore they can move in either direction. The direction and magnitude of net movement of ions through a channel depends on the concentration gradient of that ion type across the plasma membrane.

Many ion channels in the plasma membranes of neurons behave as if they contain a "gate" that opens to allow ions to pass under some conditions, but closes under other conditions. Voltage-gated channels open or close in response to a change in the voltage across the plasma membrane. Gated channels open or close depending on

Na⁺

The Na⁺-K⁺ pump moves Na⁺ and K⁺ ions against their concentration gradients which would otherwise run down because...

...K⁺ and Na⁺ ions tend to leak down their concentration gradients through ion-specific channels.

The presence or absence of a specific chemical that binds to the channel protein, or to a separate receptor that in turn alters the channel protein. Both voltage-gated and chemically gated channels play important roles in neuronal function.

Potassium channels are the most common open channels in the plasma membranes of resting (non-stimulated) neurons. As a consequence, resting neurons are more permeable to K⁺ than to any other ion. As Figure 44.7 shows, this characteristic explains the resting potential. Because the plasma membrane is permeable to K⁺, and because the sodium-potassium pump keeps the concentration of K⁺ inside the cell much higher than that outside the cell, K⁺ tends to diffuse out of the cell through the potassium channels.

As positively charged K⁺ ions diffuse out of the cell, they leave unbalanced negative charges behind, generating a membrane potential that tends to pull positively charged K⁺ ions back into the cell. The membrane potential at which the tendency of the K⁺ ions to diffuse out is balanced by the negative electric potential pulling them back in is called the potassium equilibrium potential.

44.6 Ion Pumps and Channels

(a) The sodium-potassium pump actively moves K⁺ ions to the inside of a neuron and Na⁺ ions to the outside. (6) Channels allow ions to diffuse down their concentration gradient when they are open; thus K⁺ ions tend to leave neurons and Na⁺ ions tend to enter neurons through ion channels. The sodium channels shown here are gated, and one is closed.

The value of the potassium equilibrium potential can be calculated from the concentrations of K⁺ on the two sides of the membrane using an equation called the Nernst Equation, which is derived from the laws of physical chemistry (Figure 44.8).

In general, the resting potential is a bit less negative than this potential predicts, because resting neurons are also slightly permeable to other ions, for example Na^+ and Cl^- .

Outside cell

The tendency of K^+ ions to diffuse out leaves an excess of negative charges inside the cell, creating the resting potential.

$[K^+]_{out}$: of K^+ concentrations on the two sides of the membrane

Deriving the Nernst equation:

At equilibrium the electrical force equals

the diffusional force, or

$$EzF = RT \ln \frac{[K^+]_{out}}{[K^+]_{in}}$$

$[K^+]_{in}$

J

$[K^+]_{out}$

The equilibrium potential is the membrane potential that counteracts the tendency of K^+ ions to diffuse out.

Rearranging this equality, we get an expression of the Nernst equation for the potassium equilibrium potential:

The equation can be made simpler by combining the constants, assuming the temperature is 20°C , and converting the natural logarithm to base 10 logarithm. Doing this, we get:

$$E_K = (58\text{mV}) \log \left(\frac{[K^+]_{out}}{[K^+]_{in}} \right)$$

mV

-84

Oscilloscope screen

Resting potential

Time

Applying the Nernst equation:

The concentration of K^+ ions inside a mammalian neuron is about 140 mM; outside the neuron the concentration is about 5 mM. Putting these numbers into the Nernst equation gives us a predicted resting potential of about -84 mV.

44.8 The Nernst Equation

The Nernst equation calculates membrane potential when only one type of ion can cross a membrane that separates solutions with different concentrations of that ion. The resting neuron comes close to that situation, since its permeability to K^+ ions is high and its permeability to all other ions is low.

$\frac{[K^+]_{out}}{[K^+]_{in}}$

Ion channels can alter membrane potential

Changes in the gated channels may perturb the resting potential. Imagine what would happen, for example, if Na^+ channels in the plasma membrane opened. Na^+ ions would diffuse into the cell because of their higher concentration on the outside, and they would also be attracted into the cell by the negative membrane potential. As a result of the entry of Na^+ ions, the inside of the cell would tend to become less negative. When the inside of a neuron becomes less negative in comparison to its resting condition, its plasma membrane is said to be depolarized (Figure 44.9a).

An opposite change in the resting potential would occur if gated Cl^- channels opened. The concentration of Cl^- ions is normally greater in the fluid than inside the neuron. This difference is large enough so that in many neurons, the opening of Cl^- channels causes Cl^- to enter the cell, even though the membrane potential is negative. The entry of negative charges causes the membrane potential to become even more negative. When the inside of a neuron becomes more negative in comparison to its resting condition, its plasma membrane is said to be hyperpolarized (Figure 44.9b).

The opening and closing of ion channels, which result in changes in the polarity of the plasma membrane, are the basic mechanisms by which neurons respond to electrical, chemical, or other stimuli, such as touch, sound, and light. How does a neuron use a change in its resting membrane potential to process and transmit information?

A change in resting potential may result from input at a synapse. This input, however, is a very local event that affects only

a small patch of plasma membrane. How can that information be passed to other parts of the cell? A local perturbation of membrane potential causes a flow of electrically charged ions, which tends to spread the change in membrane potential to adjacent regions of the membrane. This flow of electrically charged ions is an electric current. For example, if positively charged Na^+ ions enter the cell through sodium channels at one location, that positively charged area on the inside of the membrane attracts negative charges from surrounding areas, and thus there is a flow of electric current. However, this local flow of electric current does not spread very far before it diminishes and disappears.

*~The reason why electric currents do not travel very far in cell membranes is that these membranes are permeable to ions. An electric current traveling along a membrane is like water flowing through a leaky hose. Communication of a stimulus by the flow of electric current along plasma membranes is useful over only very short distances. Therefore, axons (the long processes of neurons) do not transmit information as a continuous flow of electric current (as telephone wires do). However, the local flow of electric current is an important part of the mechanism that generates the signals that axons do transmit over long distances: action potentials.

44.9 Membranes Can Be Depolarized or Hyperpolarized

The resting potential created by the diffusion of K^+ out of the cell can change (see Figure 44.7). A shift to a less negative membrane potential, as occurs when a gated sodium channel opens, is called depolarization. Hyperpolarization occurs when the membrane potential becomes more negative, as when more Cl^- enters the cell through a gated channel.

Sudden changes in ion channels generate action potentials

An action potential is a sudden and major change in membrane potential that lasts for only 1 or 2 milliseconds. Action potentials are conducted along the axon of a neuron at speeds of up to 100 meters per second, which is equivalent to running the length of a football field in 1 second. How is an action potential generated, and how does it move down an axon?

If we place the tips of a pair of electrodes on either side of the plasma membrane of a resting axon and measure the voltage difference, the reading is about 60 mV, as we saw in Figure 44.5. If these electrodes are in place when an action potential travels down the axon, they register a rapid change in membrane potential, from -60 mV to +30 mV. The membrane potential rapidly returns to its resting level of -60 mV as the action potential passes.

Voltage-gated sodium channels in the plasma membrane of the axon are primarily responsible for action potentials. At the normal membrane resting potential, most of these channels are closed. They are called voltage-gated channels because there is a particular membrane potential, or threshold potential, that causes them to open. For example, if

higher outside the axon than inside, so when the sodium channels open, Na^+ ions from the outside rush into the axon. The entering Na^+ makes the inside of the plasma membrane electrically positive. The opening of the sodium channels causes the rising phase of the action potential, which neurobiologists call the spike (Figure 44.10).

What causes the depolarized axon to return to resting potential? The main reason is the rapid closing of the sodium channels. Some axons also have voltage-gated potassium channels. These channels open more slowly than the sodium channels and they stay open longer, allowing K^+ to carry excess positive charges out of the axon. As a result, they help return the voltage across the membrane to its resting level.

Another feature of the voltage-gated sodium channels is that once they open and close, they can be triggered again after a short delay of 1 to 2 milliseconds. This property can be explained by the assumption that they have two voltage-sensitive gates, an activation gate and an inactivation gate (see Figure 44.10). Under resting conditions, the activation gate is closed and the inactivation gate is open. Depolarization of the membrane to threshold causes both gates to change state, but the activation gate responds faster. As a result, the channel is open for the passage of Na^+ ions for a brief time between the opening of the activation gate and the closing of the inactivation gate. The inactivation gate remains closed for 1-2 milliseconds before it spontaneously opens again, thus explaining why the membrane has a refractory period (a period during which it cannot act) before it can fire another action potential. When the inactivation gate finally opens, the activation gate is closed, and the membrane is poised to respond once again to a depolarizing stimulus by firing another action potential.

The difference in concentration of Na^+ across the plasma membrane of neurons is the driving force that drives the action potential. How rapidly does the battery run down? It might seem that a substantial number of Na^+ and K^+ ions would have to cross the membrane for the membrane potential to change from -60 mV to +30 mV and back to -60 mV again.

^ 44. 7 o The Course of an Action Potential

Action potentials result from rapid changes in voltage-gated sodium and potassium channels. Like the resting potential, they can be measured using two electrodes (see

Figure 44.5).

In fact, only about one Na + (or K +) ion for every 10 million present actually moves through the channels^ during the passage of an action potential. Thus the effect of a single action potential on the concentration ratios of Na + or K + is very small, and it is not difficult for the sodium-potassium pump to keep the "battery" charged, even when the cell is generating many action potentials every second.

Action potentials are conducted down axons without reduction in the signal

Action potentials can travel over long distances with no loss ofTne jignaTTfwe place two pairs ofel ectro des at two different locations along an axon, we can record an action potential at those two location s as it travels down the ax on (Figure 44.11a). slightly and approaches the threshold potential for voltage-gated sodium channels, some of them open. Some Na⁺ ions cross the plasma membrane and depolarize it even more, bringing more voltage-gated sodium channels to threshold, and so on. This positive feedback mechanism ensures that action potentials always rise to their maximum value.

The action potential is self-regenerating because it spreads by current flow to adjacent regions of the membrane.

The resulting depolarization brings those areas of plasma membrane to the threshold potential for the voltage-gated Na⁺ channels. So when an action potential occurs at one location on an axon, it stimulates the adjacent region of axon to generate an action potential, and so on down the length of the axon (Figure 44.11b).

We can initiate an action potential by shocking an axon with an electric current delivered through a stimulating electrode that depolarizes the membrane enough to reach threshold. Now we can observe the changes in membrane potential associated with the passage of that action potential past the recording electrodes (Figure 44.11b).

Positive ions flood into the axon at the site of the action potential. Once inside, positive ions spread by current flow to adjacent regions of the axon, making those regions less negative. As this depolarization of the adjacent plasma membrane brings it to the threshold potential, an action potential is generated there. Because an action potential always brings the adjacent area of membrane to threshold, the action potential propagates itself along the axon. The action potential is self-regenerating and propagates itself in both directions; however, it cannot reverse itself, because the part of the membrane it came from is in its refractory period.

Action potentials do not travel along all axons at the same speed. They travel faster in large-diameter axons than in small-diameter axons. In invertebrates, the axon diameter determines the rate of conduction, and axons that transmit messages involved in escape behavior are very thick. The giant axons that enable squid to escape predators are almost 1 mm in diameter.

Ion channels and their properties can be studied directly

The size of the squid giant axon made it possible for the British neurophysiologists A. L. Hodgkin and A. F. Huxley to study the electrical properties of axonal membranes 60 years ago. They used thin electrodes to measure voltage differences across the plasma membrane of the squid giant axon and to pass electric current into the axon to change its resting potential. They also changed the concentrations of Na⁺ and K⁺ ions both inside and outside the axon and measured the changes in resting and action potentials.

On the basis of their many careful experiments, Hodgkin and Huxley developed the story we have discussed so far. However, they were working long before technology enabled the actual demonstration of ion channels. Hodgkin and Huxley could only hypothesize the existence of ion channels and their properties.

With current techniques, neurobiologists can record currents caused by the openings and closings of single ion channels directly. Patch clamping, developed in the 1980s by Bert Sakmann and Erwin Neher, made possible the study of single ion channels in plasma membranes. In patch clamping, a glass pipette with a tip only 1 or 2 microns in diameter is placed in contact with the plasma membrane (Figure 44.12). Slight suction makes a seal between the pipette and the patch of membrane under its tip. Retracting the pipette can detach a bit of plasma membrane. Movements of ions, and therefore electric charges, through channels in the patch of membrane can be recorded through the pipette. Frequently, a patch will contain only one or a few ion channels; thus the electrical recording from that patch can show individual channels opening and closing.

RESEARCH METHOD

Recording pipette

A recording pipette filled with a conducting solution is placed in contact with a neuron's membrane.

Slight suction clamps a patch of the membrane to the pipette tip.

Retracting the pipette removes the membrane patch, often with one or more ion channels in it.

The opening and closing of ion channels can be recorded through the pipette.

44.12 Patch Clamping

A patch clamp electrode can record the opening and closing of a single ion channel.

Point A

44.13 Saltatory Action Potentials

Action potentials appear to jump from node to node in myelinated axons.

Action potentials can jump down axons

In nervous systems that are more complex than those of invertebrates, increasing the speed of action potentials by increasing the diameter of axons is not feasible because of the huge number of axons that are required. Each of our eyes, for example, has about a million axons extending from it. Evolution has increased propagation velocity in vertebrate axons in a way that does not require large size.

Point B

Point C

When we discussed glial cells earlier in the chapter, we saw that glial cells of one type, called Schwann cells, send out projections that wrap around axons, covering them with concentric layers of plasma membrane (see Figure 44.4). These myelin wrappings are not continuous, but have regularly spaced gaps called nodes of Ranvier where the axon is not covered (Figure 44.13).

Myelin electrically insulates the axon; that is, charged ions cannot cross the regions of the plasma membrane that are wrapped in myelin. Additionally, ion channels are clustered at the nodes. Thus an axon can fire an action potential

only at a node of Ranvier, but that action potential cannot be conducted through the adjacent patch of axon covered with myelin. The positive charges that flow into the axon at the node, however, spread down the axon. When the spread of current causes the plasma membrane at the next node to depolarize to threshold, an action potential is fired at that node. Action potentials therefore appear to jump down the axon.

The speed of conduction is increased in these myelin-wrapped axons because electric current flows very fast through the cytoplasm in comparison to the time required for channels to open and close. This form of impulse propagation is called saltatory (jumping) conduction and is much quicker than continuous propagation of action potentials down an unmyelinated axon.

Neurons, Synapses, and Communication

The most remarkable abilities of nervous systems stem from interactions among connected neurons. These interactions process and integrate information. Our nervous systems can orchestrate complex behaviors, deal with complex concepts, and learn and remember because large numbers of neurons interact with one another. The mechanisms of these interactions depend on synapses between cells. Synapses are structurally specialized junctions where one cell influences another cell directly through the transfer of an electrical or chemical message. The cell that sends the message is called the presynaptic cell, and the cell that receives it is called the postsynaptic cell. The most common type of synapse in the nervous system is the chemical synapse—one in which chemical messages released by a presynaptic cell induce changes in a postsynaptic cell.

In this section, we examine the specializations and functions of presynaptic and postsynaptic cells. We discover how synapses can integrate information, and at the end of the section we examine the diversity of chemical messages released by neurons.

The neuromuscular junction is a classic chemical synapse

Synapses between motor neurons and muscle cells are called neuromuscular junctions and they are excellent models for

how chemical synaptic transmission works. Like other neurons, the motor neuron that innervates a muscle has only one axon, but that axon can have many branches, each with an axon terminal that forms a neuromuscular junction with a muscle cell. At each axon terminal is an enlarged knob or buttonlike structure that contains many spherical vesicles filled with chemical messenger molecules, or neurotransmitters (Figure 44.14). The neurotransmitter used by all neurons that innervate vertebrate skeletal muscle is acetylcholine. The portion of the axon terminal plasma membrane that forms a synapse with a

Axon terminal of presynaptic cell

Enzymes for neurotransmitter synthesis are transported along microtubules.

Neurotransmitter is synthesized in the axon terminal and packaged in the vesicles.

The presynaptic and postsynaptic membranes are separated by the synaptic cleft.

Neurotransmitter is released into the synaptic cleft from the presynaptic cell.

Neurotransmitter binds to the receptor and opens the channel.

44.14 The Neuromuscular Junction Is a Chemical Synapse

A motor neuron communicates chemically with a muscle cell at a neuromuscular junction when a neurotransmitter called acetylcholine (red dots) crosses the synaptic cleft.

muscle cell is called the presynaptic membrane. Acetylcholine is released by exocytosis when the membrane of a vesicle fuses with the presynaptic membrane.

Where does the neurotransmitter come from? Some neurotransmitters, like acetylcholine, are synthesized in the axon terminal and packaged in vesicles. The enzymes required for acetylcholine biosynthesis, however, are produced in the cell body of the motor neuron and are transported down the axon to the terminals along microtubules. Other kinds of neurotransmitters, such as peptide neurotransmitters, are produced in the cell body and transported down the axon to the terminals.

transmitters, are produced in the cell body and transported down the axon to the terminals.

the postsynaptic

membrane

If the neuromuscular junction is a modified part of the muscle cell plasma membrane called a motor end plate. The space between the presynaptic membrane and the postsynaptic membrane is the synaptic cleft. In chemical synapses, the synaptic cleft is, on average, about 200 nm wide, and the neurotransmitter released into the cleft diffuses across to the postsynaptic membrane (see Figure 44.14).

The patches of muscle cell plasma membrane that form a motor end plate contain acetylcholine receptor molecules. These receptors are chemically gated channels that allow both Na^+ and K^+ to pass through. Since the resting membrane is already permeable to K^+ , the major change that occurs when these channels open is the movement of Na^+ into the cell. When a receptor binds acetylcholine, its channel opens, and Na^+ moves across the membrane, depolarizing the motor end plate (Figure 44.15).

Acetylcholine action is limited by the enzyme, acetylcholinesterase, found in the synaptic cleft. This powerful enzyme cleaves any acetylcholine molecules it encounters.

:

786 CHAPTER FORTY-FOUR

The acetylcholine receptor-mediated channel is normally closed.

When ACh binds at specific sites on the receptor the channel opens, allowing Na^+ to enter the postsynaptic cell.

Acetylcholinesterase breaks down ACh, causing the receptor-mediated channel to close.

ACh receptor

T

Postsynaptic cell depolarizes

Thus, the activity of the neuromuscular junction is a balance between the release of acetylcholine by the presynaptic membrane and its destruction by acetylcholinesterase in the synaptic cleft. The breakdown products of neurotransmitter degradation are taken up by the presynaptic terminal and resynthesized into acetylcholine.

The arrival of an action potential causes the release of neurotransmitter

Neurotransmitter is released from the presynaptic membrane when an action potential arrives at the axon terminal. The presynaptic membrane has a type of voltage-gated ion channel found nowhere else on the axon: a voltage-gated calcium channel. When the action potential reaches the axon terminal, it causes these calcium channels to open (Figure 44.16). Because Ca^{2+} concentration is greater outside the cell than inside the cell, Ca^{2+} rushes in.

The increase in Ca^{2+} inside the presynaptic cell causes the vesicles containing acetylcholine to fuse with the presynaptic membrane and empty their contents into the synaptic cleft. The acetylcholine molecules diffuse across the cleft and bind to the receptors on the motor end plate, causing the sodium channels to open briefly and depolarize it.

The postsynaptic membrane integrates synaptic input

The postsynaptic membranes of neuromuscular junctions differ from the presynaptic membranes in an important way. Motor end plates have very few voltage-gated sodium channels; therefore, they do not fire action potentials. This is true not only of motor end plates, but also of dendrites and of most regions of neuronal cell bodies. The binding of neurotransmitter to receptors at the motor end plate and the resultant opening of chemically gated ion channels per-

44.15 The Actions of Acetylcholine and Acetylcholinesterase Balance Out

When a receptor on the motor end plate binds acetylcholine (ACh), a chemically gated channel opens, and Na^+ ions move into the postsynaptic cell, making the cell more positive inside (depolarization). Acetylcholinesterase in the synapse destroys ACh, closing the channel; the breakdown products are then resynthesized into more ACh.

turb the resting potential of the postsynaptic membrane. This local change in membrane potential spreads to neighboring regions of the plasma membrane of the postsynaptic cell.

Eventually, the spreading depolarization may reach an area of membrane that does

com

tage-gated channels. The entire

plasma membrane of a skeletal muscle fiber, except for the motor end plates, has voltage-gated sodium channels. If the axon terminal of a motor neuron releases sufficient amounts of neurotransmitter to depolarize a motor end plate enough to bring the surrounding membrane to threshold, an action potential is fired. This action potential is then conducted throughout the muscle cell's system of membranes, causing the cell to contract. (We'll learn more about muscle membrane action potentials and the contraction of muscle cells in Chapter 47.)

How much neurotransmitter is enough? Neither a single acetylcholine molecule nor the contents of an entire vesicle (about 10,000 acetylcholine molecules) are enough to bring the plasma membrane of a muscle cell to threshold. However, a single action potential in an axon terminal releases about 100 vesicles, which is enough to fire an action potential in the muscle cell and cause it to contract.

Synapses between neurons can be excitatory or inhibitory

In vertebrates, the synapses between motor neurons and skeletal muscle are always excitatory; that is, motor end

plates always respond to acetylcholine by depolarizing the postsynaptic membrane. However, synapses between neurons can be either excitatory or inhibitory.

Recall that a neuron may have many dendrites. Axon terminals from many neurons may make synapses with those dendrites and with the cell body. The axon terminals of different presynaptic neurons may store and release different neurotransmitters, and membranes of the dendrites and cell body of a postsynaptic neuron may have receptors for a variety

of neurotransmitters. Thus a postsynaptic neuron can receive various chemical messages. If the postsynaptic neuron's response to a neurotransmitter is depolarization, as at the neuromuscular junction, the synapse is

An action potential arrives and initiates synaptic transmission.

t

Na⁺ channels open, depolarizing the axon terminal membrane.

Depolarization of the terminal membrane causes voltage-gated Ca²⁺ channels to open.

Ca²⁺ enters the cell and triggers fusion of neurotransmitter vesicles with the presynaptic membrane.

Action potential

1. Neurotransmitter molecules diffuse across the synaptic cleft and bind to receptors on the postsynaptic membrane.

2. Activated receptors open chemically gated Na⁺ channels and depolarize the postsynaptic membrane. The spreading depolarization fires an action potential in the adjacent membrane.

Figure 44.16 Synaptic Transmission Begins with the Arrival of an Action Potential

The figure diagrams the sequence of events involved in transmission at the motor end plate, a typical chemical synapse.

If the response is hyperpolarization, the synapse is inhibitory (see Figure 44.9).

How do inhibitory synapses work? In vertebrates, the two most common inhibitory neurotransmitters are γ -amino butyric acid (GABA) and glycine. The postsynaptic cells at inhibitory-synapses have chemically gated chloride channels. When these channels are activated by a neurotransmitter, they can hyperpolarize the postsynaptic membrane. Thus the release of neurotransmitter at an inhibitory synapse makes the postsynaptic cell less likely to fire an action potential.

Neurotransmitters that depolarize the postsynaptic membrane are excitatory; they bring about an excitatory postsynaptic potential (EPSP). Neurotransmitters that hyperpolarize the postsynaptic membrane are inhibitory; they bring about

an inhibitory postsynaptic potential (IPSP).

The postsynaptic membrane sums excitatory and inhibitory input

Individual neurons "decide" whether or not to fire an action potential by summing excitatory and inhibitory post-synaptic potentials. This summation ability of neurons is the major mechanism by which the nervous system integrates information. Each neuron may receive 1,000 or more synaptic inputs, but it has only one output: an action potential in a single axon. All the information contained in the thousands of inputs a neuron receives is reduced to the rate at which that neuron generates action potentials in its axon. For most neurons, the area for "decision making" is the axon hillock, the region of the cell body at the base of the axon. The plasma membrane of the axon hillock is not insulated by glial cells and has many voltage-gated channels. Excitatory and inhibitory post synaptic potentials from synapses anywhere on the dendrites or the cell body spread to the axon hillock by current flow. If the resulting combined ΔV potential depolarizes the axon hillock to threshold, the axon fires an action potential. Because postsynaptic potentials de-

Resting potential

788 CHAPTER FORTY-FOUR

crease as they spread from the site of the synapse, all postsynaptic potentials do not have equal influences on the axon hillock. A synapse at the end of a dendrite has less influence than a synapse on the cell body near the axon hillock.

Excitatory and inhibitory postsynaptic potentials can be summed over space or over time. ΔV summation adds up the simultaneous influences of synapses at different sites on the postsynaptic cell (Figure 44.17a). Temporal summation adds up postsynaptic potentials generated at the same site in a rapid sequence (Figure 44.17b).

All the neuron-to-neuron synapses that we have discussed up to now are between the axon terminals of a presynaptic cell and the cell body or dendrites of a postsynaptic cell. Synapses can also form between the axon terminals of one neuron and the axon terminals of another neuron. Such a synapse can modulate how much neurotransmitter the second neuron releases in response to action potentials traveling down its axon. We refer to this mechanism of regulating synaptic strength as presynaptic excitation/inhibition.

There are two types of neurotransmitter receptors

Most neurotransmitter receptors induce changes in postsynaptic cells by opening or closing ion channels. How they do so is the basis for grouping receptors into two general families.

► Ionotropic receptors are themselves ion channels. Ionotropic neurotransmitter binding by an ionotropic receptor causes a direct change in ion movements across the postsynaptic cell membrane.

► Metabotropic receptors are not ion channels, but they induce changes in the postsynaptic cell that can secondarily lead to changes in ion channels.

Postsynaptic cell responses mediated by metabotropic receptors are generally slower and longer-lasting than those induced by ionotropic receptors.

The acetylcholine (ACh) receptor of the motor end plate of muscle cells is an example of an ionotropic receptor. This receptor is called the nicotinic ACh receptor because it also binds the drug nicotine. The receptor consists of five sub-units, each of which extends through the plasma membrane (see Figure 44.15). When assembled, the subunits create a central pore that is the ion channel. There are several different kinds of subunits, and only one kind has the ability to bind ACh or nicotine. Each functional receptor-ion channel has two α and three β subunits.

other subunits.

Temporal summation means that postsynaptic potentials created at the same synapse in rapid succession can be summed.

Milliseconds •

Synapse number

44.17 The Postsynaptic Membrane Sums Information

Individual neurons sum excitatory and inhibitory postsynaptic potentials over space and time. When the sum of the potentials depolarizes the axon hillock to threshold, the neuron generates an action potential.

Metabotropic receptors are also transmembrane proteins, but instead of acting as ion channels, they initiate an intracellular signaling process that can result in the opening or closing of an ion channel. These receptors have seven transmembrane domains, and they are coupled to G proteins (Figure 44.18; see Chapter 15). When a neurotransmitter binds to the extracellular domain of a metabotropic receptor, the intracellular domain activates a G protein. In its inactive state, the G protein has three subunits, one of which (the α subunit) is bound to a molecule of GDP. When the receptor binds its neurotransmitter, the GDP is replaced with a GTP molecule, and the α subunit separates from the other two subunits (called β and γ). The separated subunits move across the membrane to where they can either directly activate an ion channel or activate an intermediate effector protein that eventually activates the ion channel.

An example of a metabotropic receptor is the muscarinic ACh receptor, so called because it binds both ACh and a molecule called muscarine that is a toxin in some poisonous mushrooms. Muscarinic ACh receptors are found in heart muscle. When activated, they cause the opening of potassium channels, which slows the heartbeat.

Metabotropic receptors can induce intracellular changes other than the opening or closing of ion channels. G proteins can activate a number of intracellular second messenger systems.

terns (see Chapter 15). Through these signaling pathways, the metabotropic receptor can activate protein kinases, activate or inactivate enzymes, and alter gene expression.

Electrical synapses are fast but do not integrate information well

Electrical synapses, or gap junctions, are different from chemical synapses because they couple neurons electrically. At gap junctions, the presynaptic and postsynaptic cell membranes are separated by a space of only 2 to 3 nm, and specific membrane proteins called connexons link the two neurons by forming molecular tunnels between the two cells. Ions and small molecules can pass directly from cell to cell through the connexons (see Figure 15.19). Electrical transmission across gap junctions is very fast and can proceed in either direction; that is, stimulation of either neuron can result in an action potential in the other. In contrast, chemical synapses are slower, and they are unidirectional.

Gap junctions are less common in the complex nervous systems of vertebrates than are chemical synapses for several reasons. First, electrical continuity between neurons does not allow temporal summation of synaptic inputs, which is one way that complex nervous systems integrate

information. Second, an effective electrical synapse requires a large area of contact between the presynaptic and postsynaptic cells. This condition rules out the possibility of

thousands of synaptic inputs to a single neuron—which is the norm in complex nervous systems. Third, electrical synapses cannot be inhibitory. Finally, there appears to be little plasticity (modifiability) in electrical synapses. Thus, electrical synapses are good for rapid communication but not for processes of integration and

The action of a neurotransmitter depends on the receptor to which it binds

More than 25 neurotransmitters are now recognized, and more will surely be discovered. Table 44.1 gives some examples. Acetylcholine; as we have seen, is an important neurotransmitter because it is the means whereby nerves command skeletal muscles to contract. Acetylcholine also

plays roles in certain synapses between neurons in the central nervous system, but it accounts for only a small percentage of the total neurotransmitter content of the CNS. The workhorse neurotransmitters of the CNS are simple amino acids: glutamate (excitatory) and glycine and GABA (inhibitory).

Another important group of neurotransmitters in the CNS is the monoamines, which are derivatives of amino acids. They include dopamine and norepinephrine (derivatives of tyrosine) and serotonin (a derivative of tryptophan). Peptides also function as neurotransmitters. An exciting recent discovery revealed that two gases, carbon monoxide and nitric oxide, are used by neurons as intercellular messengers even though they do not have the characteristics of classic neurotransmitters (that is, they do not have receptors).

The complexity of neurotransmission is increased by the fact that each neurotransmitter has multiple receptor types. We have already seen that acetylcholine has two well-known receptor types, nicotinic and muscarinic, one being ionotropic and the other metabotropic. Both types of ACh receptors are found in the CNS, where nicotinic receptors tend to be excitatory

and muscarinic receptors tend to be inhibitory. ACh actions can differ outside of the CNS as well. ACh acting through nicotinic receptors causes the smooth muscle of the gut to depolarize and therefore increases its motility, but ACh acting through muscarinic receptors causes cardiac muscle to hyperpolarize and therefore decreases the contractility of the heart.

We could give many more examples of neurotransmitters that have different effects in different tissues, but the important thing to remember is that the action of a neurotransmitter depends on the receptor to which it binds.

Glutamate receptors may be involved in learning and memory

Glutamate can bind to a variety of receptors, including

metabotropic receptors that activate G proteins and ionotropic receptors that are directly linked to ion channels that open when the receptor binds glutamate. The glutamate receptors are divided into several classes because they are differentially activated by other chemicals that mimic the action of glutamate. One class of ionotropic glutamate receptor is the NMDA receptor; they can be activated by the chemical N-methyl-D-aspartate. Another class of ionotropic glutamate receptors is activated by a different chemical, abbreviated as AMPA.

790 CHAPTER FORTY-FOUR

Glutamate is an excitatory neurotransmitter, so activation of all glutamate receptors results in sodium entry into the neuron and depolarization. But the timing of the response to activation of these different types of receptors differs significantly. The AMPA receptors, for example, allow a rapid influx of Na^+ into the postsynaptic cell. The NMDA receptors allow a slower and longer-lasting influx of Na^+ . The NMDA receptors also require the cell to be somewhat depolarized through the action of other receptors before they will open channels and permit Na^+ influx. When they do respond, the channels they open also allow Ca^{2+} to enter the cell. Ca^{2+} ions act as second messengers in the cell and can trigger a variety of long-term cellular changes.

Figure 44.19 shows how the AMPA and NMDA receptors can work in concert. The critical difference is that at normal resting potential the NMDA channel is blocked by a magnesium ion (Mg^{2+}). Slight depolarization of the neuron due to other inputs displaces Mg^{2+} from the NMDA channels and allows Na^+ and Ca^{2+} to pass through the channels when they are activated by glutamate. These special properties of the NMDA receptor are probably involved in learning and memory.

Most of the synaptic events we have studied so far happen very quickly. It is therefore a special challenge to understand how the messages carried by action potentials can result in long-term events such as learning and memory. Our understanding of these processes has been greatly af-

affected by a phenomenon called long-term potentiation, or

LTP, that was discovered by neurobiologists working with slices of brain that they kept alive in dishes of culture medium. Using these brain slice preparations, it is possible to stimulate and record from specific brain regions, or even specific cells.

In the studies leading to the discovery of LTP, experimenters repeatedly stimulated the synaptic inputs to a particular neuron and observed the usual action potential response. When the neuron was stimulated repeatedly in rapid succession, however, they found that the properties of the responding neuron changed. The size of the postsynaptic response was enhanced, or potentiated, and this change lasted for days or weeks (Figure 44.20).

How does this potentiation occur? The answer in some areas of the brain now seems quite clear. With low levels of stimulation, the glutamate released by presynaptic cells activates only the AMPA receptors, and the postsynaptic cell simply responds with action potentials. With higher levels of stimulation, however, the NMDA receptor is activated, allowing both Na^+ and Ca^{2+} ions to enter the postsynaptic neuron. The Ca^{2+} ions induce long-term changes in the postsynaptic neuron that make it more sensitive to synaptic input.

Exploiting the LTP system, Dr. Joe Tsien and his students and collaborators at Princeton University have made mice smarter by increasing the ability of their NMDA receptors to induce long-term changes in synaptic transmission. The experimenters genetically engineered mice so that their NMDA receptors had a slightly altered structure and were activated for a longer time whenever they bound a molecule of glutamate. The mice with these altered NMDA re-

ceptors learned tasks better, ran mazes faster, and remembered the mazes longer than normal mice. Maybe the world does not need smarter mice, but these exciting experiments confirm that we are on the right track to understanding how the brain achieves learning and memory.

To turn off responses, synapses must be cleared of neurotransmitter

The action of neurotransmitters is as important as turning it on. If released neurotransmitter molecules simply remained in the synaptic cleft, the postsynaptic membrane would become saturated with neurotransmit-

ter, and receptors would be constantly bound. As a result, the postsynaptic cell would remain hyperpolarized and would be unresponsive to short-term changes in the presynaptic cell. The more discrete each separate neural signal is, the more information can be processed in a given time. Thus neurotransmitter must be cleared from the synaptic cleft shortly after it is released by the axon terminal.

Neurotransmitter action may be terminated in several ways. First, enzymes may destroy the neurotransmitter. As we have seen, acetylcholine is rapidly destroyed by the enzyme acetylcholinesterase, which is present in the synaptic cleft in close association with the acetylcholine receptors on the postsynaptic membrane. Some of the most deadly nerve gases that were developed for chemical warfare work by inhibiting acetylcholinesterase. As a result, acetylcholine lingers in the

synaptic clefts, causing the victim to die of spastic (contracted) muscle paralysis. Some agricultural insecticides, such as malathion, also inhibit acetylcholinesterase and can poison farm workers if used without safety precautions.

Second, neurotransmitter may simply diffuse away from the cleft. Third, neurotransmitter may be taken up via active transport.

Conclusion: High frequency stimulation of synapses can cause a long-lasting change in sensitivity of these synapses—long-term potentiation (synaptic "memory").

44.20 Repeated Stimulation Can Cause Long-Term Potentiation

When a cell receives regular synaptic input, the resulting postsynaptic potential remains constant. If, however, that same synaptic pathway is stimulated briefly at a high frequency, the subsequent sensitivity of the postsynaptic cell to the original level of synaptic input is potentiated for a long time.

CjSL[^]tive transport by nearby cell memb ranes. The mode of action of JErozac, a commonly prescribed drug for depression, is to slow the reuptake of the neurotransmitter [^]exoton-in, thus enhancing its activity at the synapse.

Neurons in Networks

Because neurons can interact in the complex ways we have just discussed, network s of neurons can process and integrate information. Multiple neuronal networks constitute the nervous systems of animals. In subsequent chapters, we will see many examples of how neurons work together in networks to accomplish specific tasks. These networks use all of the mechanisms we have discussed: excitatory and inhibitory synapses, presyna ptic excitatio n and inhibition, and mechanisms of long-term po tent iation (and depression). Through these operations, our brains solve puzzles, create inventions, remember experiences, fall in love, and learn about biology. The challenge for the future is to understand how 7 these networks work.

Chapter Summary

Nervous Systems: Cells and Functions

- ▶ Nervous systems consist of cells that process and transmit information.
- ▶ Sensory cells transduce information from the environment and the body and communicate commands to effectors such as muscles or glands.
- ▶ The nervous systems of different species vary, but all are composed of cells called neurons. Review Figures 44.1, 44.2
- ▶ In vertebrates, the brain and spinal cord form the central nervous svstem, which communicates with other tissues of the body via the peripheral nervous system.
- ▶ Neurons receive information mostly via their dendrites and transmit information over their axons. Neurons function in networks. Review Figure 44.3
- ▶ The information that neurons process is in the form of electrical events in their plasma membranes. Where neurons and other cells meet, information is transmitted between them, mostly by the release of chemical signals called neurotransmitters.
- ▶ Glial cells physically support neurons and perform many housekeeping functions. Schwann cells and oligodendrocytes produce myelin, which insulates neurons. Astrocytes create the blood-brain barrier. Review Figure 44.4

Neurons: Generating and Conducting Nerve Impulses

- ▶ Neurons have an electric charge difference across their plasma membranes. This resting potential is created by ion pumps and ion channels. Review Figure 44.5

NEURONS AND NERVOUS SYSTEMS 793

- ▶ The sodium-potassium pump concentrates K⁺ on the inside of neurons and Na⁺ on the outsides. Ion channels allow K⁺ to leak out, leaving behind unbalanced negative charges and leading to the resting potential. Review Figures 44.6, 44.7

- ▶ A potassium equilibrium potential exists when the electric charge that develops across the membrane is sufficient to prevent a net diffusion of K^+ down its concentration gradient. This potential can be calculated with the Nernst equation. Review Figure 44.8
- ▶ The resting potential is perturbed when ion channels open or close, thus changing the permeability of the plasma membrane to charged ions. Through this mechanism, neurons become depolarized or hyperpolarized in response to stimuli. Review Figure 44.9
- ▶ Rapid reversals in charge across portions of the plasma membrane resulting from the opening and closing of voltage-gated sodium and potassium channels produce action potentials. These changes in voltage-gated channels occur when the plasma membrane depolarizes to a threshold level. Review Figure 44.10
- ▶ Action potentials are conducted down axons because of local current flow, which depolarizes adjacent regions of membrane and brings them to threshold for the opening of voltage-gated sodium channels. Review Figure 44.11
- ▶ Patch clamping allows us to study single ion channels. Review Figure 44.12
- ▶ In myelinated axons, the action potentials appear to jump between nodes of Ranvier, patches of plasma membrane that are not covered by myelin. Review Figure 44.13

Neurons, Synapses, and Communication

- ▶ Neurons communicate with each other and with other cells at specialized junctions called synapses, where the plasma membranes of two cells come close together.
- ▶ The classic chemical synapse is the neuromuscular junction, a synapse between a motor neuron and a muscle cell. Its neurotransmitter is acetylcholine, which causes a depolarization of the postsynaptic membrane when it binds to its receptor. Review Figure 44.14
- ▶ When an action potential reaches an axon terminal of the presynaptic cell, it causes the release of neurotransmitters, chemical signals that diffuse across the synaptic cleft and bind to receptors on the postsynaptic membrane. Review Figures 44.15, 44.16
- ▶ Synapses between neurons can be either excitatory or inhibitory. Synapses can also form on presynaptic membranes and thereby influence the release of neurotransmitter by the presynaptic cell.
- ▶ A postsynaptic neuron integrates information by summing its synaptic inputs in both space and time. Review Figure 44.17
- ▶ Ionotropic neurotransmitter receptors are ion channels. Metabotropic receptors influence the postsynaptic cell through various signal transduction pathways that involve G proteins. These pathways can result in changes in ion channels, alterations of enzyme activity, and even gene expression. The actions of ionotropic synapses are generally faster than those of metabotropic synapses. Review Figures 44.18, 44.19
- ▶ Electrical synapses pass electric signals between cells without the use of neurotransmitters.
- ▶ There are many different neurotransmitters and even more receptors. The action of a neurotransmitter depends on the receptor to which it binds. Review Table 44.1
- ▶ Glutamate binds to both ionotropic and metabotropic receptors, and may be involved in learning and memory. Review Figure 44.19
- ▶ With repeated stimulation, a neuron can become more sensitive to its inputs. Since this increased sensitivity can last a long time, it is called long-term potentiation, or LTP. The properties of the NMDA glutamate receptor appear to explain LTP. Review Figure 44.20
- ▶ In chemical synapses, the transmitter must be cleared rapidly from the synapse. Some poisons and some drugs act by blocking or slowing the clearance of transmitter from the synapse.

Neurons in Networks

- ▶ Neurons work together in networks to accomplish specific tasks. These networks use all of the mechanisms we have discussed in this chapter.

For Discussion

1. The language of the nervous system consists of one "word," the action potential. How can this single message convey a diversity of information, how can that information be quantitative, and how can it be integrated?
2. If you stimulate an axon in the middle, action potentials are conducted in both directions. Yet when an action potential is generated at the axon hillock, it goes only toward the axon terminals and does not backtrack. Explain why action potentials are bidirectional in the first example and unidirectional in the second.
3. The nature of synapses presents various opportunities for plasticity in the nervous system. Discuss at least four synaptic mechanisms that could be altered to change the response of a neuron to a specific input.

4. If Dr. Tsien had genetically engineered the AMPA receptor to remain open longer when activated, would it have made his mice smarter? Why or why not?

<S

Sensory Systems

How Animals perceive the world through their

Many senses. Different species look through different many sensory windows, so their views of the world are not the same. Dogs, for example, do not see color well, but they have keener senses of hearing and smell than humans do. While you enjoy a beautiful sunset, your dog might be enjoying sniffing around in the bushes and listening for the sounds of small animals in the underbrush.

Human hunters have exploited the remarkable sensory abilities of dogs for thousands of years. Most recently that hunt has extended to illicit drugs, smuggled contraband, bombs, and firearms. Dogs can be trained to detect the signature odors of such items, so they are used by police, customs agents, and other investigators to identify those odors wherever suspicious activities are occurring.

A black Labrador named Charlie (badge K9-001) was the first dog trained by the U.S. Treasury Department's Bureau of Alcohol, Tobacco, and Firearms to sniff out firearms and explosives. Charlie has sniffed out more than 200 illegal guns and 500 pounds of hidden explosives. With a nose that outperforms electronic sensors, Charlie helped solve a terrorist bombing case by discovering a tiny fragment of the bomb hundreds of yards from the site of the explosion. Charlie's nose is never off duty; on a recreational visit to a U.S. Civil War battlefield, it smelled out cannonball fragments that had been buried for 130 years. ATF dogs receive a lot of expert training, but their careers are based on their remarkable sense of smell.

In this chapter, we look at the general properties of sensory cells and see how they convert environmental stimuli to neural information. Sensory cells are generally called receptors, which creates some confusion with the receptor proteins that bind signaling molecules. To avoid this confusion, we use the terms sensory cells or receptor cells in this chapter. We examine in detail the cells responsible for chemoreception, mechanoreception, and photoreception and see how they are incorporated into sensory systems that provide the CNS with information about the world around and within us. In the course of our study of sensory systems, we will learn about the unusual sensory abilities of many animals.

Sensory Cells, Sensory Organs, and Transduction

Sensory cells transduce (convert) physical or chemical stimuli into signals that are transmitted to other parts of the nervous system for processing and interpretation. Most sensory cells are modified neurons, but some are other types of cells closely associated with neurons. Sensory cells are specialized for detecting specific kinds of stimuli, such as pressure, heat, or light.

Most sensory cells possess a membrane receptor protein that detects a stimulus and responds by altering the flow of ions across the plasma membrane (Figure 45.1). The resulting change in membrane potential causes the sensory cell either to fire action potentials itself or to change its secretory neurotransmitter onto an associated cell that fires ac-

tion potentials. The intensity of the stimulus is encoded in the frequency of action potentials.

Sensation depends on which neurons in the CNS receive action potentials from sensory cells

If the messages derived from all sensory cells are the same—action potentials—how can we perceive different sensations? Sensations such as heat, itch, pressure, pain, light, smell, and sound differ because the messages from sensory cells arrive at different places in the central nervous

45.1 Sensory Cell Membrane Receptor Proteins Respond to Stimuli

The receptors in mechanoreceptors, thermoreceptors, and electroreceptors are themselves ion channels. The activated receptor proteins of chemoreceptors and photoreceptors initiate biochemical cascades that eventually open or close ion channels.

system (CNS). Action potentials arriving in the visual cortex are interpreted as sight, in the auditory cortex as sound, in the olfactory bulb as smell, and so forth.

A small patch of skin on your arm contains sensory cells that increase their firing rates when the skin is warmed. Others increase their activity when the skin is cooled. Other types of sensory cells in the same patch of skin respond to touch, movement of hairs, irritants such as mosquito bites, and pain from cuts or burns. These sensory cells in your arm transmit their messages through axons that enter the CNS through the spinal cord. The synapses made by those axons in the spinal cord and the subsequent pathways of transmission determine whether the stimulation of the patch of skin on your arm is perceived as warmth, cold, pain, touch, itch, or tickle.

The specificity of these sensory circuits is dramatically illustrated in persons who have had a limb or part of a limb amputated. Although the sensory cells from that region are gone, the axons that communicated information from those sensory cells to the CNS may remain. If those axons are stimulated, the person feels specific sensations as if they were coming from the limb that is no longer there—a 'phantom limb'.

The messages from some sensory cells communicate information about internal conditions in the body, but we may not be consciously aware of that information. The brain receives continuous information about body temperature, blood sugar, blood carbon dioxide and oxygen concentration, arterial pressure, muscle tension, and the position of the limbs. All this information is important for the maintenance of homeostasis, but we don't have to think about it. If we did, there would be no time to think about anything else. All sensory cells produce information that

the nervous system can use, but that information does not always result in conscious sensation.

Sensory organs are specialized for detecting specific stimuli

Some sensory cells are assembled with other types of cells into sensory organs, such as eyes, ears, and noses, that enhance

the ability of the sensory cells to collect, filter, and amplify stimuli. A photoreceptor cell, for example, detects electromagnetic radiation of only a particular range of wavelengths. This selectivity is the basis for color vision and explains why some insects can see ultraviolet light. In some simple organisms photoreceptors sense only the presence of light, but in more complex animals, photoreceptors are combined with other cell types into eyes. We'll learn how eyes collect light and focus it onto sheets of photoreceptors so that patterns of light can be detected.

Sensory transduction involves changes in membrane potentials

In this chapter we examine several sensory cell types and the sensory organs with which they are associated. In each case we can ask the same general question: How does the sensory cell transduce energy from a stimulus into an action potential? The details differ for different sensory cells, but those details all fit into a general pattern.

We have already seen the first step of sensory transduction in Figure 45.1: the activation of a receptor protein. A receptor protein in the plasma membrane of the sensory cell is activated by a specific stimulus. The activated receptor protein opens or closes ion channels in the membrane by one of several mechanisms. The receptor protein may be part of an ion channel, much like an ionotropic synaptic receptor, and by changing its conformation it may open or close the channel directly. Alternatively, the activated receptor protein may function like a metabotropic synaptic receptor coupled to a G protein, setting off intracellular events that eventually affect ion channels (see Figures 15.8 and 15.10). Figure 45.2 reviews these first steps of sensory transduction and outlines the subsequent steps.

• •

&

45.2 Sensory Transduction Is a Series of Steps

The sensory cell itself may generate action potentials as a result of stimulation, or it may vary its release of neurotransmitter

in response to changes in its membrane potential, and the neurotransmitter may induce another cell to generate action potentials.

The opening or closing of ion channels in response to a stimulus changes the membrane potential of the sensory cell, which is called the receptor potential. Such changes in membrane potential can spread by current flow over short distances, but to travel long distances in the nervous system, receptor potentials must be converted into action potentials. The intracellular events involved in the conversion of the original stimulus-induced alteration of ion channels to action potentials can amplify the signal. In other words, the energy in the output of the sensory cell can be greater than the energy in the stimulus.

Receptor potentials produce action potentials in two ways: by generating action potentials within the sensory cell itself, or by releasing a neurotransmitter that induces an afferent synapse on a neuron, which generates action potentials (see Figure 45.2). In the first case, the sensory cell has a region of plasma membrane with voltage-gated sodium channels. A receptor potential that spreads to this region is called an action potential because it generates action potentials by causing the voltage-gated sodium channels to open.

A good example of generator potentials is found in the stretch receptors of crayfishes (Figure 45.3). By placing an electrode in the cell body of a crayfish stretch receptor cell, we can record the changes in the receptor potential that result from stretching the muscle to which the dendrites of the cell are attached. These changes in receptor potential become a generator potential at the base of the sensory cell's axon, where there are voltage-gated sodium channels. Action potentials generated here travel down the axon to the CNS. The rate at which action potentials are fired by the axon depends on the magnitude of the generator potential; that, in turn, depends on how much the muscle is stretched.

In sensory cells that do not fire action potentials, the spreading receptor potential reaches a presynaptic patch of plasma membrane and induces the release of a neurotransmitter.

Whether or not the sensory cell itself fires action potentials, ultimately the stimulus is transduced into action potentials and the intensity of the stimulus is encoded by the frequency of action potentials.

- Stretching a muscle stimulates the opening of ion channels in stretch receptor dendrites.
- The resulting depolarization spreads to the cell body, creating a receptor potential...
- ...which becomes a generator potential at the axon hillock, causing an action potentials to fire.
- The action potential travels down the neuron.

45.3 Stimulating a Sensory Cell Produces a Generator Potential

The stretch receptor of a crayfish produces a generator potential when the muscle is stretched. At the axon hillock, the receptor produces action potentials

that travel down the axon.

SENSORY SYSTEMS 797

Many receptors adapt to repeated stimulation

Some sensory cells give gradually diminishing responses to maintained or repeated stimulation. This phenomenon is known as *sensory adaptation*, and it enables an animal to ignore background or unchanging conditions while remaining sensitive to changes or to new information. (Note that this use of the term "adaptation" is different from its application in an evolutionary context.) When you dress, you feel each item of clothing touch your skin, but the sensation of clothes touching your skin is not constantly on your mind throughout the day. You are immediately aware, however, when a seam rips, your shoe comes untied, or someone lightly touches your back.

The ability of animals to discriminate between continuous and changing stimuli is due partly to the fact that some sensory cells adapt; it is also due to information processing by the CNS. Some sensory cells adapt very little or very slowly; examples are pain receptors and mechanoreceptors for balance.[^]

In the rest of this chapter we will learn how sensory systems gather and filter stimuli, transduce specific stimuli into action potentials, and transmit action potentials to the CNS.

Chemoreceptors: Responding to Specific Molecules

Animals receive information about chemical stimuli through chemoreceptors. Chemoreceptors are responsible for smell, taste, and the monitoring of aspects of the internal environment such as the level of carbon dioxide in the blood. Chemosensitivity is universal among animals.

A colony of corals responds to a small amount of meat extract in the seawater around it by extending bodies and tentacles and searching for food. A solution of a single amino acid can stimulate this response. Humans have similar reactions to chemical stimuli. When we smell freshly

45.4 Some Scents Travel Great Distances

Mating in silkworm moths of the genus *Bombyx* is coordinated by a pheromone called bombykol.

baked bread, we salivate and feel hungry, but we gag and retch when we smell diamines from rotting meat. Information from chemoreceptors can cause powerful behavioral and physiological responses.

Arthropods provide good examples for studying chemosensation

Arthropods use chemical signals to attract mates. These signals, called pheromones, demonstrate the sensitivity of chemosensory systems. One of the best-studied examples of this phenomenon is the silk worm moth.

To attract a mate, the female silkworm moth releases a pheromone called bombykol from a gland at the tip of her abdomen. The male silkworm moth has receptors for this molecule on his antennae (Figure 45.4). Each feathery antenna carries about 10,000 bombykol-sensitive hairs. A single molecule of bombykol is sufficient to generate action potentials in the antennal nerve that transmits the signal to the CNS. Because of the male's high degree of sensitivity, the sexual message of a female moth is likely to reach any male that happens to be within a downwind area stretching over several kilometers. When approximately 200 hairs per second are activated, the male flies upwind in search of the female. Because the rate of firing in the male's sensory nerves is proportional to bombykol concentrations in the air, he can follow a concentration gradient and home in on the signaling female.

•4-

Many arthropods have chemoreceptor hairs, each containing one or more specific types of receptors. Crabs and flies, for example, have chemoreceptor hairs on their feet; these hairs have receptors for sugars, amino acids, salts, and other molecules. A fly tastes a potential food by stepping in it.

Olfaction is the sense of smell

The sense of smell, known as olfaction, also depends on chemoreceptors. In vertebrates, the olfactory sensors are neurons embedded in a layer of epithelial cells at the top of the nasal cavity. The axons of these neurons project to the olfactory bulb of the brain, and their dendrites end in olfac-

45.5 Olfactory Receptors Communicate Directly with the Brain

The receptors of the human olfactory system are embedded in tissues lining the nasal cavity and send their axons to the olfactory bulb of the brain.

tory hairs at the surface of the nasal epithelium. A protective layer of mucus covers the epithelium. Molecules from the environment must diffuse through this mucus to reach the receptor proteins on the olfactory hairs. When you have a cold, the amount of mucus increases and the epithelium swells. With this in mind, study Figure 45.5 and you will easily understand why respiratory infections can cause you to lose your sense of smell.

A dog has up to 40 million nerve endings per square centimeter of nasal epithelium, many more than we do. Humans have a fairly sensitive olfactory system, but we are unusual among mammals in that we depend more on vision than on olfaction (we tend to join bird-watching societies more often than mammal-smelling societies). Whales and porpoises have no olfactory receptors and hence no sense of smell.

How does an olfactory sensory cell transduce the structure of a molecule from the environment into action poten-

tials? A molecule that triggers an olfactory receptor is called an o dorant. Odorants bind to receptor proteins on the olfactory hairs of the sensory cells. Olfactory receptor proteins are specific for particular odorant molecules—the two fit together like a lock and key.

If a "key" (an odorant molecule) fits the "lock" (the receptor protein), then a G protein is activated, which in turn activates an enzyme that causes an increase of a second messenger in the cytoplasm of the sensory cell. The second messenger binds to sodium channels in the sensory cell's plasma membrane and opens them, causing anmflux of NaVThe sensory cell thus

depolarizes to threshold and fires action potentials (see Figure 15.16).

The olfactory world has an enormous number of "keys"—molecules that produce distinct smells. The number of "locks"—receptor proteins—is large, but not nearly as large as the number of possible odorants. A family of about a thousand genes codes for olfactory receptor proteins. Each receptor protein is expressed in a limited number of sensory cells in the olfactory epithelium, and those cells all project to the same regions in the olfactory bulb. A given odorant molecule may bind to one or to more than one receptor protein. Therefore, each odorant molecule can excite a unique selection of cells in the olfactory bulb, so an olfactory system with a thousand different receptor proteins can discriminate a large number of smells.

How does the sensory cell signal the intensity of a smell? It responds in a graded fashion to the concentration of odorant molecules: The more odorant molecules that bind to receptors, the more action potentials are generated and the greater the intensity of the perceived smell.

Gustation is the sense of taste

The sense of taste, or gustation, in humans and other vertebrates depends on clusters of sensory cells called taste buds. The taste buds of terrestrial vertebrates are confined to the mouth cavity, but some fishes have taste buds in the skin that enhance their ability to sense their environment. Some fishes living in murky water are very sensitive to small amounts of amino acids in the water around them and can find food without the use of vision. The duckbilled platypus, a monotreme mammal (see Figure 33.22b), has similar talents as a result of taste buds on the sensitive skin of its bill. What is a taste bud and how does it work?

A taste bud is a cluster of sensory cells (Figure 45.6). A human tongue has approximately 10,000 taste buds. The taste buds are embedded in the epithelium of the tongue, and many are found on the raised papillae of the tongue. (Look at your tongue in a mirror—the papillae make it look fuzzy.) Each papilla has many taste buds. The outer surface of a taste bud has a pore that exposes the tips of the sensory cells. Microvilli (tiny hairlike projections) increase the surface area of the sensory cells where their tips converge at the pore. These sensory cells, unlike olfactory receptors, are not

45.6 Taste Buds Are Clusters of Sensory Cells

Each taste bud contains a number of sensory cells that are not neurons.

neurons. At their bases, they form synapses with dendrites of sensory neurons.

Gustation begins with receptor proteins in the membranes of the microvilli. As with olfactory transduction, receptor proteins on the sensory cells bind specific molecules (such as sugar). This binding causes changes in the membrane potential of the sensory cells, which release neurotransmitters onto the dendrites of the sensory neurons. The sensory neurons fire action potentials that are conducted to the CNS.

The tongue does a lot of hard work, so its epithelium is shed and replaced at a rapid rate. Individual taste buds last only a few days before they are replaced, but the sensory neurons associated with them live on, always forming new synapses as new taste buds form.

You have probably heard that humans can perceive only four tastes: sweet, salty, sour, and bitter. In actuality, taste buds can distinguish among a variety of sweet-tasting molecules and a variety of bitter-tasting molecules. The full complexity of

the chemosensitivity that enables us to enjoy the subtle flavors of food comes from the combined activation of gustatory and olfactory receptors; that is the reason you lose some of your sense of taste when you have a cold.

Why does a snake continually sample the air by darting its forked tongue in and out? The forks of the snake's tongue fit into cavities in the roof of its mouth that are richly endowed with olfactory receptors. The tongue samples the air and presents the sample directly to the olfactory receptors. Thus the snake is really using its tongue to smell its environment, not to taste it. Why doesn't the snake simply use the flow of air to and from its lungs, as we do, to smell the environment? In reptiles, air flows to and from the lungs slowly (and can even stop entirely for long periods of time), but the tongue can dart in and out many times in a second. It is a quick source of olfactory information.

Mechanoreceptors: Detecting Stimuli that Distort Membranes

Mechanoreceptors are cells that are sensitive to mechanical forces. In the skin, different kinds of mechanoreceptors are responsible for the perception of touch, pressure, and tickle. Stretch receptors in muscles, tendons, and joints provide information about the position of the parts of the body in space and the forces acting on them. Stretch receptors in the walls of blood vessels signal changes in blood pressure. "Hair" cells with extensions that are sensitive to bending are incorporated into mechanisms for hearing and for signaling the body's position in space.

Physical distortion of a mechanoreceptor's plasma membrane causes ion channels to open, altering the membrane potential of the cell, which in turn leads to the generation of action potentials. The rate of action potentials tells the CNS the strength of the stimulus exciting the mechanoreceptor.

Many different sensory cells respond to touch and pressure

Objects touching the skin generate varied sensations because skin is packed with diverse mechanoreceptors (Figure 45.7). The outer layers of skin contain whorls of nerve endings enclosed in connective tissue capsules. These very sensitive mechanoreceptors, called Meissner's corpuscles, respond to objects that touch the skin even lightly. Meissner's corpuscles adapt rapidly. That is why you roll a small object between your fingers, rather than holding it still, to discern its shape and texture. As you roll it, you continue to stimulate these receptors anew.

Also in the outer regions of the skin are expanded-tip tactile receptors of various kinds. They differ from Meissner's corpuscles in that they adapt only partially and slowly. They are useful for providing steady-state information about objects that continue to touch the skin.

The density of these tactile mechanoreceptors varies across the surface of the body. A two-point discrimination

test demonstrates this fact.

If you lightly touch someone's back with two toothpicks, you can determine how far apart the two stimuli have to be before the person can distinguish whether he or she was touched with one or two points. On the back, the stimuli have to be rather far apart. The same test applied to the person's lips or fingertips reveals finer spatial discrimination; that is, the person can identify as separate two stimuli that are close together.

Deep in the skin, the dendrites of neurons wrap around hair follicles. When the hairs are displaced, those neurons are stimulated. Also deep within the skin is another type of mechanoreceptor, the Pacinian corpuscle. Pacinian corpuscles look like onions because they are made up of concentric layers of connective tissue, which encapsulate an extension of a sensory neuron. Pacinian corpuscles respond especially well to vibrations applied to the skin, but they adapt rapidly to steady pressure. The connective tissue capsule is important in this adaptation. An initial pressure distorts the corpuscle and the plasma membrane of the neuron at its core, but the layers of the capsule rapidly rearrange to redistribute the force, thus eliminating the distortion of the neuronal plasma membrane.

Stretch receptors provide information about the stresses on muscles and joints in an animal's limbs, (a) Signals from muscle spin-

dles to the CNS initiate muscle contraction. (fc>) Golgi tendon organs in tendons and ligaments inhibit a contraction that becomes too forceful, triggering relaxation and protecting the muscle from tearing.

A lateral line canal lies just below the skin surface.

Structures called cupulae project into the lateral line canal. As the fish moves through the water, fluid in the lateral line canal pushes against the cupulae.

Each cupula contains hair cells whose stereocilia are embedded in gelatinous material.

Stereocilia on hair cells in the cupula bend...

...creating a signal that causes depolarization of the dendrites in the lateral line nerve.

45.9 The Lateral Line System Contains Mechanoreceptors

Hair cells in the lateral line of a fish detect movement of the water around the animal, giving the fish information about its own movements and the movements of objects nearby.

Stretch receptors are found in muscles, tendons, and ligaments

An animal receives information from stretch receptors about the position of its limbs and the stresses on its muscles and joints. These mechanoreceptors are activated by being stretched. They continuously feed information to the CNS, and that information is essential for the coordination of movements.

The stretch receptors in skeletal muscle are called muscle spindles. They are embedded in connective tissue within skeletal muscle. They consist of modified muscle fibers that are innervated in the center with extensions of sensory neurons. Whenever the muscle stretches, muscle spindles are also stretched and the neurons transmit action potentials to the CNS (Figure 45.8a). Earlier in this chapter, we saw how crayfish stretch receptors transduce physical force into action potentials (see Figure 45.3). The actions of muscle spindles are similar.

Another stretch receptor, the Golgi tendon organ, is found in tendons and ligaments. It provides information about the force generated by a contracting muscle. When a contraction becomes too forceful, the information from the Golgi tendon organ feeds into the spinal cord, inhibits the motor neuron, and causes the contracting muscle to relax, thus protecting the muscle from tearing (Figure 45.8b).

Hair cells provide information about balance, orientation in space, and motion

Hair cells are also mechanoreceptors. Projecting from the surface of each hair cell is a set of stereocilia, which looks like a set of organ pipes. When these stereocilia (which are

SENSORY SYSTEMS 801

really microvilli) are bent, they alter receptor proteins in the hair cell's plasma membrane. When the stereocilia of some hair cells are bent in one direction, the receptor potential becomes more negative; when they are bent in the opposite direction, it becomes more positive. When the receptor potential becomes more positive, the hair cell releases neurotransmitter to the sensory neuron associated with it and the sensory neuron sends action potentials to the CNS.

Hair cells are found in the lateral line sensory system of fish. The lateral line consists of a canal just under the surface of the skin that runs down each side of the fish (Figure 45.9). The lateral line provides information about movements of the fish through the water, as well as about moving objects, such as predators or prey, that cause pressure waves in the surrounding water.

Many invertebrates have equilibrium organs called statocysts that use hair cells to signal the position of the animal with respect to gravity (Figure 45.10). A statocyst is a chamber lined with hair cells that contains a dense object called a statolith. As the animal changes its position, the statolith moves in response to gravity, stimulating the hair cells below it. Replacing the statoliths of a lobster with iron filings and holding a magnet over the animal causes it to swim upside down. When a magnet is held to the lobster's side, it swims on its side.

Vertebrates also have equilibrium organs. The mammalian inner ear has two equilibrium organs that use hair cells to detect the position of the body with respect to gravity: semicircular canals and the vestibular apparatus. The

45.11 Organs in the Inner Ear of Mammals Provide the Sense of Equilibrium

The bony inner ear has three parts: the snail-shaped cochlea, the semicircular canals, and the vestibule. The cochlea is for hearing; the semicircular canals and the vestibular apparatus provide the sense of equilibrium.

Layers of otoliths are moved by gravity when the head changes position, or they are moved by their inertia if the head accelerates or decelerates.

The human ear uses hair cells to transduce sound waves into action potentials.

SENSORY SYSTEMS 803

inner ear contains three semicircular canals at right angles to one another. The structure and function of these organs are described in Figure 45.11. The vestibular apparatus has two chambers that perform a function similar to that of the statocysts of invertebrates.

Auditory systems use hair cells to sense sound waves

The stimuli that animals perceive as sounds are pressure waves. Auditory systems use mechanoreceptors to transduce pressure waves into action potentials. Auditory systems include special structures to gather sound waves, direct them to the sensory organ, and amplify their effect on the mechanoreceptors.

Human hearing provides a good example of an auditory system. The organs of hearing are the ears. The two prominent structures on the sides of our heads usually thought of as ears are the ear pinnae. The pinna of an ear collects sound waves and directs them into the auditory canal, which leads to the actual hearing apparatus in the middle ear and the inner ear (Figure 45.12). If you have ever watched a rabbit, a horse, or a dog change the orientation of its ear pinnae to focus on a particular sound, then you have witnessed the role of ear pinnae in hearing.

The eardrum, or tympanic membrane, covers the end of the auditory canal. The tympanic membrane vibrates in response to pressure waves traveling down the auditory canal. The middle ear, an air-filled cavity, lies on the other side of the tympanic membrane.

The middle ear is open to the throat at the back of the mouth through the eustachian tube. Because air flows through the eustachian tube, pressure equilibrates between the middle ear and the outside world. When you have a cold or allergy, the tube can become blocked by mucus or by tissue swelling, so you have difficulty "clearing your

ears," or equilibrating the pressure in the middle ear with the outside air pressure. As a result, the flexible tympanic

membrane bulges in or out, dampening your hearing and sometimes causing earaches.

The middle ear contains three delicate bones called the ear ossicles, individually named the malleus (hammer), incus (anvil) and stapes (stirrup). The ossicles transmit the vibrations of the tympanic membrane to another flexible membrane called the oval window. The leverlike action of the ossicles amplifies the vibrations of the tympanic membrane about 20-fold in transmitting them to the oval window membrane. Behind the oval window lies the fluid-filled inner ear. Movements of the oval window result in pressure changes in the inner ear. These pressure waves are transduced into action potentials.

The inner ear is a long, tapered, coiled chamber called the cochlea (from Latin and Greek words for "snail" or "shell").

A cross section of this chamber reveals that it is composed of three parallel canals separated by two membranes: Reissner's membrane and the basilar membrane (see Figure 45.12). Sitting on the basilar membrane is the organ of Corti, the apparatus that transduces pressure waves into action potentials in the auditory nerve, which in turn conveys information from the ear to the brain. The organ of Corti contains hair cells whose stereocilia are in contact with an overhanging, rigid shelf called the tectorial membrane. Whenever the basilar membrane flexes, the tectorial membrane bends the hair cell

stereocilia. As a consequence, the hair cells depolarize or hyperpolarize, altering the rate of action potentials transmitted to the brain by their associated sensory neurons.

804 CHAPTER FORTY-FIVE

What causes the basilar membrane to flex, and how does this mechanism distinguish sounds of different frequencies? In Figure 45.13, the cochlea is shown uncoiled to make it easier to understand its structure and function. To simplify matters, we have left out Reissner's membrane, thus combining the upper and the middle canals into one upper canal. The purpose of Reissner's membrane is to contain a specific aqueous environment for the organ of Corti separate from the aqueous environment in the rest of the cochlea.

The simplified diagram of the cochlea shown in Figure 45.13 reveals two additional features that are important to its function. First, the upper and lower chambers separated by the basilar membrane are joined at the distal end of the cochlea (the end farthest from the oval window), making one continuous canal that folds back on itself. Second, just as the oval window is a flexible membrane at the beginning of the cochlea, the round window is a flexible membrane at the end of the long cochlea.

canal.

Air is highly compressible, but fluids are not. Therefore, a sound pressure wave can travel through air without much displacement of the air, but a sound pressure wave in fluid causes displacement of the fluid. When the stapes pushes the oval window in, the fluid in the upper canal of the cochlea is displaced. The cochlear fluid displacement travels down the upper canal, around the bend, and back through the lower canal. At the end of the lower canal, the displacement is absorbed by the outward bulging of the round window. ~~~~

If the oval window vibrates in and out rapidly, the waves of fluid displacement do not have enough time to travel all the way to the end of the upper canal and back through the lower canal. Instead, they take a shortcut by crossing the basilar membrane, causing it to flex. The more rapid the vibration, the closer to the oval and round windows the wave of displacement will flex the basilar membrane. Thus different pitches of sound flex the basilar membrane at different locations and activate different sets of hair cells (see Figure 45.13).

The ability of the basilar membrane to respond to vibrations of different frequencies is enhanced by its structure. Near the oval and round windows, at the proximal end, the basilar membrane is narrow and stiff, but it gradually becomes wider and more flexible toward the opposite (distal) end. So it is easier for the proximal basilar membrane to resonate with high frequencies and for the distal basilar membrane to resonate with lower frequencies. A complex sound made up of many frequencies distorts the basilar membrane at many places simultaneously and activates a unique subset of hair cells. Action potentials stimulated by the mechanoreceptors at different positions along the organ of Corti travel to the brain stem along the auditory nerve.

Deafness^ the loss of the sense of hearing, has two general causes. Conduction deafness is caused by the loss of function of the tympanic membrane and the ossicles of the middle ear. Repeated infections of the middle ear can cause scarring of the tympanic membrane and stiffening of the

45.13 Sensing Sound Pressure Waves in the Inner Ear

For simplicity, this diagram illustrates the cochlea as uncoiled, and leaves out Reissner's membrane. Pressure waves of different frequencies flex the basilar membrane at different locations. Information about sound frequency is specified by which hair cells are activated.

connections between the ossicles. The consequence is less efficient conduction of sound waves from the tympanic membrane to the oval window. With increasing age, the ossicles progressively stiffen, resulting in a gradual loss of the ability to hear high-frequency sounds. Nerve deafness is caused by damage to the inner ear or the auditory pathways. A common cause of nerve deafness is damage to the hair cells of the delicate organ of Corti by exposure to loud sounds such as jet engines, pneumatic drills, or highly amplified rock music. This damage is cumulative and permanent.

SENSORY SYSTEMS 805

Photoreceptors and Visual Systems: Responding to Light

Sensitivity to light—\photosensitivityj-coniers on the simplest animals the ability to orient to the sun and sky and gives more complex animals rapid and extremely detailed information about objects in their environment. It is not surprising that both simple and complex animals can sense and respond to light. What is remarkable is that across the entire range of animal species, evolution has conserved the same basis for photosensitivity: the family of pigments called rhodopsins.

In this section -we will learn how rhodopsin molecules respond when stimulated by light energy and how that response is transduced into neural signals. We will also examine the structures of eyes, the organs that gather and focus light energy onto photoreceptor cells.

Rhodopsin is responsible for photosensitivity

Photosensitivity depends on the ability of rhodopsins to absorb photons of light and to undergo a change in conformation. A rhodopsin molecule consists of a protein, opsin (which by itself does not absorb light), and a light-absorbing prosthetic group, 11-cis-retinal. The light-absorbing group is cradled in the center of the opsin and the entire rhodopsin molecule sits within the plasma membrane of a photoreceptor cell (Figure 45.14).

When the 11-cis-retinal absorbs a photon of light energy, its shape changes into a different isomer of retinal—all-trans-retinal. This change puts a strain on the bonds between retinal and opsin, changing the conformation of opsin. This change in conformation signals the detection of light. In vertebrate eyes, the retinal and the opsin eventually separate from each other—a process called bleaching, which causes the molecule to lose its photosensitivity. When the retinal spontaneously returns to its 11-cis isomer and recombines with opsin, it once again becomes photosensitive rhodopsin.

How does the light-induced conformational change of rhodopsin transduce light into a cellular response? After retinal converts from the 11-cis into the all-trans form, its interactions with opsin pass through several unstable intermediate stages. One of these stages is known as

45.75 The Rod Cell: A Vertebrate Photoreceptor

-becomes

^^

photoexcited rhodopsin because it triggers a cascade of reactions that results in the alteration of membrane potential that is the photoreceptor cell's response to light.

To get a better idea of how rhodopsin alters the membrane potential of a photoreceptor cell and how that photoreceptor cell signals that it has been stimulated by light, let's look at a vertebrate photoreceptor cell, the rod cell. Like other vertebrate photoreceptor cells, the rod cell is a modified neuron (Figure 45.15). The back of the vertebrate eye is the retina, which consists of several layers of __neuron __. One of these layers contains the photoreceptor cells. The other layers of the retina transduce the visual world into action potentials.

Each rod cell in the retina has an outer segment, an inner segment, and a synaptic terminal. The inner segment contains the usual organelles of a cell. The synaptic terminal is

where the rod cell communicates with other neurons. The outer segment is highly specialized and contains a stack of discs of plasma membrane densely packed with rhodopsin. The function of the discs is to capture photons of light passing through the rod cell.

To see how a rod cell responds to light, we can penetrate a single rod cell with an electrode and record its receptor potential in the dark and in the light (Figure 45.16a). From what we have learned about other types of sensory cells, we might expect stimulation of the rod cell by light to make its receptor potential less negative. But photoreceptor cells are atypical, and the opposite is true. When a rod cell is kept in the dark, it already has a relatively depolarized resting potential in comparison with other neurons. In fact, the plasma membrane of the rod cell is almost as permeable to Na^+ ions as to K^+ ions, and Na^+ ions are continually entering the outer segment of the cell.

When a light is flashed on the dark-adapted rod cell, its receptor potential becomes more negative—it hyperpolarizes (Figure 45.16b). The rod cell itself does not generate action potentials. However, the rod cell changes its rate of neurotransmitter release as its membrane potential changes (since the rod cell hyperpolarizes, neurotransmitter released decreases). Later in this section we will learn how other cells in the retina respond to neurotransmitter released from the photoreceptor cells.

How does the absorption of light by rhodopsin hyperpolarize the rod cell? When rhodopsin is excited by light, it initiates a cascade of events. The photoexcited rhodopsin combines with and activates another protein, a G protein

45.17 Light Absorption Closes Sodium Channels

The absorption of light by rhodopsin initiates a cascade resulting in the hyperpolarization of the rod cell.

Activated PDE hydrolyzes cGMP to 5'-GMP, causing Na^+ channels to close. ...

Nerves to brain

Pigmented eye cups

called transducin. Activated transducin in turn activates a phosphodiesterase, which converts cyclic GMP (cGMP) to 5'-GMP. This reaction plays a central role in phototransduction. In the dark, the cGMP in the outer segment binds to sodium channels, keeping them open and allowing Na^+ to enter the outer segment. As cGMP is converted to 5'-GMP, the sodium channels close, and the cell hyperpolarizes.

This may seem like a roundabout way of doing business, but its advantage is its enormous amplification ability. Each molecule of photoexcited rhodopsin can activate as many as 500 transducin molecules, thus activating a large number of phosphodiesterase molecules. The catalytic capacity of a molecule of phosphodiesterase is great: it can hydrolyze more than 4,000 molecules of cGMP per second. The bottom line is that a single photon of light can cause more than a million sodium channels to close, thereby changing the rod cell's receptor potential (Figure 45.17).

Now let's see how photoreceptors of different types are incorporated into different kinds of visual systems.

Invertebrates have a variety of visual systems

Flatworms obtain directional information about light from photoreceptor cells that are organized into eye cups (Figure

The compound eyes of a fruit fly each contain hundreds of ommatidia.

45.18). The eye cups are bilateral structures, each partly shielded from light by a layer of pigmented cells lining the cup. The photoreceptors on the two sides of the animal are unequally stimulated unless the animal is facing directly toward or away from a light source. The flatworm generally uses directional information about light sources to move away from light.

Arthropods (crustaceans, spiders, and insects) have evolved compound eyes that provide them with information about patterns or images in the environment. Each compound eye consists of many optical units called ommatidia (singular ommatidium) (Figure 45.19). The number of ommatidia in a compound eye varies from only a few in some ants, to 800 in fruit flies, to 10,000 in some dragon-flies.

Each ommatidium has a lens structure that directs light onto photoreceptors called retinal cells. Flies, for example, have seven elongated retinula cells in each ommatidium. The inner borders of the retinula cells are covered with microvilli that contain rhodopsin and thus trap light. Since the microvilli of the different retinula cells overlap, they appear to form a central

rod, called a rhabdom, down the center of the ommatidium.

Axons from the retinula cells communicate with the nervous system. Since each ommatidium of a compound eye is directed at a slightly different part of the visual world, only a crude, or perhaps a broken-up, image can be communicated from the compound eye to the CNS.

Image-forming eyes evolved independently in vertebrates and cephalopods

Both vertebrates and cephalopod mollusks have evolved eyes with exceptional abilities to form images of the visual world. Like cameras, these eyes focus images on a surface sensitive to light. Considering that they evolved independently of each other, their high degree of similarity is remarkable (Figure 45.20).

808 CHAPTER FORTY-FIVE

45.20 Eyes Like Cameras

The lenses of cephalopod and vertebrate eyes focus images on layers of photoreceptor cells, just as a camera's lens focuses images on film.

The vertebrate eye is a spherical, fluid-filled structure bounded by a tough connective tissue layer called the sclera. At the front of the eye, the sclera forms the transparent cornea through which light passes to enter the eye. Just inside the cornea is the pigmented iris, which gives the eye its color. The function of the iris is to control the amount of light that reaches the photoreceptor cells at the back of the eye, just as the diaphragm of a camera controls the amount of light reaching the film. The central opening of the iris is the pupil. The iris is under neural control. In bright light the iris constricts and the pupil is very small. As light levels fall, the iris relaxes and the pupil enlarges.

Behind the iris is the crystalline protein lens, which helps focus images on the photoreceptors at the back of the eye. The cornea and the fluids of the eye chambers are mostly responsible for focusing light on the retina, but the lens allows the eye to accommodate—that is, to focus on objects at various locations in the near visual field. To focus a camera on objects close at hand, you adjust the distance between the lens and the film. Fishes, amphibians, and reptiles accommodate in a similar manner, moving the lenses of their eyes closer to or farther from their retinas. Mammals and birds use a different method: they alter the shape of the lenses.

The lens is contained in a connective tissue sheath that tends to keep it in a spherical shape, but it is attached to suspensory ligaments that pull it into a flatter shape. Circular muscles called the ciliary muscles counteract the pull of the suspensory ligaments and permit the lens to round up. With the ciliary muscles at rest, the flatter lens has the correct optical properties to focus distant objects on the retina, but not close images. Contracting the ciliary muscles rounds up the lens, changing its light-bending properties to bring close images into focus (Figure 45.21). As we age, our lenses become less elastic and we lose the ability to focus on objects close at hand without the help of corrective lenses. As a consequence, most adults over the age of 45 need the assistance of bifocal lenses or reading glasses to compensate for their lost ability to accommodate.

The vertebrate retina receives and processes visual information

During development, neural tissue grows out from the brain to form the retina. In addition to a layer of photoreceptor cells, the retina includes layers of cells that process the visual information

from the photoreceptors and produce an output signal that is transmitted to the brain via the optic nerve. A curious feature of the anatomy of the retina is that the light-absorbing outer segments of the photoreceptor cells are all the way at the back of the retina. Light must pass through all the layers of retinal cells before reaching the place where photons are captured by rhodopsin. We will explore in detail how the cells of the retina process information, but first let's describe some general features of retinal organization.

THE CELLULAR STRUCTURE OF THE RETINA. The density of

photoreceptor cells is not the same across the entire retina. Light coming from the center of the visual field falls on an area of the retina called the fovea, where the density of photoreceptor cells is the highest. The human fovea has about 160,000 photoreceptors per square millimeter. A hawk has about 1 million photoreceptors per square millimeter of fovea, making its vision sharper than ours. In addition, the hawk has two foveas in each eye: one receives light from

For near vision (accommodation), ciliary muscles contract, causing the lens to round up.

Optic nerve

Ciliary muscles / » Suspensory filaments

Fovea

For distant vision, ciliary muscles relax and suspensory ligaments pull the lens to a flatter shape.

45.21 Staying in Focus

Mammals and birds focus their eyes by changing the shape of the lens.

Cone cells

Rod cells

45.22 Rods and Cones

This scanning electron micrograph of photoreceptors in the retina of a mud puppy (an amphibian) shows cylindrical rods and tapered cones.

straight ahead, while the other receives light from below. Thus while the hawk is flying, it sees both its projected flight path and the ground below, where it might detect a mouse scurrying in the grass.

The fovea of a horse is a long, vertical patch of retina. The horse's lens is not good at accommodation, but it focuses distant objects that are straight ahead on one part of this long fovea and close objects that are below the head on another part. When horses are startled by an object close at hand, they pull their heads back and rear up to bring the object into focus on the close-vision part of the fovea.

Where blood vessels and the bundle of axons going to the brain (the optic nerve) pass through the back of the eye, there are no photoreceptors, so there is a blind spot on the retina. You are normally not aware of your blind spot, but you can find it. Stare straight ahead, holding a pencil in your outstretched hand so that the eraser is in the center of your field of vision. While continuing to stare straight ahead, slowly move the pencil to the side until the eraser disappears. When this happens, the light from the eraser is focused directly on your blind spot.

Until now we have referred to only one kind of photoreceptor cell, the rod cell. But there are two major kinds of vertebrate photoreceptors, both named for their shapes—rod cells and cone cells (Figure 45.22). A human retina has about 3 million cones and about 100 million rods. Rod cells are more sensitive to light, but do not contribute to color vision! Some cone cells are responsible for color vision, but are less sensitive to light. Cones are also responsible for our sharpest vision. Even though there are many more rods than cones in human retinas, our foveas contain only cones.

Because cones have low sensitivity to light

they are of

no use in dim light. At night our vision is not very sharp and we see mostly in shades of gray. You may have trouble seeing a small object such as a keyhole at night when you are looking straight at it—that is, when its image is falling on your fovea. If you look a little to the side, so that the image falls on a rod-rich area of your retina, you can see the

SENSORY SYSTEMS 809

object better. Astronomers looking for faint objects in the sky learned this trick a long time ago. Animals that are nocturnal (such as mice or flying squirrels) may have retinas made up almost entirely of rods and have little or no color vision. By contrast, some animals that are active only during the day (such as chipmunks and ground squirrels) have only cones in their retinas.

How do cone cells enable us to see color? The human retina has three kinds of cone cells, each containing slightly different types of opsin molecules. These opsin molecules differ in the wavelengths of light they absorb best. Although the same 11-trans-retinal group is the light absorber (see Figure 45.14), its molecular interactions with opsin tune the spectral sensitivity of the rhodopsin molecule as a whole. Some opsins cause retinal to absorb most efficiently in the blue region, some in the green, and some in the yellow and red (Figure 45.23). Intermediate wavelengths of light excite these different classes of cones in different proportions. The genes that encode the different opsins of humans have been cloned: One codes for blue-sensitive opsin, one for green-sensitive opsin, and several for red-sensitive opsin.

The human retina is organized into five layers of neurons that receive visual information and process it before sending it to the brain (Figure 45.24). As mentioned earlier, the layer of photoreceptors is the way at the back of the retina. The outer segments of the rods and cones are partly buried in a layer of pigmented epithelium that absorbs photons not captured by rhodopsin and prevents any backscattering of light that might decrease visual sharpness.

INFORMATION FLOW IN the RETINA. A first step in investigating how the human retina tells the brain what it sees is to study how its five layers of neurons are interconnected and how they influence one another. As we know, the photoreceptor cells at the back of the retina hyperpolarize in response to light and do not generate action poten-

Human color vision is based on three kinds of cone cells. Each absorbs a different band of wavelengths most effectively.

tials. The cells at the front of the retina are gang lion cells. They fi re action potentials, and their axons form the optic nerves that travel to the b rain. The photoreceptors and ganglion cells are connected by bi polar cel ls. Like rods and cones, bipolar ce lls do not fire actioy! potent ials.

Changes in the membrane potential of rods and cones in response to light alter the rate at which the rods and cones release neuro transmit ter at their synapses with the bipolar cells. In response to neurotransmitter from the photoreceptors, the membrane potentials of the bi polar c eLte change, a ltering the rate at which they release neurotransm itter on to ganglion ce lls. The gang lion cells gene rate action pote ntials, and the rate of neurotransmitter releas e from the bipola r cells de t ermines the rate at w hich they do so. Thus the direct flow of information in the retina is from photo rece ptor to bipolar cell to ganglion cell. Ganglion cells send the information to the brain.

The other two cell layers, the horizontal cells and the amac rine c ells, communicate laterally across the retina. Hori-zontafcells connect neighboring pairs of photoreceptors and bipolar cells. Thus the communication between a photoreceptor and its bipolar cell can be influenced by the amount of li ght absorbed by neighboring photoreceptors. This lateral flow of information enables the retina to sharp en the perception of contrast between light and dark patterns.

(Amacrine ce Us\ connect neighboring pairs of bipolar cells and ganglion cells. The role of amacrine cells is still poorly understood. Some amacrine cell types are highly sensi tive to changing illumination or to motion. Others assist in adjusting the sensitivity of the eyes according to the overall level of light falling on the retina. When background light levels change, amacrine cell connections to the ganglion cells help the ganglion cells remain sensitive to temporal changes in stimulation. Thus even with large changes in background illumination, the eyes are sensitive to smaller, more rapid changes in the pattern of light falling on the retina.

Information processing in the retina. Knowing the paths of information flow through the retina still doesn't tell us how that information is processed. What does the eye tell the brain in response to a pattern of light falling on the ret ina? One aspect of info rmation processing in the retina \ \$folroergence of information }^ here are more than 100 mil-ljonpho toreceptors in each reti na, but only about 1 million

Axons of ganglion cells

t

Visual information is processed forward through several layers of neurons...

...and finally converges on ganglion cells, which send their axons to the brain.

t 45.24 The Retina

The human retina has five layers of neurons that receive and process visual information.

ganglion cells sending messages to the brain. How is the information from all those photoreceptors integrated by the ganglion cells?

This question was addressed in some elegant, classic experiments in which electrodes were used to record the activity of single ganglion cells in living animals while their retinas were stimulated with spots of light. These studies revealed that each ganglion cell has a well-defined receptive field that consists of a specific group of photoreceptor cells. Stimulating these photoreceptors with light activates the ganglion cell (Figure 45.25). Information from many photoreceptor cells is integrated in this way to produce a single message.

The receptive fields of many ganglion cells are circular, but the way a spot of light influences the activity of the ganglion cell depends on where in the receptive field it falls. The receptive field of a ganglion cell can be divided into two concentric areas, called the center and the surround. There are two kinds of receptive fields, on-center and off-center. Stimulating the center of an on-center receptive field excites the ganglion cell, and stimulating the surround inhibits it. Stimulating the center of an off-center receptive field inhibits the ganglion cell, and stimulating the surround excites it. Center effects are always stronger than surround effects.

The response of a ganglion cell to stimulation of the center of its receptive field depends on how much of the surround area is also stimulated. A small dot of light hitting the center has the maximal effect. A bar of light hitting the center and pieces of the surround has less of an effect, and a large, uniform patch of light falling equally on center and surround has very little effect. Ganglion cells commu-

nicate information about contrasts between light and dark that fall on different regions of their receptive fields.

How are receptive fields related to the connections among the neurons of the retina? The photoreceptors in the center of the receptive field of a ganglion cell are connected to that ganglion cell by bipolar cells. The photoreceptors in

^ 45.25 What Does the Eye Tell the Brain?

When the retina is stimulated with dots and rings of light, individual ganglion cells show different responses.

the surround send information to the center photoreceptors, and thus to the ganglion cell, through the lateral connections of horizontal cells. Thus the receptive field of a ganglion cell consists of a pattern of synapses among photoreceptors, horizontal cells, bipolar cells, and ganglion cells.

The receptive fields of neighboring ganglion cells can overlap greatly; a given photoreceptor can be effectively connected to several ganglion cells. Thus the ganglion cells send simple messages to the brain about the pattern of light

H

EXPERIMENT

Question: How do retinal ganglion cells code patterns of light falling on the retina?

METHOD

| Light stimulates a small, circular area of the retina. (In reality, the light would come from the other direction.)

I Photoreceptors in a circular receptive field give input to a single ganglion cell.

A retinal ganglion cell receives input from all photoreceptors in its receptive field.

EJ An oscilloscope shows action potentials generated by the ganglion cell.

t> To visual cortex

Pattern of light stimulating retina

RESULTS

Bipolar cells

Axon in optic nerve

Stimulus patterns

Complete darkness

Small spot falling on center of receptive field

Large spot covering receptive field

Ring of light excluding center of receptive field

On

StimulusN

An on-center ganglion cell is inhibited by a ring of light falling on its receptive field's surround.

An off-center ganglion cell is stimulated by light falling on its receptive field's surround and is inhibited by light falling on its center.

Conclusions: 1. Ganglion cells have circular receptive fields that are divided into center and surround areas.

2. Some ganglion cells are maximally stimulated by light falling on the center of their receptive fields. Others are maximally stimulated by light falling on the surround of their receptive fields.

3. Ganglion cells encode patterns of light and dark contrast.

Pit organ

intensities falling on small, circular patches of retina. In Chapter 47 we will see how the brain reassembles that information into our view of the world.

Sensory Worlds Beyond Our Experience

Humans make use of only a subset of the information available to us in the environment. Other animals have sensory systems that enable them to use different subsets and different types of information.

Some species can see infrared and ultraviolet light

When discussing vision, we use the term "visible light," but what we really mean is light visible to humans. Our visible spectrum is a very narrow region of the entire, continuous range of electromagnetic radiation in the environment (see Figure 8.5). We cannot see ultraviolet radiation, for example, but many other animals can.

One of the seven photoreceptors in each ommatidium of a fruit fly is sensitive to ultraviolet light. The visual sensitivity of many pollinating insects includes the ultraviolet part of the spectrum. Some flowers have patterns that are invisible to us but show up if we photograph them with film that is sensitive to ultraviolet light. Those patterns provide information to

prospective pollinators, but humans are not equipped to receive that information.

At the other end of the spectrum is infrared radiation, which we sense as heat. Other animals extract much more information from infrared radiation—especially that emitted by potential prey. Pit vipers such as rattlesnakes have pit organs, one just in front of each eye, that use highly sensitive heat detectors and a simple pinhole camera arrangement to sense and locate infrared radiation (Figure 45.26). In total darkness, these snakes can locate a prey animal such as a mouse, orient to it, and strike it with great accuracy.

Echolocation is sensing the world through reflected sound

Some species emit intense sounds and create images of their environments from the echoes of those sounds. Bats, porpoises, dolphins, and (to a lesser extent) whales are accomplished echolocators. Some species of bats have elaborate modifications of their noses to direct the sounds they emit, as well as impressive ear pinnae to collect the returning echoes. The high-frequency sounds they emit as pulses (about 20 to 80 per second) are above the range of human hearing, but they are extremely loud in contrast to the resulting faint echoes bouncing off small insects. An echolocating bat is similar to a construction worker who is trying to overhear a whispered conversation on a street corner while using a pneumatic drill. To avoid deafening themselves, bats use muscles in their middle ears to dampen their sensitivity while they emit sounds, then relax them quickly enough to hear the echoes. The ability of bats to use echolocation to sense their environment is so good that in a totally dark room strung with fine wires, they can capture tiny flying insects while navigating around the wires.

Crotalus molossus

45.26 Stalking in the Dark

The black-tailed rattlesnake of the southwestern United States is a pit viper. Pit vipers can locate prey in total darkness on the basis of infrared radiation they sense through their pit organs.

Some fish can sense electric fields

We discussed the mechanoreceptors in the lateral lines of fishes (see Figure 45.9). The lateral lines of some species, especially those such as catfish that live in murky waters, also contain electroreceptors. These sensory cells enable the fish to detect weak electric fields, which can help them locate prey.

The use of electroreceptors is even more sophisticated in species called electric fishes. These fishes have evolved electric organs in their tails that generate a continuous series of electric pulses, creating a weak electric field around their bodies. Any objects in the environment, such as rocks, plants, or other fish, disrupt the electric fish's electric field, and the electroreceptors of the lateral line detect those disruptions. In some electric fish species, each individual in a group emits its electric pulses at a different frequency. If a new fish is added to the group, they all readjust their frequencies.

Chapter Summary

Sensory Cells, Sensory Organs, and Transduction

- Sensory cells transduce information about an animal's external and internal environment into action potentials. Review Figures 45.1, 45.2
- The interpretation of action potentials as particular sensations depends on which neurons in the CNS receive them.
- Sensory cells have membrane receptor proteins that cause ion channels to open or close, generating receptor potentials. Receptor potentials can spread to regions of the sensory cell plasma membrane that generate action potentials, or they can influence the release of neurotransmitter from the sensory cell. Review Figure 45.3
- Adaptation enables the nervous system to ignore irrelevant stimuli while remaining responsive to relevant or to new stimuli.

Chemoreceptors: Responding to Specific Molecules

- Smell, taste, and the sensing of pheromones are examples of chemosensation. Chemoreceptor cells have receptor proteins that can bind to specific molecules that come into contact with the sensory cell membrane. Review Figure 45.5

SENSORY SYSTEMS 813

teins that can bind to specific molecules that come into contact with the sensory cell membrane. Review Figure 45.5

- The binding of an odorant molecule to a receptor protein causes the production of a second messenger in the chemoreceptor cell. The second messenger alters ion channels and creates a receptor potential. Review Figure 15.17

- Chemoreceptors in the mouth cavities of vertebrates are responsible for the sense of taste. Review Figure 45.6

Mechanoreceptors: Detecting Stimuli that Distort Membranes

- In the skin there are a diversity of mechanoreceptors that respond to touch and pressure. The density of mechanoreceptors in any skin area determines the sensitivity of that area to touch and pressure. Review Figure 45.7
- Stretch receptors in muscles, tendons, and ligaments inform the CNS of the positions of and the loads on parts of the body. Review Figure 45.8
- Hair cells are mechanoreceptors that are not neurons. The bending of their stereocilia alters their membrane proteins and therefore their receptor potentials. Hair cells are found in organs of equilibrium and orientation such as the lateral line system of fishes, the statocysts of invertebrates, and the semicircular canals and vestibular apparatus of mammals. Review Figures 45.9, 45.10, 45.11
- Hair cells are responsible for mammalian auditory sensitivity. Ear pinnae collect and direct sound waves to the tympanic membrane, which vibrates in response to sound waves. The movements of the tympanic membrane are amplified through a chain of ossicles that conduct the vibrations to the oval window. Movements of the oval window create pressure waves in the fluid-filled cochlea. Review Figure 45.12
- The basilar membrane running down the center of the cochlea is distorted at specific locations that depend on the frequency of the pressure wave. These distortions cause the bending of hair cells in the organ of Corti, which rests on the basilar membrane. Changes in hair cell receptor potentials create action potentials in the auditory nerve, which conducts the information to the CNS. Review Figure 45.13

Photoreceptors and Visual Systems: Responding to Light

- Photosensitivity depends on the capture of photons of light by rhodopsin, a photoreceptor molecule that consists of a protein called opsin and a light-absorbing prosthetic group called retinal. Absorption of light by retinal is the first step in a cascade of intracellular events leading to a change in the receptor potential of the photoreceptor cell. Review Figure 45.14
- When excited by light, vertebrate photoreceptor cells hyperpolarize and release less neurotransmitter onto the neurons with which they form synapses. They do not fire action potentials. Review Figures 45.15, 45.16, 45.17
- Vision results when eyes focus patterns of light onto layers of photoreceptors. Eyes vary from the simple eye cups of flatworms, which enable the animal to sense the direction of a light source, to the compound eyes of arthropods, which enable the animal to detect shapes and patterns, to the lensed eyes of cephalopods and vertebrates. Review Figures 45.18, 45.19
- The eyes of vertebrates and cephalopods focus detailed images of the visual field onto dense arrays of photoreceptors that transduce the visual image into neural signals. Review Figures 45.20, 45.21
- The vertebrate photoreceptors are rod cells, responsible for dim light and black-and-white vision, and cone cells, responsible for color vision by virtue of their spectral sensitivities. Review Figure 45.23
- The vertebrate retina is a dense array of neurons lining the back of the eyeball. It consists of five layers of cells. The outermost layer consists of the rods and cones. The innermost layer consists of the ganglion cells, which send their axons in the optic nerve to the brain. Between the photoreceptors and the ganglion cells are neurons that process the information from the photoreceptors. Review Figure 45.24
- The area of the retina that receives light from the center of the visual field, the fovea, has the greatest density of photoreceptors. In humans the fovea contains almost exclusively cone cells, which are responsible for color vision but are not very sensitive in dim light.
- Each ganglion cell is stimulated by light falling on a small circular patch of photoreceptors called a receptive field. Receptive fields have a center and a surround, which have opposing effects on the ganglion cell. If the center is excitatory, the surround is inhibitory, and vice versa. Review Figure 45.25

Sensory Worlds Beyond Our Experience

- Many animals have sensory abilities that we do not share. Bats echolocate, insects see ultraviolet radiation, pit vipers "see" infrared radiation, and fish sense electric fields.

For Discussion

1. Compare and contrast the functioning of olfactory receptors and photoreceptors. How do these sensory cells enable the CNS to discriminate between an apple and an orange?
2. Amplification of signal is an important feature of sensory systems. Compare mechanisms of amplification in olfactory, visual, and auditory systems.
3. If you were blindfolded and placed in a wheelchair, how would you know if you were being pushed forward or backward?
4. Describe and contrast two sensory systems that enable animals to "see" in the dark. What problems or limitations are inherent in these systems in comparison with vision?

5. Communication is the transfer of information from one animal to another. Animals can use visual, olfactory, tactile, and auditory signals to communicate. From what you know about these sensory systems, discuss the relative advantages and disadvantages of these systems for communication.

The Mammalian Nervous System: Structure and Higher Functions

Phineas Gage was an industrious, responsible, considerate young man. He was 25 years old, working as a railroad construction foreman. He had the respect of his men, and he looked out for them to the extent that he took on himself the most dangerous tasks associated with blasting the rocks in the path of the railroad.

Late one afternoon the last hole had been drilled for the day. Gage poured blasting powder into the hole and tamped it with a meter-long, 3-cm wide iron rod. The tamping iron hit the side of the hole, struck a spark, and ignited the powder. The explosion shot the rod out of the hole like a bullet. It struck Phineas below his left eye, penetrated his skull, passed through the part of his brain behind his forehead, and exited out the top of his head. Was this the end of Phineas Gage?

Gage regained consciousness within minutes and could speak. He was taken to a hotel, where a physician dressed his wounds, but the doctor could do little else. Infections were a problem, but Gage's senses and memory were intact. In 3 weeks he left his bed, but he did not return to his work at the railroad. The recovered Phineas Gage was quarrelsome, bad-tempered, lazy, and irresponsible. He was impatient and obstinate, and he used profane language, which he had never done before.

The body of Phineas Gage survived the accident, but he was an entirely different person. He spent the rest of his days as a drifter, earning money by telling his story, exhibiting his scars and his tamping iron. If you are in Cambridge, Massachusetts, you can pay him a visit. His skull, death mask, and the tamping iron are on display in the Museum of the Medical College of Harvard University.

The sad story of Phineas Gage reveals that the essence of individuality and personality resides in the brain. What is this miraculous organ, and what does it do? The human brain weighs about 1.5 kg, is mostly water, and has the consistency of custard. Yet the complexity of this small mass of tissue exceeds that of any other known matter. The work of the brain is to process and store information and to control the physiology and behavior of the body. The brain is con-

An Unintentional Experiment

In a nineteenth-century railroad construction accident, an explosion blew a tamping iron through the brain of Phineas Gage. Unbelievably, Gage survived, but his personality was radically changed. This drawing of Gage's skull was made at the time of his death.

stantly receiving, integrating, and interpreting information from all the senses. To respond to that information, it generates commands to the muscles and organs of the body.

The unit of function of the brain is the neuron. The human brain consists of about 10 billion neurons, which account for its ability to handle vast amounts of information. In the previous two chapters we learned about the cellular properties of neurons: how they generate and conduct action potentials, how they transduce sensory information, how they communicate with each other at synapses, and how information is integrated at synapses. In this chapter we take on the challenge of understanding the functions of the human nervous system in terms of these cellular mechanisms.

The Nervous System: Structure, Function, and Information Flow

The human nervous system is more than the brain. The brain and spinal cord together constitute the central nervous system (CNS). Information is brought to and from the

I The brain and spinal cord are the central nervous system.

Nerve -

The nerves of the peripheral nervous system extend to all tissues of the body.

Blood vessel

Axons

Nerve sheath

Bundles of axons are surrounded by connective tissue.

46.1 Anatomy of the Human Nervous System

(a) Information is communicated between the central nervous system and the other tissues of the body through the peripheral nervous system. (fc>) A nerve contains the axons of many neurons. Some of these neurons conduct information to and others from the central nervous system.

THE MAMMALIAN NERVOUS SYSTEM 815

cal regulation (for example, blood pressure, deep body temperature, blood oxygen supply).

The efferent portion of the peripheral nervous system carries information from the CNS to the muscles and glands of the body. Efferent pathways can be divided into a voluntary division, which executes our conscious movements, and an involuntary, or autonomic, division, which controls physiological functions.

In addition to neural information, the CNS receives chemical information in the form of hormones circulating in the blood. Neurohormones released by neurons into the extracellular fluids of the brain can send chemical information to other neurons in the brain or can leave the brain and enter the circulation. In Chapter 41 we learned of the important role of neurohormones in the control of the anterior pituitary and saw that other neurohormones are released from the posterior pituitary into the circulation. Now we can begin to translate our conceptual scheme of information flow into an anatomical view of the nervous system. It can be difficult to learn the relationships between the different structures of the adult nervous system, but the task is much easier if we begin with the development of the nervous system from a simple tubular structure that forms

Connective tissue

in the embryo.

CNS by means of an enormous network of nerves that make up the peripheral nervous system (Figure 46.1a). The peripheral nervous system reaches every tissue of the body. It connects to the CNS via spinal nerves and cranial nerves. A nerve is a bundle of axons (Figure 46.1b) that carries information about many things simultaneously. It is important to distinguish between the axon of a single neuron and a nerve. Some axons in a nerve may be carrying information to the CNS while other axons in the same nerve are carrying information from the CNS to the organs of the body.

A conceptual diagram of the nervous system traces information flow

The nervous system is an information processing system— a very complex one that handles many tasks simultaneously. It will help to organize our thinking about the nervous system by beginning with a conceptual diagram of information flow (Figure 46.2). We can then plug anatomical and functional details into this general model.

The afferent portion of the peripheral nervous system carries information to the CNS. We are consciously aware of much of the information that moves through these afferent pathways (for example, vision, hearing, temperature, pain, the position of limbs), but we are not consciously aware of other afferent information that is important for physiologi-

46.2 Organization of the Nervous System

The peripheral nervous system carries information both to and from the central nervous system. The CNS also receives hormonal inputs and produces hormonal outputs.

816 CHAPTER FORTY-SIX

The vertebrate CNS develops from the embryonic neural tube

Early in the development of all vertebrate embryos, a hollow tube of neural tissue forms (see Chapter 43). This neural tube runs the length of the embryo on its dorsal side. At the anterior end of the embryo, the neural tube forms three swellings that become the basic divisions of the brain: the hindbrain, the midbrain, and the forebrain. The rest of the neural tube becomes the spinal cord (Figure 46.3). The cranial and spinal nerves, which make up the peripheral nervous system, sprout from the neural tube and grow throughout the embryo.

Each of the three regions of the embryonic brain develops into several structures in the adult brain. From the hind-brain come the medulla, the pons, and the cerebellum. The medulla is continuous with the spinal cord. The pons is in front of the medulla, and the cerebellum is a dorsal outgrowth of the pons. The medulla and pons contain distinct groups of neurons that are involved in the control of physiological functions such as breathing and circulation or basic motor patterns such as swallowing and vomiting. All neural information traveling between the spinal cord and higher brain areas must pass through the pons and the medulla.

The cerebellum is like the conductor of an orchestra; it receives "copies" of the commands going to the muscles from higher brain areas, and it receives information coming up the spinal cord from the joints and muscles. Thus it can compare the motor "score" with the actual behavior of the muscles and refine the motor commands.

From the embryonic midbrain come structures that process aspects of visual and auditory information. In addition, all information traveling between higher brain areas and the spinal cord must pass through the midbrain.

The embryonic forebrain develops a central region called the diencephalon and a surrounding structure called the telencephalon. The diencephalon is the core of the forebrain and consists of an upper structure called the thalamus and a lower structure called the hypothalamus. The thalamus is the final relay station for sensory information going to the telencephalon, and the hypothalamus is responsible for the regulation of many physiological functions and biological drives.

The telencephalon consists of two cerebral hemispheres, left and right (also referred to as the cerebrum). In humans, the telencephalon is by far the largest part of the brain and plays major roles in sensory perception, learning, memory, and conscious behavior.

Understanding the relationships among the many structures of the complex adult brain is a little easier if you keep this linear organization of the neural axis in mind: Communication between the spinal cord and the telencephalon travels through the medulla, pons, midbrain, and diencephalon. The medulla, pons, and midbrain are referred to collectively as the brain stem. In general, more primitive and autonomic functions are localized farther down this neural axis, while more complex and evolutionary advanced functions are found higher on the axis.

The stretched-out neural tube, viewed from above, shows three swellings that will form the adult brain.

46.3 Development of the Human Nervous System

Three swellings at the anterior end of the hollow neural tube in early vertebrate embryos develop into the parts of the adult brain. The final view is an adult human brain section cut in half through the midline.

As we go up the vertebrate phylogenetic scale from fish to mammals, the telencephalon increases in size, complexity, and importance. The forebrain dominates the nervous systems of mammals, and damage to this region results in severe impairment of sensory, motor, or cognitive functions, and even coma. In contrast, a shark with its telencephalon removed can swim almost normally.

46.4 The Spinal Cord Processes Information

Sensory information (afferent) enters through the dorsal horns (blue pathway), and motor output (efferent) leaves via the ventral horns (orange and red pathways). The extensor component of the knee-jerk response is a monosynaptic reflex circuit, but the flexor inhibition component involves a spinal interneuron (black).

Functional Subsystems of the Nervous System

When we talk about the development of the nervous system, we describe it in terms of anatomically distinct structures. However, the nervous system is always engaged in many tasks at the same time—a phenomenon called parallel processing of information. Any one task usually involves many different anatomical structures. Understanding the nervous system is made simpler if we recognize its functional subsystems, such as the spinal cord, reticular system, limbic system, and cerebrum. Any one anatomical structure may play roles in several functional subsystems.

AFPA The spinal cord receives and processes information from the body

The spinal cord conducts information in both directions between the brain and the organs of the body. It also integrates a great deal of the information coming from the peripheral nervous system and responds to that information by issuing motor commands.

The conversion of afferent to efferent information in the spinal cord without participation of the brain is called a spinal reflex. The simplest type of spinal reflex involves only two neurons and one synapse and is therefore called a monosynaptic reflex. An example is the knee-jerk reflex, which your physician checks by tapping just below your knee with a small mallet. We can diagram the wiring of a monosynaptic reflex by following the flow of information through the spinal cord.

A cross section of the spinal cord reveals a central area of gray matter in the shape of a butterfly, surrounded by an area of white matter (Figure 46.4). In the nervous system, gray matter is tissue rich in neuronal cell bodies, and white matter contains axons. The gray matter of the spinal cord contains the cell bodies of the spinal neurons; the white matter contains axons.

the axons that conduct information up and down the spinal cord. Spinal nerves leave the spinal cord at regular intervals on each side. Each spinal nerve has two roots connecting to the gray matter—one connecting with the dorsal horn, the other with the ventral horn. Each spinal nerve carries both afferent and efferent information. The afferent axons enter the spinal cord through the dorsal roots and the efferent axons leave the spinal cord through the ventral roots.

In the case of the knee-jerk reflex, sensory information comes from stretch receptors in the leg muscle that is suddenly stretched when the mallet strikes the tendon that runs over the knee. Each stretch receptor initiates action potentials that are conducted by the axon of a sensory neuron in through the dorsal horn of the spinal cord and all the way to the ventral horn. In the ventral horn, the sensory neuron synapses with motor neurons, causing them to fire action potentials that are then conducted back to the leg extensor muscle, causing it to contract. The function of this simple circuit is to sense an increased load on the limb, and to cause the muscle to increase its strength of contraction to compensate for the added load.

Most spinal circuits are more complex than this monosynaptic reflex. We can demonstrate that by building on the circuit we have just traced. Limb movement is controlled by antagonistic sets of muscles—muscles that work against each other. When one member of an antagonistic set of muscles contracts, it bends or flexes the limb; it is therefore called a flexor. The antagonist to this muscle straightens or extends the limb and is called an extensor. For a limb to move, one muscle of the pair must relax while the other

818 CHAPTER FORTY-SIX

contracts. 1 hus sensor) input that activates the motor neuron of one muscle also inhibits its antagonist. This coordination is achieved b\ an interneuron, which makes an inhibitor sj napse onto the motor neuron oi the antagonistic muscle (six- Figure 46.4). I bus the reciprocal inhibition of antagonistic muscles involves an interneuron between the sensory cell and the motor neuron and therefore at least two s) rtapses.

Information entering the dorsal horn is also transmitted b\ axons up the spinal cord to the brain. We are aware of the mallet hitting the knee, but the reflex response actually begins before that information registers in our consciousness. A great deal of information processing takes place in the spinal cord without any input from the brain. Spinal circuits can even generate repetitive motor patterns such as those o\ walking without commands from the brain.

The reticular system alerts the forebrain

The reticular system of the brain stem is a highly complex network of neuronal axons and dendrites. Within the reticular system are many discrete groups of neurons. Such an anatomically distinct group of neurons in the CNS is called a nucleus.

The reticular system is distributed through the core of the medulla, pons, and midbrain (Figure 46.5). Afferent information coming up the neural axis passes through the reticular system, where many connections are made to neurons involved in controlling many functions of the body. Information from joints and muscles, for example, is directed to nuclei in the pons and cerebellum that are involved in balance and coordination, whereas information from pain receptors is directed to nuclei in the brain stem that control sensitivity to pain. This information continues up the neural axis to the forebrain, where it results in conscious sensa-

46.5 The Reticular System

Neuronal activity within the reticular system controls levels of arousal in the nervous system.

46.6 The Limbic System

The evolutionary primitive parts of the forebrain (shown in blue) are referred to as the limbic system.

Information that can be localized to the specific sites in the body where the information originated.

The information routed through the reticular system also influences the level of arousal of the nervous system. Nuclei in the reticular system are involved in the control of sleep and waking. High levels of activity in the reticular system influence these nuclei to maintain the brain in a waking condition; low levels of activity enable sleep. Because of the alerting function of the reticular core of the brain stem, it has been called the reticular activating system.

If the brain stem of a person is damaged at midbrain or higher levels, and the alerting action of the reticular system cannot reach the forebrain, the person loses the ability to be in a conscious, waking state and becomes comatose. Damage to the brain stem or the spinal cord below the reticular system does not interfere with the ascending alerting actions of the reticular system and leaves the person with normal patterns of sleep and waking, although it can cause lack of sensation (paresthesia) and loss of motor function (paralysis).

The limbic system supports basic functions of the forebrain

The telencephalon of fishes, amphibians, and reptiles consists of only a few structures surrounding the diencephalon. In birds and mammals, these primitive forebrain structures are completely covered by the evolutionary more recent elaborations of the telencephalon called the neocortex, but they still have important functions. These primitive parts of the forebrain are collectively referred to as the limbic system (Figure 46.6).

The limbic system is responsible for basic physiological drives, instincts, and emotions. Within the limbic system are areas that when stimulated with small electric currents can cause intense sensations of pleasure, pain, or rage. If a

rat is given the opportunity to stimulate its own pleasure centers by pressing a switch, it will ignore food, water, and even sex, pushing the switch until it is exhausted. Pleasure and pain centers in the limbic system are believed to play roles in learning and in physiological drives.

One part of the limbic system, the hippocampus, is necessary in humans for the transfer of short-term memory to long-term memory. If you are told a new telephone number, you may be able to hold it in short-term memory for a few minutes, but within half an hour it is forgotten unless you make a real effort to remember it. The phenomenon of remembering something for more than a few minutes requires its transfer to long-term memory.

Regions of the cerebrum interact to produce consciousness and control behavior

The cerebral hemispheres are the dominant structures in the mammalian brain. In humans they are so large that they cover all other parts of the brain except the cerebellum (Figure 46.7). A sheet of gray matter called the cerebral cortex covers each cerebral hemisphere. The cortex is about 4 mm thick and covers a total surface area over both hemispheres of 1 square meter. The cerebral cortex is convoluted, or folded, into ridges called gyri and valleys called sulci. These convolutions allow it to fit into the skull, which is of limited size and volume. Under the cerebral cortex is white matter, made up of the axons that connect the cell bodies in the cortex with one another. They also connect with other areas of the brain.

Different regions of the cerebral cortex have specific functions. Some of those functions are easily defined, such as receiving and processing sensory information, but most of the cortex is involved in higher-order information pro-

cessing that is less easy to define. These latter areas are given the general name of association cortex.

To understand the cerebral cortex, it helps to have an anatomical road map. As viewed from the left side, a left cerebral hemisphere looks like a boxing glove for the right hand with the fingers pointing forward, the thumb pointing out, and the wrist at the rear (see Figure 46.7a). The "thumb" area is the temporal lobe, the fingers the frontal lobe, the back of the hand the parietal lobe, and the wrist the occipital lobe. A mirror image of this arrangement characterizes the right cerebral hemisphere. Let's look at each lobe of the cerebrum separately.

the temporal lobe. The upper region of the temporal lobe receives and processes auditory information. The association areas

of the temporal lobe are involved in the recognition, identification, and naming of objects. Damage to the temporal lobe results in disorders called agnosias in which the individual is aware of a stimulus but cannot identify it. Some of these deficits can be quite specific.

Damage to one area of the temporal lobe results in the inability to recognize faces. Even old acquaintances cannot be identified by facial features, although they may be identified by other attributes such as voice, body features, and characteristic style of walking. Using monkeys, it has been possible to record from neurons in this region that respond selectively to faces in general. These neurons do not respond to other stimuli in the visual field, and their responsiveness decreases if some of the features of the face are missing or appear in inappropriate locations (Figure 46.8). Damage to other association areas of the temporal lobe causes deficits in understanding spoken language, even though speaking, reading, and writing abilities may be intact.

820 CHAPTER FORTY-SIX

This neuron responds maximally to a complete face viewed from the front.

Firing rate of neuron

46.8 Neurons in One Region of the Temporal Lobe Respond to Faces

The traces represent the firing rate of a neuron in the temporal lobe of a monkey in response to the pictures shown below them.

the frontal lobe. A strip of the frontal lobe cortex just in front of the central sulcus is called the primary motor cortex (see Figure 46.7b). The neurons in this region have axons that project to muscles in specific parts of the body. The parts of the body can be mapped onto the primary motor cortex, from the head region on the lower side to the lower part of the body at the top. Areas with fine motor control, such as the face and hands, have the greatest representation (Figure 46.9). If a neuron in the primary motor cortex is electrically stimulated, the response is the twitch of a muscle, but not a coordinated, complex behavior.

The association functions of the frontal lobe are diverse and are best described as having to do with planning. The story of Phineas Gage at the beginning of this chapter demonstrates the effects of damage to these association areas. People with such deficits have drastic alterations of personality because they cannot create an accurate view of themselves in the context of the world around them and cannot plan for future events.

the parietal lobe. The frontal and parietal lobes are separated by a deep valley called the central sulcus. The strip of parietal lobe cortex just behind the central sulcus is the primary somatosensory cortex (see Figure 46.7b). This area receives information through the thalamus about touch and pressure sensations.

The whole body surface is represented in the primary somatosensory cortex—the head at the bottom and the legs at the top (see Figure 46.9). Areas of the body that have lots of sensory neurons and are capable of making fine distinctions in touch (such as the lips and the fingers) have disproportionately large representation. If a

very small area of the primary somatosensory cortex is stimulated electrically, the subject reports feeling specific sensations, such as touch, from a very localized part of the body.

A major association function of the parietal lobe is attending to complex stimuli. Damage to the right parietal lobe causes a condition called contralateral neglect syndrome, in which the individual tends to ignore stimuli from the left side of the body or the left visual field. Such individuals have difficulty performing complex tasks such as dressing the left side of the body; an afflicted man may not be able to shave the left side of his face. When asked to copy simple drawings, a person who exhibits this syndrome can do well with the right side of the drawing, but not the left (Figure 46.10). The parietal cortex is not symmetrical with respect to its role in attention. Damage to the left parietal cortex does not cause neglect of the right side of the body. We will see similar asymmetries in cortical function when we discuss language.

the occipital lobe. The occipital lobes receive and process visual information. We'll learn more about the details of that process later in this chapter. The association areas of the occipital cortex are essential for making sense out of the visual world and translating visual experience into language. Some deficits resulting from damage to association areas of the occipital cortex are quite specific. In one case, a woman with limited damage was unable to see motion. Her vision was intact, but she could see a waterfall only as a still image, and a car approaching only as a series of scenes of a stationary object at different distances.

The cerebrum has increased in size and complexity

As mentioned earlier, the size of the telencephalon relative to the rest of the brain increases substantially as we go from fishes to amphibians, to reptiles, to birds and mammals. Even when we consider only mammals, the cerebral cortex increases in size and complexity when we compare animals such as rodents, whose behavioral repertoires are relatively simple, with animals such as primates that have much more complex behavior.

The most dramatic increase in the size of the cerebral cortex took place during the last several million years of human evolution. The incredible intellectual capacities of *Homo sapiens* are associated with enlargement of the cerebral cortex. Humans do not have the largest brains in the animal kingdom; elephants, whales, and porpoises have larger brains in terms of mass. If we compare brain size to body size, however, humans and dolphins top the list. Humans have the largest ratio of brain size to body size, and they have the most highly developed cerebral cortex. Another feature of the cerebral cortex that reflects increasing behavioral and intellectual capabilities is the ratio of association cortex to primary somatosensory and

motor cortexes. Humans have the largest relative amount of association cortex.

Information Processing by Neuronal Networks

In Chapter 44 we learned how neurons interact to process information. A goal of neurobiology is to understand the complex functions of the nervous system in terms of the properties of neurons and synapses between them. We will

use two subsystems as examples to show how the functions of the nervous system can be understood in terms of neuronal networks. The first example, the autonomic nervous system, consists of efferent pathways. The second, the visual system, consists of afferent and integrative pathways. Techniques that have allowed neurobiologists to trace neuronal connections, chemically characterize synapses, and record the activities of single cells and groups of cells have advanced our understanding of how certain subsystems of the nervous system work.

The autonomic nervous system controls organs and organ systems

The autonomic nervous system is divided into two parts: the sympathetic and parasympathetic divisions. These two divisions work in opposition to each other in their effects on most organs, one causing an increase in activity and the other causing a decrease. The best-known functions of the autonomic nervous system are those of the sympathetic division called the "fight-or-flight" mechanisms, which increase heart rate, blood pressure, and cardiac output and prepare the body for emergencies (see Chapter 41). In contrast, the parasympathetic division slows the heart and lowers blood pressure.

It is tempting to think of the sympathetic division as the one that speeds things up and the parasympathetic division as the one that slows things down, but that is not always a correct distinction. The sympathetic division slows the digestive system and the parasympathetic division accelerates it. The two divisions of the autonomic nervous system are easily distinguished from each other by their anatomy, their neurotransmitters, and their actions (Figure 46.11).

Both divisions of the autonomic nervous system are efferent pathways. Each autonomic efferent pathway begins with a neuron that has its cell body in the brain stem or spinal cord and uses acetylcholine as its neurotransmitter. These cells are called preganglionic neurons because the second neuron in the pathway with which they synapse resides in a ganglion, a collection of neuronal cell bodies that is outside of the CNS). The second neuron is called a post-

ganglionic neuron

because its axon extends out from the ganglion. The axons of the postganglionic neurons end on the cells of the target organs.

The postganglionic neurons of the sympathetic division use norepinephrine as a neurotransmitter; those of the parasympathetic division use acetylcholine. In organs that receive both sympathetic and parasympathetic input, the target cells respond in opposite ways to norepinephrine and to acetylcholine. A region of the heart called the pacemaker, which generates the heartbeat, is an example. Stimulating the sympathetic nerve to the heart or dripping norepinephrine onto the pacemaker region depolarizes the pacemaker cells, increases their firing rate, and causes the heart to beat faster. Stimulating the parasympathetic nerve to the heart or dripping acetylcholine onto the pacemaker region hyperpolarizes the pacemaker cells, decreases their firing rate, and causes the heart to beat slower. In contrast,

Sympathetic division

Parasympathetic division

46.11 Organization of the Autonomic Nervous System

The autonomic nervous system is divided into the sympathetic and parasympathetic divisions, which work in opposition to each other in their effects on most organs (one causing an increase and the other a decrease in activity).

in the digestive tract, norepinephrine hyperpolarizes muscle cells, which slows digestion, and acetylcholine depolarizes muscle cells, which accelerates digestion.

The sympathetic and parasympathetic divisions of the autonomic nervous system can also be distinguished by anatomy (see Figure 46.11). The preganglionic neurons of the parasympathetic division come from the brain stem and the last segment of the spinal cord. The preganglionic neurons of the sympathetic division come from the upper regions of the spinal cord below the neck—the thoracic and

lumbar regions. The ganglia of the sympathetic division are mostly lined up in two chains, one on either side of the spinal cord. The parasympathetic ganglia are close to—sometimes sitting on—the target organs.

The autonomic nervous system is an important link between the CNS and many physiological functions of the body. Its control of diverse organs and tissues is crucial to homeostasis. In spite of its complexity, work by neurobiologists and physiologists over many decades has made it possible to understand its functions in terms of neuronal properties and circuits. In Chapter 49, for example, we will see how information from pressure receptors in the blood vessels is transmitted to the CNS, where it produces autonomic signals that control the rate of the heartbeat.

Neurons and circuits in the occipital cortex integrate visual information

In Chapter 45 we learned that the information conveyed to the brain in the optic nerve consists of action potentials that are stimulated by light falling on small circular areas of the retina called receptive fields. A receptive field contains many photoreceptor cells connected together in a circuit in such a way that the signals they produce are integrated and transmitted to the brain by a single retinal ganglion cell. The axon of each ganglion cell travels to the brain in the optic nerve. How does the brain construct visual images from information about circular patches of light falling on the retina?

Information from the retina is transmitted through the optic nerve to a relay station in the thalamus, and then to the brain's visual processing area, in the occipital cortex at the back of the cerebral hemispheres (see Figure 46.7b). David Hubel and Torsten Wiesel of Harvard University studied the activity of neurons in this visual cortex. They recorded the activities of single cells in the brains of living animals while they stimulated the animals' retinas with spots and bars of light. They found that cells in the visual cortex, like retinal ganglion cells, have receptive fields—specific areas of the retina that, when stimulated by light, influence the rate at which the action potentials.

Cells in the visual cortex, however, have receptive fields that differ from the simple circular receptive fields of retinal ganglion cells. Cortical cells called simple cells are maximally stimulated by bars of light that have specific orientations. Simple cells

probably receive input from several ganglion cells whose circular receptive fields are lined up in a row.

Complex cells in the visual cortex are also maximally stimulated by a bar of light with a particular orientation, but

46.12 Receptive Fields of Cells in the Visual Cortex

Cells in the visual cortex respond to specific patterns of light falling on the retina. Ganglion cells that project information about circular receptive fields converge on simple cells in the cortex in such a way that the simple cells have linear receptive fields. Simple cells project to complex cells in such a way that the complex cells can respond to linear stimuli falling on different areas of the retina.

the bar may fall anywhere on a large area of retina described as that cell's receptive field. Complex cells receive input from several simple cells that share a certain stimulus orientation, but have receptive fields in different places on the retina (Figure 46.12). Some complex cells respond most strongly when the bar of light moves in a particular direction.

The concept that emerges from these experiments is that the brain assembles a mental image of the visual world by analyzing edges of patterns of light falling on the retina.

EXPERIMENT

Question: How do cells in the visual cortex respond to patterns of light falling on the retina?

METHOD

The bar of light moves across the screen.

A moving bar of light stimulates receptive fields in the retina.

As the cat views the screen, the electrode records the cells in the occipital cortex.

RESULTS

On-center ganglion cell receptive field

Retinal ganglion cells that are aligned project to thalamic relay cells.

On-center ganglion cell response

Simple cells in the cortex respond to a static bar of light at a particular angle and location.

Complex cells in the cortex respond to a moving bar of light

INTERPRETATION This model would explain the

results of cell-to-cell connections.

Relay cells Simple cells Complex cells Retinal ganglion cells in thalamus in cortex in cortex

Conclusion: Cells in the retina, thalamus, and cortex are connected in ways to respond to specific patterns of light.

824 CHAPTER FORTY-SIX

illumination in brain (viewed from underneath)

46.13 The Anatomy of Binocular Vision

Each eye transmits information to both sides of the brain; however, the right brain processes all information from the left visual field, and the left brain processes all information from the right visual field. The visual cortex sorts visual field information according to whether it comes from the right eye or the left eye.

Optic chiasm Relay areas in thalamus

Neurons from relay areas to visual cortex

This analysis is conducted in a massively parallel fashion. Each retina sends a million axons to the brain, but there are hundreds of millions of neurons in the visual cortex. Each bit of information from a retinal ganglion cell is received by hundreds of cortical cells, each responsive to a different combination of orientation, position, and even movement of contrasting lines in the pattern of light falling on the retina.

Cortical cells receive input from both eyes

How do we see objects in three dimensions? The quick answer is that our two eyes see overlapping, yet slightly different, visual fields; that is, we have binocular vision. Turn a typical conical flowerpot upside down and look down at it so that the bottom of the pot is exactly in the center of your overall field of vision. You see the bottom of the pot, and you see equal amounts of the sides and rim of the pot as concentric circles. Now, if you close your left eye, you see more of the right side and right rim of the pot. With your right eye closed, you see more of the left side and left rim of the pot. The discrepancies in the information coming from your two eyes are interpreted by the brain to provide information about the depth and the three-dimensional shape of the flowerpot. If you are blind in one eye, you have great difficulty discriminating distances. Animals whose eyes are on the sides of their heads have nonoverlapping fields of vision and, as a result, poor depth vision, but they can see predators creeping up from behind.

The story of how the brain integrates information from two eyes begins with the paths of the optic nerves. If you look at the underside of the brain, the optic nerves from the two eyes appear to join together just under the hypothalamus and then separate again. The place where they join is called the optic chiasm (Figure 46.13). Axons from the half of each retina closest to your nose cross in the optic chiasm and go to the opposite side of your brain. The axons from the other half of each retina go to the same side of the brain.

The result of this division of axons in the optic chiasm is that all visual information from your left visual field

Right eye

Left eye

Right eye

Left eye

The visual cortex is organized in columns that receive input from the right eye (yellow) and the left eye (blue).

Binocular cells at the borders of columns receive input from both the right and left eyes.

(everything left of straight ahead) goes to the right side of your brain, as shown in red in Figure 46.13. All visual information from your right visual field goes to the left side of your brain, as indicated in green in the figure. Both eyes transmit information about a specific spot in your right visual field, for example, to the same place in the left visual cortex. How are the

two sources of information integrated?

Cells in the visual cortex are organized in columns. These columns alternate: left eye, right eye, left eye, right eye, and so on. Cells closest to the border between two columns receive input from both eyes and are therefore called binocular cells. Binocular cells interpret distance by measuring the disparity between where the same stimulus falls on the two retinas.

What is disparity? Hold your finger out in front of you and look at it, closing one eye and then the other. Your finger appears to jump back and forth because its image falls on a different position on each retina. Repeat the exercise with an object at a distance. It doesn't appear to jump back and forth as much because there is less disparity in the positions of the image on the two retinas. Certain binocular cells respond optimally to a stimulus falling on both retinas with a particular disparity. Which set of binocular cells is stimulated depends on how far away the stimulus is.

When we look at something, we can detect its shape, color, depth, and movement. Where does all this information come together? Is there a single cell that fires only when a red sports car drives by? Probably not. A specific visual experience comes from simultaneous activity in a large collection of cells. In addition, most visual experiences are enhanced by information from the other senses and from memory as well. This realization helps explain why about 75 percent of the cerebral cortex is association cortex.

Understanding Higher Brain Functions in Cellular Terms

Very few functions of the nervous system have been worked out to the point of identifying the underlying neuronal networks. The processes responsible for the higher brain functions discussed in the remaining pages are unde-

THE MAMMALIAN NERVOUS SYSTEM 825

niably complex. Nevertheless, neurobiologists, using a wide range of techniques, are making considerable progress in understanding some of the mechanisms involved. The following discussion presents several complex aspects of brain and behavior that present challenges to neurobiologists: sleep and dreaming, learning and memory, language use, and consciousness.

Sleeping and dreaming involve electrical patterns in the cerebrum

A dominant feature of our behavior is the daily cycle of sleep and waking. All birds and mammals, and probably all other vertebrates, sleep. We spend OQ£-thkd_aJLmu4ives sleepjn^j^etLwe_dojiot know why or how.

We do know, however, that we need to sleep. Loss of sleep impairs alertness and performance. Most people in our society—certainly most college students—are chronically sleep-d epriv ed. Large numbers of accidents and serious mistakes that endanger lives can be attributed to impaired alertness due tosleep.loss. Yet insomnia (difficulty in falling or staying asleep) is one of the most common medical complaints. To discover ways of dealing with these problems, it is important to learn more about the neural control of sleep.

the electroencephalogram. A common tool of sleep researchers is the electroencephalogram jCEEG^. To record an EEG, electrodes are placed at differemTocations on the scalp, and changes in the electric potential differences between electrodes are recorded through time. These electric potential differences reflect the electrical activity of the neurons in the brain regions under the electrodes, primarily regions of the cerebral corte x. Pens writing on a moving chart are used to record the patterns of electric potential differences between electrodes (Figure 46.14rt,fr). Usually, the

electrical activity of one or more skeletal muscles is also recorded on the chart; this record is called an electromyogram (EMG).

EEG and EMG patterns reveal the transition from being awake to being asleep. They also reveal that there are different states of sleep. In mammals other than humans, two major sleep states are easily distinguished. They are called slow-wave sleep and rapid-eye-movement (REM) sleep. In humans, we characterize sleep statesasTibn-kXM sleep and REM^sleep. Humaji_ non-REM sleep is divided into four stages. o>nly the two deepest stages are considered true^ko^y^wave_sleep.

When a person falls asleep at night, the first sleep state entered is non-REM^sleep, which progresses from stage 1 to stage_4. Stages 3 and 4 are deep, restorative, slow-wave sleep. After this first episode 6Fhon-REM sleep follows an episode of REM sleep. Throughout the night, we have four or five cycles of non-REM and REM sleep (Figure 46.14c). About JO percent of our sleep is non-REM sleep and 20 percent is REM sleep .

We have vivid dreams and nightmares during REM sleep, which gets its name from the jerky movements of the eyeballs that occur during this state. The most remarkable feature of REM sleep is that in hibitory commands from th e br ain almost completely paralyze the skeletal muscles^. Occasional muscle twitches break through the paralysis, as can be seen in a dog that appears to be trying to run in its sleep. If you look closely at a sleeping dog when its legs and paws are twitching, you will be able to see the rapid eye movements as well. Probably the functionofmuscle paralysis during REM sleep is to prevent the acting out of drea ms^ Sleepwalking, however, occurs during non-REM sleep.

The EEG characterization of sleep raises many questions. Why do we have such very different states of sleep?

(«)

46.14 Patterns of Electrical Activity in the Cerebral Cortex Characterize Stages of Sleep

826 CHAPTER FORTY-SIX

\\ h\ does non-REM sleep precede and cycle with REM sleep 1 \\ In do we dream in REM sleep? Why do we have deeper non-REM sleep (stages 3 and 4) earlier in the night and more REM sleep later in the night? The answers to these questions are beginning to be revealed as we improve our understanding of the cells and circuits that underlie sleep.

cellular changes during sleep. There are striking neuropil biological differences between non-REM and REM sleep. Non-REM sleep is characterized by a decrease in the $rp^{pnngjvpe}n^n^{jQa^{TTTTTrT}}11b4^{H4JTrejmd}rprphrafor-tex$. Remember that neurons have a resting membrane potential that is negative (the inside of the cell is negative relative to the outside), and a threshold potential for firing action potentials. Usually the resting potential is below the threshold potential, so the neuron is not firing. When synaptic input causes the plasma membrane to become less negative (depolarized), the cell can reach the threshold potential and fire action potentials.

During waking, several nuclei in the brain stem are continuously active. Many axons from these nuclei extend to the thalamus and the cortex, and the neurotransmitters released by the terminals of these axons are generally depolarizing. Therefore, these broadly distributed neurotransmitters keep the resting potential of the neurons of the thalamus and cortex close to threshold and sensitive to synaptic inputs, and thereby maintain waking.

With the onset of sleep, the activity in these brain stem nuclei decreases, and their terminals in the thalamus and cerebral cortex release less neurotransmitter. With the withdrawal of these depolarizing neurotransmitters, the resting potentials of the cells of the thalamus and cerebral cortex become more negative (hyperpolarized), and the cells are less sensitive to synaptic input. Their processing of information is inhibited, and consciousness is lost.

An interesting neuronal event happens as a result of thalamo-cortical hyperpolarization: The cells begin to fire in bursts. The synchronization of these bursts over broad areas of cerebral cortex results in the EEG slow-wave pattern that characterizes non-REM sleep. Studies of neurons of the thalamus and the cortex using intracellular recording techniques have shown that their hyperpolarization during non-REM sleep is due to increased opening of K^+ channels, and the bursting is due to Ca^{2+} channels that rapidly deactivate and require hyperpolarization to be reactivated. We can therefore explain the EEG pattern of non-REM sleep in terms of the properties of neurons and ion channels.

In addition to the brain stem nuclei that bring on sleep by decreasing their activity and causing general hyperpolarization, a substance that is broadly distributed in the extracellular fluid of the brain has a strong hyperpolarizing influence. This substance is adenosine —part of the molecule ATP, which supplies energy for most cellular processes. When cells cannot maintain an adequate supply of ATP they release adenosine. It has therefore been suggested that increased concentrations

of adenosine in the

brain reflect the depletion of brain energy reserves, and that due to its hyperpolarizing influence, adenosine contributes to sleepiness and to the depth of non-REM sleep. A corollary of this hypothesis is that one function of non-REM sleep could be to restore brain energy reserves. There are many other molecules in the brain that influence sleep. Understanding their role in sleep control will provide new information on the possible functions of sleep.

At the transition from rapid eye movement (REM) sleep, dramatic changes occur. Some of the brain stem nuclei that were inactive during non-REM sleep become active again, causing a general depolarization of cortical neurons. Thus the bursts of firing cease, the slow waves in the EEG disappear, and the EEG resembles that of the waking brain. Because the resting potentials of the neurons return to near threshold levels, the cortex can process information, and vivid dreams occur.

During sleep, however, the brain inhibits both afferent (sensory) and efferent (motor) pathways; therefore the activity in the cortex is unconstrained by its usual sources of information. One example of the effect of this loss of motor output and sensory input is the frequently reported dream in which a person is trying to run but cannot move. We do not know the function of REM sleep, but since a wide variety of mammals have about the same percentage of total sleep time that is REM sleep, it is probably a rather basic, cellular function.

One prominent hypothesis about the functions of sleep is that it is essential for the maintenance and repair of neural connections, and for the neural changes that are involved in learning and memory. However, evidence for such functions is still meager.

Some learning and memory can be localized to specific brain areas

Learning is the modification of behavior by experience. Memory is the ability of the nervous system to retain what is learned and what is experienced. Even very simple animals can learn and remember, but these two abilities are most highly developed in humans.

Consider the amount of information associated with learning a language. The capacity of memory and the rate at which items can be retrieved are remarkable features of the human nervous system. A major challenge in neurobiology is to understand these phenomena in terms of the cells and molecules that make up the brain. Such knowledge could help us find ways to prevent the tragic loss of learning abilities and memory that occurs in the common condition of the elderly called Alzheimer's disease.

learning. Learning that leads to long-term memory and modification of behavior must involve long-lasting synaptic changes. Synaptic changes that last for weeks have been discovered, as we saw in Chapter 44. High-frequency electrical stimulation of certain identifiable circuits of the mammalian hippocampus makes them more sensitive to subsequent stimulation. This phenomenon, called long-term

potentiation (LTP), is an effect of ion channels controlled by the neurotransmitter glutamate. These channels allow both Na^+ and Ca^{2+} ions to enter the neurons, and the increase in intracellular Ca^{2+} activates enzymes that cause modifications in the cell that enhance its responsiveness.

In contrast, continuous, repetitive, low-level stimulation of the hippocampal circuit reduces its responsiveness, a phenomenon that has been called long-term depression (LTD). LTP and LTD have been demonstrated in circuits other than hippocampal circuits, and they may be fundamental cellular or molecular mechanisms involved in learning and memory.

A form of learning that is widespread among animal species is associative learning, in which two unrelated stimuli become linked to the same response. The simplest example of associative learning is the conditioned reflex, discovered by the Russian physiologist Ivan Pavlov. Pavlov was studying the control of digestive functions in dogs and observed that a dog salivates at the sight or smell of food—a simple autonomic reflex. He discovered that if he rang a bell just before food was presented to the dog, after a few trials the dog would salivate at the sound of the bell, even if no food followed. The salivation reflex was conditioned to be associated with the sound of a bell, which normally is unrelated to feeding and digestion.

This simple form of learning has been studied extensively in efforts to understand its underlying neural mechanisms. In a series of studies led by Richard Thompson, the eye-blink reflex of a rabbit in response to a puff of air directed at its eyes was conditioned to be associated with a tone stimulus. After conditioning, the rabbit blinked when presented with just the tone (Figure 46.15). A small and specific area of the cerebellum was discovered to be necessary for this conditioned reflex. Thus it was possible to localize learning to an identifiable set of synapses in the mammalian brain.

memory. Attempts to treat human neurological diseases have led to the localization of areas of the brain involved in the formation and recall of memories. Epilepsy is a disorder characterized by uncontrollable increases in neural activity in specific parts of the brain. The resulting seizures, or "epileptic fits," can endanger the afflicted individual. In the past, serious cases of epilepsy were sometimes treated by destroying the part of the brain from which the surge of activity originated.

To find the right area, the surgery was done under local anesthesia, and different regions of the brain were electrically stimulated with fine electrodes while the patient reported on the resulting sensations. When some regions of association cortex were stimulated, patients reported vivid

Conclusion: The cerebellar nucleus is necessary for learning this conditioned reflex.

828 CHAPTER FORTY-SIX

memories. Such observations were the first evidence that

memories have anatomical locations in the brain and exist, b properties of neurons and networks of neurons. Yet the destruction of a small area does not completely erase a memory so it is postulated that memory is a function distributed over many brain regions and that a memory may be stimulated via many different routes.

You can recognize several forms of memory from your own experience. There is immediate memory for events that are happening now. Immediate memory is almost perfectly photographic, but it lasts only seconds. Short-term memory contains less information, but it lasts longer—on the order of 10 to 13 minutes. If you are introduced to a group of new people, you may remember most of their names for 5 or 10 minutes, but you will have forgotten them in an hour or so if you have not repeated them, written them down, or used them in a conversation. Repetition, use, or reinforcement by something that gets your attention (such as the title President) facilitates the transfer of short-term memory to long-term memory, which can last for days, months, or years.

Knowledge about neural mechanisms for the transfer of short-term memory to long-term memory has come from observations of persons who have lost parts of the limbic system, notably the hippocampus. A famous case is that of a man identified as H.M., whose hippocampus on both sides of the brain was removed in an effort to control severe epilepsy. Since that surgery, H.M. has not been able to transfer information to long-term memory. If someone is introduced to him, has a conversation with him, and then leaves the room, when that person returns he or she is unknown to H.M.—it is as if the previous conversation had never taken place. H.M. retains memories of events that happened before his surgery, but he remembers post-surgery events for only 10 or 15 minutes.

Memory of people, places, events, and things is called declarative memory because you can consciously recall and describe them. Another type of memory, called procedural memory, cannot be consciously recalled and described: It is the memory of how to perform a motor task. When you learn to ride a bicycle, ski, or use a computer keyboard, you form procedural memories. Although H.M. is incapable of forming declarative memories, he is capable of forming procedural memories. When taught a motor task day after day, he cannot recall the lessons of the previous day, yet his performance steadily improves. Thus procedural learning and memory must involve mechanisms different from those used in declarative learning and memory.

Our understanding of learning and memory in cellular terms is very rudimentary. New techniques that enable functional imaging of the brain in ways that reveal changes in the metabolic activity of specific regions and structures are greatly enhancing progress in this area.

Language abilities are localized in the left cerebral hemisphere

No aspect of brain function is as integrally related to human consciousness and intellect as is language. There-

fore, studies of the brain mechanisms that underlie the acquisition and use of language are extremely interesting to neuroscientists. A curious observation about language abilities is that they are usually located in only one cerebral hemisphere—which in 97 percent of people is the left hemisphere. This phenomenon is referred to as the lateralization of language functions.

Some of the most fascinating research on this subject was conducted by Roger Sperry and his colleagues at the California Institute of Technology; Sperry received the Nobel prize in medicine for this work. The two cerebral hemispheres are connected by a tract of white matter called the corpus callosum. In one severe form of epilepsy, bursts of action potentials travel from hemisphere to hemisphere across the corpus callosum. Cutting the tract eliminates the problem, and patients function nearly normally following the surgery. But experiments revealed interesting deficits in the language abilities of these "split-brain" persons. Without the connection between the two hemispheres, the knowledge or experience of the right hemisphere could no longer be expressed in language, nor could language be used to communicate with the right hemisphere.

Another curious feature of our nervous systems is that the left side of the body is served (in both sensory and motor aspects) mostly by the right side of the brain, and the right side of the body is served mostly by the left side of the brain. Thus, sensory input from the right hand goes to the left cerebral hemisphere, and sensory input from the left hand goes to the right

cerebral hemisphere. Language abilities reside predominantly in the left hemisphere.

The mechanisms of language in the left hemisphere have been the focus of much research. Again, the experimental subjects are persons who have suffered damage to the left hemisphere and are left with one of many forms of aphasia, a deficit in the ability to use or understand words. These studies have identified several language areas in the left hemisphere (Figure 46.16).

Broca's area, located in the frontal lobe just in front of the motor cortex, is essential for speech. Damage to Broca's area results in halting, slow, poorly articulated speech or even complete loss of speech, but the patient can still read and understand language. In the temporal lobe, close to its border with the occipital lobe, is Wernicke's area, which is more involved with sensory than with motor aspects of language. Damage to Wernicke's area can cause a person to lose the ability to speak sensibly while retaining the abilities to form the sounds of normal speech and to imitate its cadence. Moreover, such a patient cannot understand spoken or written language. Near Wernicke's area is the angular gyrus, which is believed to be essential for integrating spoken and written language.

Normal language ability depends on the flow of information among various areas of the left cerebral cortex. Input from spoken language travels from the primary auditory cortex to Wernicke's area (see Figure A6A6a). Input from written language travels from the primary visual cortex to the angular gyrus to Wernicke's area (see Figure

46.76 Language Areas of the Cortex

Different regions of the left cerebral cortex participate in the processes of (a) repeating a word that is heard versus (b) repeating a written word.

(a) Repeating a heard word

Motor

(b) Speaking a written word

Angular gyrus

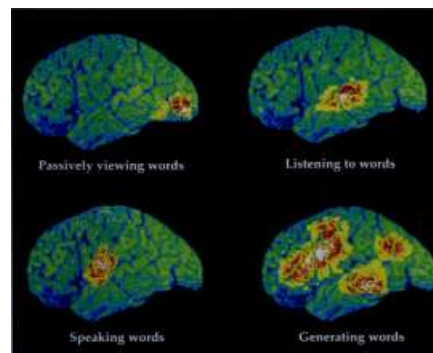

Vision

46.16fr). Commands to speak are formulated in Wernicke's area and travel to Broca's area and from there to the primary motor cortex. Damage to any one of those areas or the pathways between them can result in aphasia. Using modern methods of functional brain imaging, it is possible to see the metabolic activity in different brain areas when the brain is using language (Figure 46.17).

What is consciousness?

This chapter has only scratched the surface of our knowledge about the organization and functions of the human brain, but it may give you some idea of the incredible challenge that neurobiologists face in trying to understand their own brains. Progress is being aided by powerful new technologies, such as patch clamping (see Chapter 44), functional imaging (see Figure 46.17), and neurochemical and molecular methods. However, even these sophisticated new research tools may not allow us to answer the question "What is consciousness?"

If you look at a black dog, you are conscious of the fact that it is a dog, it is black, and it is a Labrador retriever, and you may remember that its name is Sarina, it is 3 years old, it belongs to your friend Meera, and so on. From what you have learned in this chapter, imagine how many neurons would be active during this experience: neurons in the visual system, the language areas, and in different regions of association cortex. But is being conscious of the black dog simply a result of the fact that all of these neurons are firing at the same time? Your brain is simultaneously processing many other sensory inputs, but you are not necessarily conscious of those inputs. What makes you conscious of the black dog and associated memories and not conscious of other information the brain is processing at the same time? If we could describe all the neurons and all the synapses involved in the conscious experience of seeing and naming a black dog, and then build a computer with devices that modeled all these neurons and connections, would that computer be conscious? It has been said that the question of consciousness resolves into two types of problems: "easy" and "hard." The easy problems deal with all the cells and circuits that process the information that is involved in conscious experience. The implication of "easy" is that we seem to have the tools to solve these kinds of problems, as complex as they may be. The hard problems involve explaining how properties of cells and networks result in consciousness, and we seem to lack the proper tools or concepts even to begin to solve these problems.

46.17 Imaging Techniques Reveal Active Parts of the Brain

Positron emission tomography (PET) scanning reveals the brain regions that are activated by different aspects of language use. A radioactive form of glucose is given to the subject. Radioactivity accumulates in brain areas in proportion to their metabolic use of glucose. The PET scan visualizes levels of radioactivity in specific brain regions.

830 CHAPTER FORTY-SIX

Chapter Summary

The Nervous System: Structure, Function, and Information Flow

- The brain and spinal cord make up the central nervous

-\ -torn: the cranial and spinal nerves make up the peripheral nei \ ous Sj -tern. A nerve is a bundle of many axons carrying information to and from the central nervous system. Review Figure 46.1

- The nervous system can be modeled conceptually in terms of the direction of information flow and whether or not we are conscious of the information. Review Figure 46.2
- The vertebrate nervous system develops from a hollow dorsal neural tube. The brain forms from three swellings at the anterior end of this neural tube, which become the hind-brain, the midbrain, and the forebrain. Review Figure 46.3
- The forebrain develops into the cerebral hemispheres (the telencephalon) and the underlying thalamus and hypothalamus (the diencephalon). The midbrain and hindbrain develop into the brain stem. More primitive and autonomic functions are localized in the brain stem, and conscious experience depends on the cerebrum.

Functional Subsystems of the Nervous System

- The nervous system is composed of many subsystems that function simultaneously. Some important subsystems are the spinal cord, the reticular system, the limbic system, and the cerebrum.
- The spinal cord communicates information between the brain and the body. It also processes and integrates much information, and can issue some commands to the body without input from the brain. Review Figure 46.4
- The reticular system of the brain stem is a complex network that directs incoming information to appropriate brain stem nuclei that control autonomic functions, as well as transmitting the information to the forebrain that results in conscious sensation. The reticular system controls the level of arousal of the nervous system. Review Figure 46.5
- The limbic system is an evolutionarily primitive part of the forebrain that is involved in emotions, physiological drives, instincts, and memory. Review Figure 46.6
- The cerebral hemispheres are the dominant structures of the human brain. Their surfaces consist of a layer of neurons called the cerebral cortex.
- Most of the cerebral cortex is involved in higher-order information processing, and these areas are generally called

association cortex.

► The cerebral hemispheres can be divided into temporal, frontal, parietal, and occipital lobes. Many motor functions are localized in parts of the frontal lobe, information from many receptors around the body projects to a region of the parietal lobe, visual information projects to the occipital lobe, and auditory information projects to a region of the temporal lobe. Review Figures 46.7, 46.8, 46.9, 46.10

Information Processing by Neuronal Circuits

► The functions of the nervous system are beginning to be understood in terms of the properties of cells organized in neuronal circuits.

► The autonomic nervous system consists of efferent pathways that control the organs and organ systems of the body. Its sympathetic and parasympathetic divisions normally work in opposition to each other. These divisions are characterized by their anatomy, neurotransmitters, and effects on target tissues. Review Figure 46.11

► Neuronal circuits in the occipital cortex integrate visual information. Receptive field responses of retinal ganglion

cells are communicated to the brain in the optic nerves. This information is projected to the visual cortex in such a way as to create receptive fields for cortical cells.

► A simple cell is stimulated by a bar of light with a specific orientation falling at a specific location on the retina. A complex cell is maximally stimulated by such a stimulus moving across the retina. The visual cortex seems to assemble a mental image of the visual world by analyzing edges of patterns of light. Review Figure 46.12

► Binocular vision results from circuits that communicate information from both eyes to binocular cells in the visual cortex. These cells interpret distance by measuring the disparity between where the same stimulus falls on the two retinas. Review Figure 46.13

Understanding Higher Brain Functions in Cellular Terms

► Humans have a daily cycle of sleep and waking. Sleep can be divided into slow-wave (non-REM) sleep and rapid-eye-movement (REM) sleep. Human non-REM sleep is divided into four stages of increasing depth. Review Figure 46.14

► Some learning and memory processes have been localized to specific brain areas. Repeated activation of identified circuits in brain regions such as the hippocampus have revealed long-lasting changes in synaptic properties referred to as long-term potentiation and long-term depression, which may be involved in learning and memory. Review Figure 46.15

Complex memories can be elicited by stimulating small regions of association cortex. Damage to the hippocampus can destroy the ability to form long-term declarative memories, but not procedural memories.

► Language abilities are localized mostly in the left cerebral hemisphere, a phenomenon known as lateralization.

► Different areas of the left hemisphere—including Broca's area, Wernicke's area, and the angular gyrus—are responsible for different aspects of language. Review Figure 46.16

For Discussion

1. The mammalian nervous system begins as a hollow tubular structure, but just before the three regions of the brain begin to form, this hollow tube constricts at the site that will become the junction between the brain and the spinal cord. What could be the significance of this constriction? What does it suggest about the mechanism by which the brain develops?
2. The stretch receptors in muscles are modified muscle fibers, and they have their own motor neurons. What is the function of these motor neurons? To think about this question, remember that the function of the monosynaptic reflex is to adjust muscle tension to a change in load so that the position of the limb does not change.
3. A patient is unable to speak coherently. He can read and write, and he has no obvious loss of muscle function. Where would you expect to find an abnormality if you did brain scans of this patient?
4. We described the organization of the visual cortex as columns of cells that alternately receive input from the left eye and the right eye. If a young kitten is allowed to see light out of only one eye for a day, more synapses begin to form in the cortical columns receiving input from that eye, while synapses decrease in the intervening columns. This redistribution of synapses does not occur, however, if the kitten is not allowed to sleep. What hypotheses could you propose on the basis of these results?

Effectors: Making Animals Move

The central nervous system is more v^{\wedge} than a processor and storage medium for $^{\wedge}$ information. It also allows animals to respond to that information. Effectors are tissues and organs commanded by the CNS to carry out these responses, and most responses of animals involve movement.

A fascinating array of adaptations enable animals to move. Consider the act of jumping. When you jump, neural signals from the visual cortex of your brain are routed through spinal circuits that tell certain leg muscles to contract, extending your legs, and hence you jump. Highly skilled and trained athletes can actually outleap their own body height.

But as "record jumpers" go, many other animals—cats, spiders, kangaroos, and fleas to name just a few—far surpass even the Olympian feats of humans. A flea, for example, can jump more than 200 times its body length. Unlike a human jumper, the flea's jumping mechanism doesn't involve muscles but works like a slingshot. The flea is so small, and its initial acceleration is so great, that no muscle can contract fast enough to cause such a movement. Instead, at the base of its jumping legs is an elastic material that is compressed by muscles while the flea is resting. When a trigger mechanism is released, the elastic material recoils and "fires" the flea up and over to its target (or away from an enemy).

Jumping is just one adaptation an animal can use to respond to information received by its sensory receptors. Effectors include the internal organs and organ systems that the animal uses to control its internal environment; these effectors are the subjects of subsequent chapters. In this chapter, we focus on cilia, flagella, muscles, and skeletons—the mechanisms that create mechanical forces and use those forces to change shape and move, and which are the basis for most animal behavior. At the end we will briefly consider a few effectors other than those that create movement.

A Champion Jumps

Sergey Kliugin of Russia won the gold medal for high jumping in the 2000 Summer Olympics. His winning jump was 2.35 meters, or about 1.3 times his height.

Cilia, Flagella, and Cell Movement

Two subcellular structures, microtubules and microfilaments (see Figure 4.21), generate cell movement. Both of these structures consist of long protein molecules that can change length or shape. Microtubules generate the small-scale movements of cilia and flagella. Microfilaments reach their highest level of organization in muscle cells, which generate large-scale movements.

Cilia are tiny, hairlike appendages of cells

Certain protists are covered by dense patches of cilia that propel them through their aqueous environment. Each cilium is tiny, about 0.25 μm in diameter. Multicellular animals use ciliated cells to move liquids and particles over cell surfaces. Many invertebrates use ciliated cells to obtain food and oxygen. Some mollusks, for example, use cilia to circulate a current of water across their gas exchange and feeding surfaces (Figure 47.1).

The airways of many animals are lined with and cleaned by ciliated cells (Figure 47.2). In humans, the cilia continuously sweep a layer of mucus from deep down in the lungs, up through the windpipe, and into the throat. The mucus carries particles of dirt and dead cells. We can then either swallow or spit out the mucus, and with it the trapped detritus. Ciliated cells lining the female reproductive tract create currents that sweep eggs from the ovaries into the oviducts and all the way down to the uterus.

A drop of dye demonstrates the unidirectional flow of water through a clam's siphons.

47.1 Cilia Create Water Currents in a Clam's Siphons

In burrowing mollusks such as clams, cilia lining the siphons maintain a unidirectional flow of water: in one siphon, over the gills, and out the other siphon. The gills extract oxygen and food from this flow of water.

A cilium moves with the same basic motion as a swimmer's arms during the breaststroke (Figure 47.3a). During the power stroke, the cilium projects stiffly outward and moves backward, propelling the cell forward (or the medium backward). During the recovery stroke, the cilium folds as it returns to its original position. The power stroke is fast, the recovery stroke slow. As you know from moving your arms or legs in water, there is less resistance the slower you move. The resistance of the medium to the recovery stroke is thus slight compared with its resistance to the power stroke. Groups of cilia typically beat in coordinated waves. At any particular moment, some cilia of a cell are moving through the power stroke and others are recovering.

Flagella are like long cilia

The flagella of eukaryotes are identical to cilia except that they are longer and occur singly, or in groups of only a few, on any one cell. Flagellated cells maintain a flow of water through the bodies of sponges, bringing in food and oxygen and removing carbon dioxide and wastes. Flagella power the movement of the sperm of most species. Because of their greater length, flagella have a whiplike stroke pattern rather than the "swimming" stroke pattern of cilia (Figure 47.3b).

Cilia and flagella are moved by microtubules

The core of a cilium or a flagellum is called the axoneme. The axoneme contains a ring of nine pairs of microtubules. In the center of the ring may be an additional pair of microtubules, a single microtubule, or no microtubule. As dis-

(«)

47.2 Cilia Line Respiratory Passages

A scanning electron micrograph of a rabbit's airway shows many cilia.

As discussed in Chapter 4, microtubules are hollow tubes formed from polymerization of the globular polypeptide tubulin. Other proteins in the axoneme form spokes, side arms, and cross-links. Side arms composed of the protein dynein generate force (see Figures 4.24 and 4.25). Dynein is an enzyme that catalyzes the hydrolysis of ATP and uses the released energy to change its shape, thereby generating mechanical force.

When the dynein arms on one microtubule pair contact a neighboring microtubule pair and bind to it, ATP is broken down, and the resulting conformational changes in the dynein molecules cause the arms to point toward the base of the axoneme (Figure 47.4). This action pushes the microtubule pair ahead in relation to its neighbor. The dynein arms then detach from the neighboring pair and reorient to their starting horizontal position. As the cycle is repeated,

A cilium moves in a pattern similar to an arm of a swimmer doing the breaststroke.

Power stroke

Recovery stroke

(b)

Flagella are much longer than cilia. A flagellum moves in an undulating, whiplike pattern.

47.3 Cilia and Flagella Move Differently

Dynein

"arms"

| When microtubule pairs try to slide past each other, the axoneme bends because the microtubules are anchored at the base.

adjacent microtubule pairs try to "row" past each other, with the dynein arms acting as "oars." Axonemes severed from cells continue to flex in a normal pattern if exposed to calcium ions (Ca^{2+}) and ATP, demonstrating that the motile mechanism is part of the axoneme itself and not derived from the associated cell.

Microtubules are intracellular effectors

Microtubules, as components of the cytoskeleton, contribute to the shape of eukaryotic cells. Microtubules are important intracellular effectors for changing cell shape, moving organelles, and enabling cells to respond to their environment. Microtubules change the shapes of cells and move cells by polymerizing and depolymerizing the protein tubulin.

As we saw in Chapter 9, the spindle that moves chromosomes to the mitotic poles at anaphase is made up of microtubules. Another example of microtubule involvement in cell movement is the growth of the axons of neurons in the developing nervous system. Neurons find and make their appropriate connections by sending out long extensions that search for the correct contact cells. If polymerization of tubulin is chemically inhibited, the neurons do not extend.

J

Microfilaments change cell shape and cause cell movements

Microfilaments are proteins that change conformation as a means of generating forces. The dominant microfilament in animal cells is the protein actin. Bundles of cross-linked actin strands form important structural components of cells. The microvilli that increase the absorptive surface area of the cells lining the gut are stiffened by actin microfilaments (see Figure 4.23), as are the stereocilia of the sen-sow hair cells in the mammalian ear (see Figure 45.12). Actin microfilaments can change the shape of a cell simply by polymerizing and depolymerizing.

47.4 Microtubules Create Motion by Pushing Against Each Other

Cilia and flagella move because of interactions between microtubules in the axoneme.

Together with the protein myosin, actin microfilaments generate the contractile forces responsible for many aspects of cell movement and changes in cell shape. The contractile ring that divides an animal cell undergoing mitosis into two daughter cells is composed of actin microfilaments in association with myosin. The mechanisms that many cells employ to engulf materials (endocytosis; see Chapter 5 and ure 19.4) also rely on interactions between actin microfilaments and myosin. Nets of actin and myosin beneath the cell membrane change a cell's shape during endocytosis.

Certain cells in multicellular animals travel within the body by amoeboid movement, which is generated by the activity of actin microfilaments and myosin. During development, many cells migrate by amoeboid movement. Throughout an animal's

life, phagocytic cells circulate in the blood, squeeze through the walls of the blood vessels, and wander through the tissues by amoeboid movement. The mechanisms of amoeboid movement have been studied extensively in the protist for which this type of movement was named—the amoeba, which lives in freshwater streams and ponds (see the photograph on page 476).

Amoebas move by extending lobe-shaped projections called pseudopods and then seemingly squeezing themselves into those pseudopods. The cytoplasm in the core of the amoeba, called plasmasol, is relatively liquid, but just beneath the plasma membrane the cytoplasm is much thicker, and is called plasmagel. Reversible changes between plasmasol and plasmagel move the cytoplasm.

To form a pseudopod, the thick plasmagel in one area of the cell thins, allowing a bulge to form. Just under the cell surface, in the plasmagel, is a network of actin microfilaments that interacts with myosin to squeeze plasmasol into the bulge. As the microfilament network continues to contract, cytoplasm streams in the direction of the pseudopod. Eventually the cytoplasm at the leading edge of the pseudopod converts to plasmagel, and the pseudopod stops forming. Thus the basis for amoeboid motion is the ability of the cytoplasm to cycle through sol and gel states and the ability of the microfilament network under the cell membrane to contract and cause the cytoplasmic streaming that pushes out a pseudopod.

Muscle Contraction

Most behavioral and many physiological responses depend on muscle cells. Muscle cells are specialized for contraction and have high densities of actin and myosin. Such cells are found throughout the animal kingdom. Wherever whole tissues contract in animals, muscle cells are responsible.

In muscle cells, actin and myosin molecules are organized into filaments consisting of two or more molecules.

834 CHAPTER FORTY-SEVEN

Muscle fiber Intercalated discs

47.5 Vertebrate Muscle Tissue

The fibers of cardiac, or heart muscle (top), branch and create a meshwork that resists tearing or breaking. Intercalated discs provide strong mechanical adhesions between the cells. In smooth muscle (center), the cells are usually arranged in sheets. Skeletal muscle (bottom) appears striped, or striated. The individual cells, called muscle fibers, are very large and are multinucleated.

Actin filaments consist of two actin molecules twisting around each other, and myosin filaments are bundles of many myosin molecules. The actin and myosin filaments lie parallel to each other. When contraction is triggered, the actin and myosin filaments slide past each other in a telescoping fashion.

There are three types of vertebrate muscle: smooth muscle, cardiac (heart) muscle, and skeletal muscle

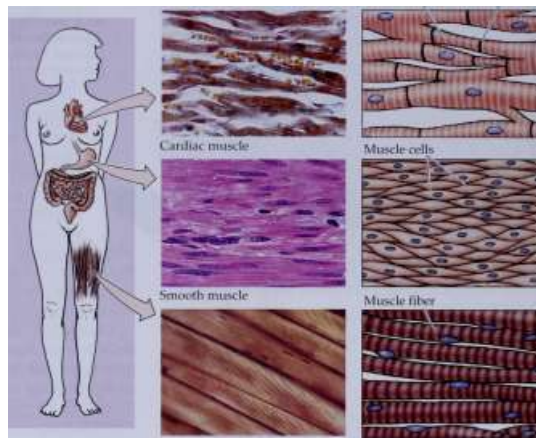

(Figure 47.5). Contraction in all three types is triggered by action potentials moving along their membranes. Although they all use the same contractile mechanism, these three muscle types have important differences that adapt them to their particular functions.

Smooth muscle causes slow contractions of many internal organs

Smooth muscle provides the contractile force for most of our internal organs, which are under the control of the autonomic nervous system. Smooth muscle moves food through the digestive tract, controls the flow of blood through blood vessels, and empties the urinary bladder. Structurally, smooth muscle cells are the simplest muscle cells. They are usually long and spindle-shaped, and each cell has a single nucleus. Because the filaments of actin and myosin in smooth muscle are not as regularly arranged as those in the other muscle types, the contractile machinery is not obvious when the cells are viewed under the light microscope (Figure 47.5, center).

If we study smooth muscle tissue from a particular organ, such as the wall of the digestive tract, we find that it has some interesting properties. The cells are arranged in sheets, and individual cells in the sheets are in electrical contact with one another through gap junctions. As a result, an action potential generated in the membrane of one smooth muscle cell can spread to all the cells in the sheet of tissue.

Another interesting property of a smooth muscle cell is that the resting potential of its membrane is sensitive to being stretched. If the wall of the digestive tract is stretched in one location (as by receiving a mouthful of food), the membranes of the stretched cells depolarize, reach thresh-

Skeletal muscle

old, and fire action potentials that cause the cells to contract. Thus smooth muscle contracts after being stretched, and the harder it is stretched, the stronger the contraction. (Later in this chapter we will see how membrane depolarization triggers contraction.)

Other factors that alter the membrane potential of smooth muscle cells are the neurotransmitters of the autonomic nervous system (see Figure 46.11). In the case of the digestive tract, acetylcholine causes smooth muscle cells to depolarize and thus makes them more likely to fire action potentials and contract. Norepinephrine causes these muscle cells to hyperpolarize and therefore makes them less likely to fire action potentials and contract (Figure 47.6).

Cardiac muscle causes the heart to beat

Cardiac muscle looks different from smooth muscle or skeletal muscle when viewed under the microscope (Figure 47.5, top). The cells appear striped, or striated, because of the regular arrangement of bundles of actin and myosin filaments within them. Actin and myosin are arranged in a similar way in skeletal muscle, as we'll see below.

The unique feature of cardiac muscle cells is that they branch. The branches of adjoining cells are interdigitated into a meshwork that gives cardiac muscle an ability to resist tearing. As a result, the heart walls can withstand high pressures while pumping blood without the danger of developing leaks. Also adding to the strength of cardiac muscle are intercalated discs that provide strong mechanical adhesions between adjacent cells.

As is true of smooth muscle, the individual cells in a sheet of cardiac muscle are in electrical contact with one another. Gap junctions present in the intercalated discs present low resistance to ions or electric currents. Therefore, a

47.6 Smooth Muscle Action

Stretching depolarizes the membrane of smooth muscle cells, and this depolarization causes action potentials that activate the contractile mechanism. The neurotransmitters acetylcholine and norepinephrine also alter the membrane potential of smooth muscle, making it more or less likely to contract.

depolarization initiated at one point in the heart spreads rapidly through the mass of cardiac muscle.

An interesting feature of vertebrate cardiac muscle is that certain specialized muscle cells, called pacemaker cells, initiate the rhythmic contractions of the heart. We'll learn about the molecular basis for this pacemaking func-

tion in Chapter 49. Because of these specialized pacemaker cells, the heartbeat is myogenic —generated by the heart muscle itself. The autonomic nervous system modifies the rate of the pacemaker cells, but is not essential for their continued rhythmic function. A heart removed from an animal continues to beat with no input from the nervous system. The myogenic nature of the heartbeat is a major factor in making heart transplants possible.

Skeletal muscle carries out behavior

Skeletal muscle carries out, or effects, all voluntary movements, such as running or playing a piano, and generates the movements of breathing. Skeletal muscle is also called

47.7 The Structure of Skeletal Muscle

A skeletal muscle is made up of bundles of muscle fibers. Each muscle fiber is a multinucleate cell containing numerous myofibrils, which are highly ordered assemblages of thick myosin and thin actin filaments. The structure of the myofibrils gives muscle fibers their characteristic striated (striped) appearance.

Q The structure of the myofibrils gives muscle fibers their characteristic striated appearance, as seen in this electron micrograph. Where there are only actin filaments the myofibril appears light; where there are both actin and myosin filaments the myofibril appears dark.

striated muscle because the highly regular arrangement of its actin and myosin filaments gives it a striped appearance. Skeletal muscle cells, called muscle fibers, are large. Unlike smooth muscle and cardiac muscle cells, each of which has a single nucleus, skeletal muscle fibers have many nuclei because they develop through the fusion of many individual cells. A muscle such as your biceps (which bends your arm) is composed of many muscle fibers bundled together by connective tissue.

What is the relation between a muscle fiber and the actin and myosin filaments responsible for its contraction? Each muscle fiber is composed of myofibrils —bundles of contractile filaments made up of actin and myosin (Figure 47.7). Within each myofibril are thin actin filaments and thick myosin filaments. If we cut across the myofibril at certain locations, we see only thick filaments; if we cut at other locations, we see only thin filaments. But, in most regions of the myofibril, each thick myosin filament is surrounded by six thin actin filaments.

A longitudinal view of a myofibril reveals the reason for the striated appearance of skeletal muscle. The band pattern of the myofibril is due to repeating units called sarcomeres, which are the units of contraction (see Figure 47.7). Each sarcomere is made of overlapping filaments of actin and myosin. As the muscle contracts, the sarcomeres shorten, and the appearance of the band pattern changes.

The observation that the widths of the bands in the sarcomeres change when a muscle contracts led two British biologists, Hugh Huxley and Andrew Huxley, to propose a molecular mechanism of muscle contraction. Let's look at the band pattern of the myofibril in detail (see the micrograph in Figure 47.7). Each sarcomere is bounded by Z lines, which are structures that anchor the thin actin filaments. Centered in the sarcomere is the A band, which contains all the myosin filaments. The H zone and the I band, which appear light, are regions where actin and myosin filaments do not overlap in the relaxed muscle. The

dark stripe within the H zone is called the M band; it contains proteins that help hold the myosin filaments in their regular hexagonal arrangement.

When the muscle contracts, the sarcomere shortens. The H zone and the I band become much narrower, and the Z lines move toward the A band as if the actin filaments were sliding into the region occupied by the myosin filaments. This observation led Huxley and Huxley to propose the sliding filament theory of muscle contraction: Actin and myosin filaments slide past each other as the muscle contracts.

To understand what makes the filaments slide, we must examine the structure of actin and of myosin (Figure 47.8). Each myosin molecule consists of two long polypeptide chains coiled together, each ending in a large globular head. A myosin filament is made up of many

myosin molecules arranged in parallel, with their heads projecting laterally from one or the other end of the filament. The actin filament consists of a helical arrangement of two chains of monomers twisted together like two strands of pearls. Twisting around the actin chains is another protein, tropomyosin, and attached to it at intervals are molecules of troponin. We'll discuss the roles of these last two proteins in the following section.

The myosin heads have sites that can bind to actin and thereby form bridges between the myosin and the actin filaments. The myosin heads also have ATPase activity; that is, they bind and hydrolyze ATP. The energy released when this happens changes the orientation of the myosin head.

Together, these details explain the cycle of events that cause the actin and myosin filaments to slide past each other and shorten the sarcomere. A myosin head binds to an actin filament (see Figure 47.8). Upon binding, the head changes its orientation with respect to the myosin filament, thus exerting a force that causes the actin and myosin filaments to slide about 5 to 10 nm relative to each other. Next, the myosin head binds a molecule of ATP, which causes it to release the actin. When the ATP is hydrolyzed, the energy released causes the myosin head to return to its original conformation, in which it can bind again to actin. It is as if the energy from ATP hydrolysis is being used to cock the hammer of a pistol, and contact of the myosin head with an actin binding site pulls the trigger.

We have been discussing the cycle of contraction in terms of a single myosin head. Don't forget that each myosin filament has many myosin heads at both ends and is surrounded by six actin filaments; thus the contraction of the sarcomere involves a great many cycles of interaction between actin and myosin molecules. That is why when a single myosin head breaks its contact with actin, the actin filaments do not slip backward.

An interesting aspect of this contractile mechanism is that ATP is needed to break the actin-myosin bonds, but not to form them. Thus muscles require ATP to stop con-

Troponin has three subunits: one binds actin, one binds tropomyosin, and one binds Ca^{2+} .

47.8 Actin and Myosin Filaments Overlap to Form Myofibrils

Myosin filaments are bundles of molecules with globular heads and polypeptide tails. Actin filaments consist of two chains of actin monomers twisted together. They are wrapped by chains of the polypeptide tropomyosin and studded at intervals with another protein, troponin.

838 CHAPTER FORTY-SEVEN

Motor neuron

bracting. This fact explains why muscles

stiffen soon after animals die, a condition known as rigor mortis. Death stops the replenishment of the ATP stores of muscle cells, so the actin-myosin bonds cannot be broken, and the muscles stiffen. Eventually the proteins begin to lose their integrity, and the muscles soften. These events have regular time courses that differ somewhat for different regions of the body; therefore, an examination of the stiffness of the muscles of a corpse sometimes can help a coroner estimate the time of death.

Actin-myosin interactions are controlled by Ca^{2+}

Muscle contractions are initiated by action potentials from motor neurons arriving at the neuromuscular junction (see Figure 44.16). Motor neurons are generally highly branched and can synapse with up to a hundred muscle fibers each. All the fibers

activated by a single motor neuron constitute a motor unit and contract simultaneously in response to the action potentials fired by that motor neuron. To understand the fine control the nervous system has over muscle contraction, we must examine the membrane system of the muscle fiber and some additional protein components of the actin filaments.

Like neurons, vertebrate skeletal muscle fibers are excitable cells: When they are depolarized to a threshold that opens their voltage-gated sodium channels, their plasma membranes generate action potentials, just as the membranes of axons do. When an action potential arrives at the neuromuscular junction, neurotransmitter from the motor neuron binds to receptors in the postsynaptic membrane, causing ion channels in the motor end plate to open. Most of the ions that flow through these channels are K^+ , and therefore the motor end plate is depolarized.

The depolarization of the motor end plate spreads to the surrounding plasma membrane of the muscle fiber, which contains voltage-gated ion channels. When threshold is reached, the plasma membrane fires an action potential that is conducted rapidly to all points on the surface of the muscle fiber.

The action potential in a muscle fiber also travels deep within the cell. The plasma membrane of the muscle fiber is continuous with a system of tubules that descends into and branches throughout the cytoplasm (also called the sar-coplasm) of the muscle fiber (Figure 47.9). The action potential that spreads over the plasma membrane of the muscle fiber also spreads through this system of transverse tubules, or T tubules.

The T tubules come into very close contact with a network of intracellular membranes called the sarcoplasmic reticulum that extends throughout the sarcoplasm, surrounding every myofibril. Calcium pumps in the sarcoplas-

mic reticulum cause this membrane-enclosed compartment of the cell to take up Ca^{2+} ions from the sarcoplasm. Therefore, when the muscle fiber is at rest, there is a high concentration of Ca^{2+} in the sarcoplasmic reticulum and a low concentration of Ca^{2+} in the sarcoplasm surrounding the myofibrils.

When an action potential spreads through the T tubule system, it causes calcium channels in the sarcoplasmic reticulum to open, resulting in the diffusion of Ca^{2+} ions out of the sarcoplasmic reticulum and into the sarcoplasm surrounding the myofibrils. The Ca^{2+} stimulates the interaction of actin and myosin and the sliding of the filaments. How does this work?

An actin filament, as we have seen, is a helical arrangement of two strands of actin monomers. Lying in the grooves between the two actin strands is the two-stranded protein tropomyosin (see Figure 47.8). At regular intervals, the filament also

includes another globular protein, troponin. The troponin molecule has three subunits: one binds actin, one binds tropomyosin, and one binds Ca^{2+} .

When Ca^{2+} is sequestered in the sarcoplasmic reticulum, the tropomyosin strands block the sites on the actin filament where myosin heads can bind. When the T tubule system depolarizes, Ca^{2+} is released into the sarcoplasm, where it binds to the troponin, changing the shape of the troponin molecule. Because the troponin is bound to the tropomyosin, this conformational change of the troponin twists the tropomyosin enough to expose the actin-myosin binding sites. Thus the cycle of making and breaking actin-myosin bonds is initiated, the filaments are pulled past one another, and the muscle fiber contracts. When the

f

ATP binds to myosin, causing it to release actin.

k 47.10 The Release of Ca^{2+}

from the Sarcoplasmic Reticulum Triggers Muscle Contraction

When Ca^{2+} binds to troponin, it exposes actin-myosin binding sites. As long as binding sites and ATP are available, the cycle of actin and myosin interactions continues, and the filaments slide past each other.

Time

fiber increases and becomes more sustained. Thus an individual muscle fiber can show a graded response to increased levels of stimulation by its motor neuron.

At high levels of stimulation, the calcium pumps in the sarcoplasmic reticulum can no longer remove Ca^{2+} ions from the sarcoplasm between action potentials, and the contractile machinery generates maximum tension—a condition known as tetanus (Figure 47.11b). (Do not confuse this condition with the disease tetanus, which is caused by a bacterial toxin and is characterized by spastic contractions of skeletal muscles.)

How long a muscle fiber can maintain a tetanic contraction depends on its supply of ATP. Eventually the fiber will become fatigued. It may seem paradoxical that the lack of ATP causes fatigue, since the action of ATP is to break actin-myosin bonds. But remember that the energy released from the hydrolysis of ATP "recocks" the myosin heads, allowing them to cycle through another power stroke. When a muscle is contracting against a load, the cycle of making and breaking actin-myosin bonds must continue to prevent the load from stretching the muscle. The situation is like rowing a boat upstream: You cannot maintain your position relative to the stream bank by just holding the oars out against the current; you have to keep rowing. Likewise, actin-myosin bonds have to keep cycling to maintain tension in the muscle.

The ability of a whole muscle to generate different levels of tension depends on how many fibers in that muscle are activated. Whether a muscle contraction is strong or weak depends both on how many of the motor neurons that synapse with that muscle are firing and on the rate at which those neurons are firing. These two factors can be thought of as spatial summation and temporal summation, respectively.

Both types of summation increase the strength of contraction of the muscle as a whole. Faster twitching of individual fibers causes temporal summation (see Figure

47.11b), and an increase in the number of motor units involved in the contraction causes spatial summation. (Remember that a motor unit consists of all the muscle fibers innervated by a single neuron, and that a single muscle consists of many motor units.)

Many muscles of the body maintain a low level of tension called tonus even when the body is at rest. For example, the muscles of the neck, trunk, and limbs that maintain our posture against the pull of gravity are always working, even when we are standing or sitting still. Muscle tonus comes from the activity of a small but changing number of motor units in a muscle; at any one time, some of the muscle's fibers are contracting and others are relaxed. Tonus is constantly being readjusted by the nervous system.

Muscle fiber types determine endurance and strength

Not all skeletal muscle fibers are alike, and a single muscle may contain more than one type of fiber. The two major types of skeletal muscle fibers are slow-twitch fibers and fast-twitch fibers (Figure 47.12a). Slow-twitch fibers are also called red muscle because they have lots of the oxygen-binding molecule myoglobin, they have lots of mitochondria, and they are well supplied with blood vessels. A single twitch of a slow-twitch fiber produces low tension.

The maximum tension a slow-twitch fiber can produce is low and develops slowly, but these fibers are highly resistant to fatigue. Because slow-twitch fibers have substantial reserves of fuel (glycogen and fat), their abundant mitochondria can maintain a steady, prolonged production of ATP if oxygen is available. Muscles with high proportions of slow-twitch fibers are good for long-term aerobic work (that is, work that requires lots of oxygen). Champion longdistance runners, cross-country skiers, swimmers, and bicyclists have leg and arm muscles consisting mostly of slow-twitch fibers (Figure 47.12b).

Fast-twitch fibers are also called white muscle because, in comparison to slow-twitch fibers, they have fewer mitochondria, little or no myoglobin, and fewer blood vessels. The white meat of domestic chickens is composed of fast-twitch fibers. Fast-twitch fibers can develop maximum tension more rapidly than slow-twitch fibers can, and that maximum tension is greater, but fast-twitch fibers become

47.12 Two Types of Muscle Fibers

{a) Skeletal muscles stained with a reagent that shows slow-twitch fibers as dark. The upper photo shows muscle from a professional cyclist. The lower photo shows muscle from a nonathlete who has about 75% fast-twitch fibers; Sprinter this person would probably perform better as a sprinter than as a distance runner, (b) Athletes in different sports have different distributions of muscle fiber types.

fatigued rapidly. The myosin of fast-twitch fibers has high ATPase activity, so they can put the energy of ATP to work very rapidly, but they cannot replenish it quickly enough to sustain contraction for a long time. Fast-twitch fibers are especially good for short-term work that requires maximum strength. Champion weight lifters and sprinters have leg and arm muscles with high proportions of fast-twitch fibers. What determines the proportion of fast- and slow-twitch fibers in your skeletal muscles? The most important factor is your genetic heritage, so there is some truth to the statement that champions are born, not made. To a certain extent, however, you can alter the properties of your muscle fibers through training. With aerobic training, the oxidative capacity of fast-twitch fibers can improve substantially. But a person born with a high proportion of fast-twitch fibers will never become a champion marathon runner, and a person born with a high proportion of slow-twitch fibers will never become a champion sprinter.

Skeletal Systems Provide Support for Muscles

Muscles can only contract and relax. Without something rigid to pull against, a muscle would just be a formless mass that twitches and changes shape. Skeletal systems provide rigid supports against which muscles can pull, creating directed movements. In this section, we'll examine the three types of skeletal systems found in animals: hydrostatic skeletons, exoskeletons, and endoskeletons.

A hydrostatic skeleton consists of fluid in a muscular cavity

The simplest type of skeleton is the hydrostatic skeleton of cnidarians, annelids, and many other soft-bodied invertebrates. It consists of a volume of incompressible fluid (water) enclosed in a body cavity surrounded by muscle.

Slow-twitch fibers are better adapted for sustained aerobic activity.

[Fast-twitch fibers can generate > ~ == ~> maximum tension quickly, but they also fatigue quickly.

20
40
60
80
100

Maximum oxygen uptake (I (ml/min/kg)

When muscles oriented in a certain direction contract, the fluid-filled body cavity bulges out in the opposite direction.

The sea anemone, a cnidarian (see Figure 31.6c), has a hydrostatic skeleton. Its body cavity is filled with seawater. To extend its body and its tentacles, the anemone closes its mouth and constricts muscle fibers that are arranged in circles around its body. Contraction of these circular muscles puts pressure on the water in the body cavity, and that pressure forces the body and tentacles to extend. The anemone retracts its tentacles and body by contracting muscle fibers that are arranged

longitudinally in the body wall and along the tentacles.

An earthworm uses its hydrostatic skeleton to crawl. The earthworm's body cavity is divided into many separate, fluid-filled segments. The body wall surrounding each segment has two muscle layers: one in which the muscle fibers are arranged in circles around the body cavity, and another in which the muscle fibers run lengthwise (Figure 47.13a). If the circular muscles in a segment contract, the compartment in that segment narrows and elongates. If the lengthwise (longitudinal) muscles of a segment contract, the compartment shortens and bulges outward.

Alternating contractions of the earthworm's circular and longitudinal muscles create waves of narrowing and widening, lengthening and shortening, that travel down the body. The bulging, short segments serve as anchors as the narrowing, expanding segments project forward, and longitudinal contractions pull other segments forward. Bristles help the widest parts of the body to hold firm against the substrate (Figure 47.13b).

Another type of locomotion made possible by hydrostatic skeletons is the jet propulsion used by squid and octopuses.

842 CHAPTER FORTY-SEVEN

47.73 A Hydrostatic Skeleton

Fluid-filled compartments

Longitudinal muscles

Circular muscles

topuses. Muscles surrounding a water-filled cavity in these cephalopods contract, forcefully expelling water from the animal's body. As the water shoots out under pressure, the animal is propelled in the opposite direction.

Exoskeletons are rigid outer structures

An exoskeleton is a hardened outer surface to which muscles can be attached. Contractions of the muscles cause jointed segments of the exoskeleton to move relative to each other. The simplest example of an exoskeleton is the shell of a mollusk. Some marine mollusks, such as clams and snails, have shells composed of protein strengthened by crystals of calcium carbonate (a rock-hard material). These shells can be massive, affording significant protection against predators. The shells of land snails generally lack the hard mineral component and are much lighter. Mollusk shells can grow as the animal grows, and growth rings are usually apparent on the shells.

The most complex exoskeletons are found among the arthropods. An exoskeleton, or cuticle, covers all the outer surfaces of the arthropod's body and all its appendages. It is made up of plates secreted by a layer of cells just below the exoskeleton. A continuous, layered, waxy coating covers the entire body. The cuticle contains stiffening materials everywhere except at the joints, where flexibility must be retained. Muscles attached to the inner surfaces of the arthropod exoskeleton move its parts around the joints (Figure 47.14).

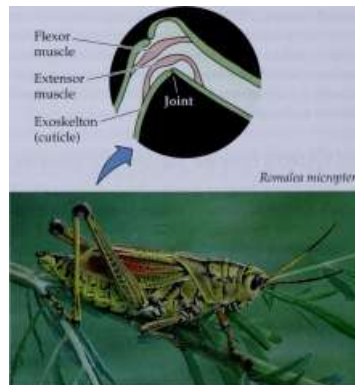

The layers of the cuticle include an outer, thin, waxy epi-cuticle that protects the bodies of terrestrial arthropods from drying out, and a thicker, inner endocuticle that forms most of the structure. The endocuticle is a tough, pliable material found only in arthropods. It consists of a complex of protein and chitin, a nitrogen-containing polysaccharide. In

marine crustaceans the endocuticle is further toughened by insoluble calcium salts. The thickness of the cuticle varies, but it can be thick enough to form a protective armor.

An exoskeleton protects all the soft tissues of the animal, but is itself subject to damage by abrasion and crushing. The greatest drawback of the arthropod exoskeleton is that

47.15 The Human Endoskeleton

Cartilage and bone make up the internal skeleton of a human being.

it cannot grow. Therefore, if the animal is to become larger, it must molt, shedding its exoskeleton and forming a new, larger one. A molting animal is vulnerable because the new exoskeleton takes time to harden. The animal's body is temporarily unprotected, and without a firm exoskeleton against which its muscles can exert maximum tension, it is unable to move rapidly. Soft-shelled crabs, a gourmet delicacy, are crabs caught when they are molting.

Vertebrate endoskeletons provide supports for muscles

The endoskeleton of vertebrates is an internal scaffolding to which muscles attach and against which they can pull. It is composed of rodlike, platelike, and tubelike bones, which are connected to each other at a variety of joints that allow a wide range of movements. Endoskeletons do not provide the protection that exoskeletons do, but their advantage is that they can grow. Because bones are inside the body, the body can enlarge without shedding its skeleton.

The human skeleton consists of 206 bones, some of which are shown in Figure 47.15. It can be divided into an axial skeleton, which includes the skull, vertebral column, and ribs, and an appendicular skeleton, which includes the pectoral girdle, the pelvic girdle, and the bones of the arms, legs, hands, and feet.

Two kinds of connective tissue cells produce large amounts of extracellular matrix material to create the vertebrate endoskeleton. The matrix material produced by cartilage cells is a rubbery mixture of proteins and polysaccharides. The principal protein in cartilage is collagen. Collagen

EFFECTORS: MAKING ANIMALS MOVE 843

fibers run in all directions through the gel-like matrix and give it the well-known strength and resiliency of "gristle."

Cartilage is found in parts of the endoskeleton where both stiffness and resiliency are required, such as on the surfaces of joints, where bones move against each other. Cartilage is also the supportive tissue in stiff but flexible structures such as the larynx (voice box), the nose, and the ear pinnae. Sharks and rays are called cartilaginous fishes (see Figure 33.11) because their skeletons are composed entirely of cartilage. In all other vertebrates, cartilage is the principal component of the embryonic skeleton, but during development most of it is gradually replaced by bone.

Bone consists mostly of extracellular matrix material that contains collagen fibers as well as crystals of insoluble calcium phosphate, which give bone its rigidity and hardness. The skeleton serves as a reservoir of calcium for the rest of the body and is in dynamic equilibrium with soluble calcium in the extracellular fluids of the body. This equilibrium is under the control of calcitonin and parathyroid hormone (see Figure 41.10). If too much calcium is taken from the skeleton, the bones are seriously weakened.

The living cells of bone—called osteoblasts, osteocytes, and osteoclasts—are responsible for the dynamic remodeling of bone that is constantly under way (Figure 47.16). Osteoblasts lay down new matrix material on bone surfaces. These cells gradually become surrounded by matrix and eventually become enclosed within the bone, at which point they cease laying down matrix but continue to exist within small lacunae (cavities) in the bone. In this state they are called osteocytes. In spite of the vast amounts of matrix between them, osteocytes remain in contact with one another through long cellular extensions that run through tiny channels in the bone. Communication between osteocytes is important in controlling the activities of the cells that are laying down new bone or eroding it away.

Small blood vessel

Newly deposited bone matrix

Osteoblasts lay down new bone to fill tunnel dug out by osteoclasts.

Osteoclasts dig a tunnel through old bone.

Old bone

Osteocytes are osteoblasts that become trapped by their own handiwork.

47.76 Renovating Bone

Bones are constantly being remodeled by osteoblasts, which lay down bone, and osteoclasts, which dissolve bone.

844 CHAPTER FORTY-SEVEN

The cells that erode or reabsorb bone are the osteoclasts. They are derived from the same cell lineage that produces white blood cells. Osteoclasts burrow into bone, forming cavities and tunnels. Osteoblasts follow osteoclasts, depositing new bone. Thus the interplay of osteoblasts and osteoclasts constantly replaces and remodels the bones.

How the activities of the bone cells are coordinated is not understood, but stress placed on bones somehow provides them with information. A remarkable finding in studies of astronauts who had spent long periods in zero gravity was that their bones had decalcified. Conversely, certain bones of athletes can thicken during training, becoming considerably thicker than the same bones in nonathletes. Both thickening and thinning of bones are experienced by someone who has a leg in a cast for a long time. The bones of the uninjured leg carry the person's weight and thicken, while the bones of the inactive leg in the cast thin. The jawbones of people who lose their teeth experience less compressional force during chewing and become considerably reduced.

Bones develop from connective tissues

Bones are divided into two types on the basis of how they develop. Membranous bone forms on a scaffolding of connective tissue membrane. Cartilage bone forms first as a cartilaginous structure and is gradually hardened (ossified) to become bone. The outer bones of the skull are membranous bones; the bones of the limbs are cartilage bones.

Cartilage bones can grow throughout the ossification process. The long bones of the legs and arms, for example, ossify first at the centers and later at each end (Figure 47.17). Growth can continue until these areas of ossification join. The membranous bones forming the skull cap grow until their edges meet. The soft spot on the top of a baby's head is the point at which the skull bones have not yet joined.

The structure of bone may be compact (solid and hard) or cancellous (having numerous internal cavities that make it appear spongy, even though it is rigid). The architecture of a specific bone depends on its position and function, but most bones have both compact and cancellous regions. The shafts of the long bones of the limbs, for example, are cylindrical.

Cartilage

Bone formation

Blood vessels entering

Marrow cavity

Long bones develop in the embryo as structures made of cartilage.

Ossification begins in the shaft.

Secondary sites of ossification form at the ends.

Secondary ossification center

Blood vessels carry calcium and nutrients to developing bone.

Growth plates are sites of elongation between the ossified regions.

Bone marrow

Eventually the areas of ossification fuse and elongation of the bone ceases.

47.17 The Growth of Long Bones

In the long bones of human limbs, ossification occurs first at the centers and later at each end.

Layers of compact bone surrounding central cavities that contain the bone marrow, where the cellular elements of the blood are made. The ends of the long bones are cancellous (Figure 47.18f). Cancellous bone is lightweight because of its numerous cavities, but it is also strong because its internal meshwork constitutes a support system. It can with-

Flexor and extensor muscles work antagonistically to operate the joint.

Femur

Fibula

stand considerable forces of compression. The rigid, tubelike shaft of compact bone can withstand compression and bending forces. Architects and nature alike use hollow tubes as lightweight structural elements.

Most of the compact bone in mammals is called Haversian bone because it is composed of structural units called Haversian systems (Figure 47.18i>). Each Haversian system is a set of thin, concentric bony cylinders, between which are the osteocytes in their lacunae. Through the center of each Haversian system runs a narrow canal containing blood vessels (see Figure 47.16). Adjacent Haversian systems are separated by boundaries called glue lines. Haversian bone is resistant to fracturing because cracks tend to stop at glue lines.

Bones that have a common joint can work as a lever

Muscles and bones work together around joints, where two or more bones come together. Since muscles can only contract and relax, they create movement around joints by working in antagonistic pairs: When one contracts, the other relaxes. With respect to a particular joint, such as the knee, we can refer to the muscle that bends or flexes the joint as the flexor and the muscle that straightens or extends the joint as the extensor. The bones that meet at the joint are

Extensor

muscle

Patella (kneecap)

Cartilage

Ligaments attach bone to bone.

Tibia

held together by ligaments, which are flexible bands of connective tissue. Other straps of connective tissue, called tendons, attach the muscles to the bones (Figure 47.19). Ligaments help direct the forces generated by muscles by holding tendons in place. In many kinds of joints, only the tendon spans the joint, sometimes moving over the surfaces of the bone like a rope over a pulley. The tendon of the quadriceps muscle traveling over the knee joint is what is tapped to elicit the knee-jerk reflex (see Figure 46.4). The human skeleton has a wide variety of joints with different ranges of movement (Figure 47.20).

Bones move around joints and the muscles that work with those bones can be thought of as systems of levers. A lever has a power arm and a load arm that work around a fulcrum (pivot). The length ratio of the two arms determines whether a particular lever can exert a lot of force over a short distance or is better

Ball-and-socket joint

At the shoulders and hips are ball-and-socket joints

that allow movement in almost any direction.

A pivot joint where the two bones of the forearm meet at the elbow allows the smaller bone to rotate when the wrist is twisted from side to side.

j - ^ = ^ - 1 Several kinds of joints

permit some rotation, but not in all directions as the ball-and-socket joints do.

The knee joint is a simple hinge that has almost no rotational movement and can flex in one direction only.

The joint in the ankle allows rotational movement in only one plane.

rn

47.20 Types of Joints

The designs of joints are similar to mechanical counterparts and enable a variety of movements.

846 CHAPTER FORTY-SEVEN

moves low weights

long distances with speed.

An example of a lever system designed for power is the human jaw. The power arm is long relative to the load arm.

I

An example of a lever system designed for speed is the human leg. The power arm is short relative to the load arm.

47.21 Bones and Joints Work Like Systems of Levers

A lever system can be designed for power or speed.

at translating force into large or fast movements. Compare the jaw joint and the knee joint, for example (Figure 47.21). The power arm of the jaw is long relative to the load arm, allowing the jaw to apply great pressures over a small distance, as when you crack a nut with your teeth. The power arm of the lower leg, on the other hand, is short relative to the load arm, so you can run fast, jump high, and deliver swift kicks, but you cannot apply nearly the pressure with a leg that you can with your jaws.

Other Effectors

Muscles are universal in animals, but other effectors are more specialized and are shared by only a few animal species. Some specialized effectors are used for defense, some for communication, and some for capture of prey or avoidance of predators. In this section we mention only a few specialized effectors to give a sampling of their evolutionary diversity.

Nematocysts capture prey and repel predators

Some animals possess highly specialized organs that are fired like miniature missiles to capture prey and repel predators. Nematocysts are elaborate cellular structures produced only by hydras, jellyfishes, and other cnidarians. They are concentrated in huge numbers on the outer surface of the tentacles. Each nematocyst consists of a slender thread coiled tightly within a capsule, armed with a spinelike trigger projecting to the outside (see Figure 31.7). When potential prey brushes the trigger, the nematocyst fires, turning the thread inside out and exposing little spines along its base. The thread either entangles or penetrates the body of the victim, and a poison may be simultaneously released around the point of contact. Once the prey is subdued, it is pulled into the mouth of the cnidarian and swallowed. A jellyfish called the Portuguese man-of-war has tentacles that can be several meters long. These animals can capture, subdue, and devour full-grown

mackerel, and the poison of their nematocysts is so potent that it can kill a human who becomes tangled in the tentacles.

Chromatophores enable animals to change color

A change in body color is a response that some animals use to camouflage themselves in a particular environment or to communicate with other animals. Chromatophores are pigment-containing cells in the skin that can change the color and pattern of the animal. Chromatophores are under nervous or hormonal control, or both; in most cases they can effect a change within minutes or even seconds.

In squid, sole, and flounder, all of which spend much time on the seafloor, the famous chameleons (a group of African lizards; see Figure 33.19fr), and a few other animals, chromatophores enable the animal to blend in with the background on which it is resting and thus escape discovery by predators. Chromatophores with different pigments enable animals to assume different hues or to become mottled to match the background more precisely. In other mollusks, fishes, and lizards, a color change sends a signal to potential mates and territorial rivals of the same species.

There are three principal types of chromatophore cells. The most common type has fixed cell boundaries, within which pigmented granules may be moved about by microfilaments. When the pigment is concentrated in the center of each chromatophore, the animal is pale; the animal turns darker when the pigment is dispersed throughout the cell. Another type of chromatophore is capable of amoeboid movement. These cells can mold themselves into shapes with a minimal surface area, leaving the tissue relatively pale, or they can flatten out to make the tissue appear darker.

The third type of chromatophore changes shape as a result of the action of muscle fibers radiating outward from the cell (Figure 47.22a). When the muscle fibers are relaxed, the chromatophores are small and compact, and the animal is pale. To darken the animal, the muscle fibers contract and spread the chromatophores over more of the body surface. These chromatophores can change so rapidly that they are

Chromatophore contracted

Pigment

47.22 Chromatophores Help Animals Camouflage Themselves or Communicate

(a) Muscle fibers around the chromatophores cause chromatophores to contract. (fc>) Cuttlefish are cephalopod mollusks that can change color patterns so fast that these changes can be used for rapid communication.

used in some species for communication during courtship and aggressive interactions. For example, the cuttlefish, a cephalopod, can signal courtship intentions to a potential mate on one side of its body while signaling aggressive threats to a rival on the other side of its body (Figure 47.22b).

Glands can be effectors

Glands are effector organs that produce and release chemicals. Some glands produce hormones for internal signaling. Other glands secrete substances into the gut or onto the body surface. Some of these secretions are used defensively or to capture prey. Others are pheromones, chemical signals released into the environment for communication with other individuals.

Certain snakes, frogs, salamanders, spiders, mollusks, and fishes have poison glands. Many of the poisons produced by these glands are extremely specific in their modes of action. For example, the poison dendrotoxin, which certain tribes of the Amazonian rainforest use on the tips of their arrows for hunting, comes from the skin of a frog and blocks certain potassium channels. The snake venom bun-garotoxin inactivates the neuromuscular acetylcholine receptors. The puffer fish poison tetrodotoxin blocks voltage-gated sodium channels. A poison from a mollusk, conotoxin, blocks calcium channels. Not all defensive secretions are poisonous, however. A well-known example is the odoriferous chemical mercaptan sprayed by skunks.

Electric organs can be shocking

Various fishes can generate electricity, as we saw in Chapter 45. These species include the electric eel, the knife fish, the torpedo (a type of ray), and the electric catfish. The electric fields they generate are used for sensing the environment, for communication, and also for stunning potential predators or prey. The electric organs of these animals evolved from muscles, and they produce electric potentials in the same general way as nerves and muscles do.

(b) *Sepia latimanu*

Electric organs consist of very large, disc-shaped cells arranged in long rows like stacks of batteries. When the cells discharge simultaneously, the electric organ can generate far more voltage and current than can nerve or muscle tissue. Electric eels, for example, can produce up to 600 volts with an output of approximately 100 watts--which is enough to light a row of light bulbs or to temporarily stun a person.

Chapter Summary

► Effectors enable animals to respond to information from their internal and external environments. Most effectors generate mechanical forces and cause movement.

Cilia, Flagella, and Cell Movement

► Cell movement is generated by two structures, microtubules and microfilaments, both of which consist of long protein molecules that can change their length or shape.

tubules and microfilaments, both of which consist of long protein molecules that can change their length or shape.

► The movements of cilia and flagella depend on microtubules. Review Figures 47.1, 47.3, 47.4

► Microfilaments allow animal cells to change their shape

and move.

Muscle Contraction

► The three types of vertebrate muscle are smooth, cardiac, and skeletal (striated). Review Figure 47.5

848 CHAPTER FORTY-SEVEN

► Smooth muscle provides contractile force for internal organs. Smooth muscle cells are electrically coupled through gap junctions, so action potentials that cause contraction spread rapidly throughout smooth muscle tissue. Autonomic neurotransmitters alter the membrane potential of smooth muscle cells. Review Figure 47.6

► The walls of the heart consist of sheets of branching cardiac muscle cells. The cells are electrically coupled through gap junctions, so that action potentials spread rapidly throughout sheets of cardiac muscle and cause coordinated contractions. Some cardiac muscle cells are pacemaker cells that generate the heartbeat.

► Skeletal, or striated, muscle consists of bundles of muscle fibers. Each muscle fiber is a huge cell containing multiple nuclei and numerous myofibrils, which are bundles of actin and myosin filaments. The regular, overlapping arrangement of the actin and myosin filaments into sarcomeres gives skeletal muscle its striated appearance. During contraction, the actin and myosin filaments slide past each other in a telescoping fashion. Review Figure 47.7

► The molecular mechanism of muscle contraction involves the binding of the globular heads of myosin molecules to actin. Upon binding, the myosin head changes conformation, causing the two filaments to move relative to each other. Release of the myosin heads from actin and their return to their original conformation requires ATP. Review Figure 47.8

► The plasma membrane of the muscle fiber is continuous with a system of T tubules that extends deep into the sarcoplasm (muscle cell cytoplasm). Review Figure 47.9

► When an action potential spreads across the plasma membrane and through the T tubules, it causes Ca^{2+} ions to be released from the sarcoplasmic reticulum. The Ca^{2+} ions bind to troponin and change its conformation, pulling the tropomyosin strands away from the myosin binding sites on the actin filament. Cycles of actin-myosin binding and release occur, and the muscle fiber contracts until the Ca^{2+} is returned to the sarcoplasmic reticulum. Review Figure 47.10

- ▶ In striated muscle, a single action potential causes a minimum unit of contraction called a twitch. Twitches occurring in rapid succession can be summed, thus increasing the strength of contraction. Review Figure 47.11
- ▶ Slow-twitch muscle fibers are adapted for extended, aerobic work; fast-twitch fibers are adapted for generating maximum forces for short periods of time. The ratio of slow-twitch to fast-twitch fibers in the muscles of an individual is genetically determined. Review Figure 47.12

Skeletal Systems Provide Support for Muscles

- ▶ Skeletal systems provide rigid supports against which muscles can pull.
- ▶ Hydrostatic skeletons are fluid-filled cavities that can be squeezed by muscles. Review Figure 47.13
- ▶ Exoskeletons are hardened outer surfaces to which internal muscles are attached. Review Figure 47.14
- ▶ Endoskeletons are internal, articulated systems of rigid rodlike, platelike, and tubelike supports consisting of bone and cartilage to which muscles are attached. Review Figure 47.15
- ▶ Bone is continually being remodeled by osteoblasts, which lay down new bone, and osteoclasts, which erode bone. Review Figure 47.16
- ▶ Bones develop from connective tissue membranes or from cartilage through ossification. Cartilage bone can grow until centers of ossification meet. Review Figure 47.17
- ▶ Bone can be solid and hard (compact bone), or it can contain numerous internal spaces (cancellous bone).
- ▶ Tendons connect muscles to bones; ligaments connect bones to each other and also help direct the forces generated by muscles by holding tendons in place. Review Figure 47.19
- ▶ Muscles and bones work together around joints as systems of levers. Review Figures 47.20, 47.21

Other Effectors

- ▶ Effector organs other than muscles include nematocysts, chromatophores, glands, and structures that produce electric pulses.

For Discussion

1. The amount of force a skeletal muscle can generate depends on its initial length. If the muscle is stretched or compressed prior to stimulation, it cannot generate maximum force of contraction. Why? Explain in terms of the molecular structure of the contractile mechanism.
2. If an intact axoneme is stimulated with Ca^{2+} and ATP, it flexes back and forth. However, if all of the proteins of the axoneme are enzymatically removed except for the microtubules and dynein, and the axoneme is then stimulated with Ca^{2+} and ATP, the microtubules telescope apart and the structure gets longer. Why?
3. Wombats are powerful digging animals, and kangaroos are powerful jumping animals. How do you think the structures of their legs would compare in terms of their designs as lever systems?
4. Why are ducks better long-distance fliers than chickens?
5. If an adolescent breaks a leg bone close to the ankle joint, after the break heals, that leg may not grow as long as the other one. Why?

48

Gas Exchange in Animals

3 ^^ In his book about his first ascent of Mt.

^^Mt. Everest, Sir John Hunt relates the following observation made at 26,000 feet, on the South Col, the last camp before the summit attempt. At this altitude climbers are almost totally incapacitated if they do not breathe supplemental oxygen from pressurized bottles:

And so back up the gradual slopes, the wind behind me. A much greater effort this, stopping every few yards with a slight anxiety lest I should not make the distance. As I approached the tents, I was astonished to see a bird, a chough, strutting about on the stones near me. ... During this day, too, Charles Evans saw what must have been a migration of small grey birds across the Col. Neither of us had thought to find any signs of life as high as this.

Birds in flight can consume oxygen at a rate that a well-trained human athlete cannot sustain for more than a few minutes. Yet birds fix over the summit of Everest, where human climbers must breathe supplemental oxygen just to plod along at a slow pace. How do they do it? Fish breathing water, with an oxygen content less than 5 percent that of air, can swim much faster, farther, and longer than the best human swimmer. How do they do it? The abilities of some animals to maintain high rates of metabolism depend in part on the capacities of their respiratory gas exchange systems.

Some animals carry out their respiratory gas exchange with water and others with air. Both water breathers and air breathers have respiratory systems with adaptations that maximize exchanges of oxygen and carbon dioxide with the environment. These adaptations include specialized surface areas where gas exchange takes place, breathing mechanisms that bring fresh air or water to those surfaces, and circulatory mechanisms for transporting respiratory gases to and from the internal sides of the gas exchange surfaces. Since gases cross the gas exchange surfaces by diffusion only, physical factors that limit diffusion determine the maximum capacities of gas exchange systems.

Flying High

Many birds can sustain the high metabolic costs of flight even at very high altitudes, where oxygen is scarce.

In this chapter we first describe the physical factors that influence respiratory gas exchange. Then we examine the respiratory gas exchange systems of a variety of species, including some highly efficient ones such as fish gills and bird lungs, and less efficient ones such as our own. We also look at the adaptations of the blood for transporting respiratory gases. Finally, we see how respiratory gas exchange systems are controlled and regulated.

Respiratory Gas Exchange

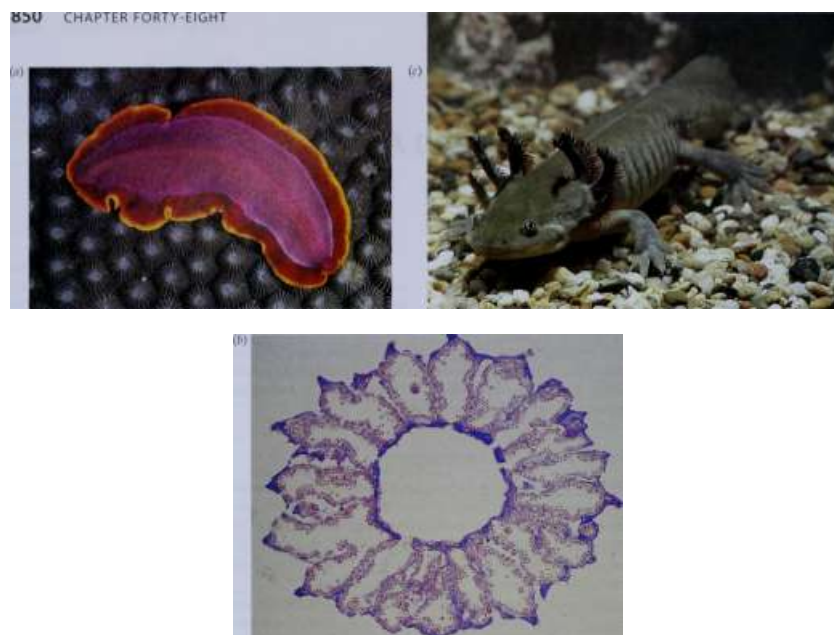

The respiratory gases are oxygen (O_2) and carbon dioxide (CO_2). Cells need to obtain O_2 from the environment to produce an adequate supply of ATP through the oxidation of nutrient molecules (see Chapter 7). An end product of the oxidative metabolism of nutrients is CO_2 which must be lost to the environment to prevent toxic effects.

Diffusion is the only means by which respiratory gases are exchanged between the internal body fluids of an animal and the outside medium—air or water. There are no active transport mechanisms to move respiratory gases across biological membranes. Because diffusion is a physical process, knowing the physical factors that influence rates of diffusion helps us understand the diverse adaptations of gas exchange systems. You might want to review what you learned about diffusion as a physical phenomenon in Chapter 5. Here, we discuss environmental factors that in-

•

850 CHAPTER FORTY-EIGHT

fluence diffusion rates, and then describe the adaptations of respiratory systems for facilitating the diffusion of respiratory gases.

Air is a better respiratory medium than water

O₂ can be obtained more easily from air than from water for several reasons.

► The oxygen content of air is much higher than the oxygen content of an equal volume of water. The maximum O₂ content of a rapidly flowing stream splashing over rocks and tumbling over waterfalls is less than 10 ml of O₂ per liter of water. The O₂ content of fresh air is about 200 ml of O₂ per liter of air.

► O₂ diffuses about 8,000 times more rapidly in air than in water. In a still pond, the O₂ content of the water can be zero only a few millimeters below the surface.

► When an animal breathes, it does work to move water or air over its specialized gas exchange surfaces. More energy is required to move water than air because water is 800 times more dense than air and about 50 times more viscous.

The slow diffusion of O₂ molecules in water is a problem for air-breathing animals as well as for water-breathing animals. Eukaryotic cells carry out cellular respiration in their mitochondria, which are located in the cytoplasm—an aqueous medium. Cells are bathed in extracellular fluid—

48.1 Keeping in Touch with the Medium

(a) No cell in the leaflike body of this marine flatworm is more than a millimeter away from seawater. (b) The same is true of sponges, which have body walls perforated by many channels lined with flagellated cells. These channels communicate with the outside world and with a central cavity. The flagella maintain currents of water through the channels, through the central cavity, and out of the animal. Every cell in the sponge is very close to the respiratory medium. (c) The gills of this newt project like a feathery fringe and provide a large surface area for gas exchange. Blood circulating through the gills comes into close contact with the respiratory medium.

also an aqueous medium. The slow rate of O₂ diffusion in water limits the efficiency of O₂ distribution from gas exchange surfaces to the sites of cellular respiration in both air-breathing and water-breathing animals.

Diffusion of O₂ in water is so slow that even animal cells with low rates of metabolism can be no more than a couple of millimeters away from a good source of environmental O₂. Therefore, in animals that lack an internal system for transporting O₂, no more than a few millimeters away from the outside world—ase^{el}ize^Tmit. One way some simple invertebrate animals have grown bigger in spite of this limit is to have a flat, leaflike body (Figure 48.1a). Another way is to have a very thin body built around a central cavity through which water circulates (Figure 48.1b). Otherwise, an animal must have specialized structures to provide an increased surface area for diffusion, an internal circulatory system to carry respiratory gases to and from these structures, and a way in which the surfaces of these gas exchange structures can be continuously bathed with fresh air or water (Figure 48.1c).

High temperatures create respiratory problems for aquatic animals

Animals that breathe water are in a double bind when environmental temperatures rise. Most water breathers are ectothermic—their body temperatures are closely tied to the temperature of the water around them. As the temperature of the water rises, so does their body temperature and metabolic rate (see Chapter 40 for a discussion of Q₁₀ relationships). Thus, with rising temperatures, water breathers

48.2 The Double Bind of Water Breathers

Fish need more oxygen in warm water, but warm water carries less oxygen than cold water.

need more CV But warm water holds less dissolved oxygen gas than cold water does (just think of what happens when you open a warm bottle of soda). So, under conditions that increase the need these animals have for O_2 , there is less O_2 in their respiratory medium (Figure 48.2). In addition, if the animal performs work to move water across its gas exchange surfaces (as fish do, for example), the energy the animal must expend to breathe is

increased.

Therefore, as water temperature goes up, the water breather must extract

level, the pressure exerted by the atmosphere is equivalent to the pressure produced by a column of mercury 760 mm high. Therefore, barometric pressure (atmospheric pressure) at sea level is 760 mm of mercury (Hg). Because dry air is 20.9 percent O_2 , the partial pressure of oxygen (P_{O_2}) at sea level is 20.9 percent of 760 mm Hg, or about 159 mm Hg.

At higher elevations, where there is less air above, barometric pressure declines. At an altitude of 5,300 m barometric pressure is only half as much as it is at sea level, so the P_{O_2} at that altitude is only 80 mm Hg. At the summit of Mount Everest (8,848 m), the P_{O_2} is only about 50 mm Hg, roughly one-third what it is at sea level. Since the movement of O_2 across respiratory gas exchange surfaces and into the body depends on diffusion, its rate of movement depends on the P_{O_2} difference between the air and the body fluids. Therefore, the dramatically reduced P_{O_2} in the air at a high altitude constrains O_2 uptake. Because of these constraints, mountain climbers who venture to the heights of Mount Everest usually breathe O_2 from pressurized bottles (Figure 48.3).

Carbon dioxide is lost by diffusion

Respiratory gas exchange is a two-way process. CO_2 diffuses out of the body as O_2 diffuses in. Given the same partial pressure gradient, CO_2 and O_2 molecules diffuse at about the same rate, whether in air or in water. However, the partial pressure gradients for the diffusion of O_2 and CO_2 across gas exchange surfaces are not the same. The

more and more O_2 from its environment, and a lower percentage of that O_2 is available to support activities other than breathing.

O_2 availability decreases with altitude

Just as a rise in temperature reduces the supply of O_2 available to aquatic animals, an increase in altitude reduces the O_2 supply for air breathers, because the amount of O_2 in the atmosphere decreases with altitude.

One of the ways to express the amounts of gases in air and in water is by the partial pressures. At sea

852 CHAPTER FORTY-EIGHT

amount of CO_2 in the atmosphere is extremely low (0.03 percent), so there is always a good partial pressure gradient for loss of CO_2 from air-breathing animals.

Water-breathing animals are much more likely than air breathers to experience high partial pressures of CO_2 in their environments. If water is well aerated, well mixed, and does not contain a lot of dead organic material, the diffusion of CO_2 from an aquatic animal is not a problem. Stagnant waters that are home to much biological activity or rotting vegetation, however, can have high levels of CO_2 and not be able to support animal life. In both air breathers and water breathers, the need to transport CO_2 from where it is produced in the cells of the body to where it diffuses into the environment can be a limiting factor in gas exchange (and hence in metabolism).

Fick's law applies to all systems of gas exchange

All adaptations that maximize respiratory gas exchange influence one or more components of a simple equation called Fick's law of diffusion,

where

$$Q = DA \frac{C_1 - C_2}{L}$$

$Q =$

L

$\frac{C_1 - C_2}{L}$

- Q is the rate at which a substance such as O_2 diffuses between two locations
- D is the diffusion coefficient, which is a characteristic of the diffusing substance, the medium, and the temperature (for example, perfume has a higher D than motor oil, and substances diffuse faster in air than in water)
- A is the cross-sectional area over which the substance is diffusing
- C_1 and C_2 are the concentrations of the substance at two locations
- L is the distance between those locations

Therefore, $(C_1 - C_2)/L$ is a concentration gradient. In discussing respiratory gas exchange, we will use partial pressures rather than concentrations; this term will therefore become a partial pressure gradient.

Animals can maximize D for respiratory gases by using air rather than water as their gas exchange medium whenever possible. All other adaptations for maximizing respiratory gas exchange must influence the surface area for exchange or the partial pressure gradient across that surface area.

Respiratory Adaptations for Gas Exchange

Now that we know the factors that determine the rates of diffusion of respiratory gases, let's take a look at the fascinating array of adaptations that animals have evolved for respiratory gas exchange.

(a) Gills

Respiratory organs have large surface areas

Many anatomical adaptations maximize the specialized body surface area (A) over which respiratory gases can diffuse. External gills are highly branched and folded elaborations of the body surface that provide a large surface area for gas exchange with water (Figure 48.4c). External gills are found in larval amphibians and in many insect species. Because they consist of thin, delicate membranes, they minimize the length of the path (L) traversed by diffusing molecules of O_2 and CO_2 (see Figure 48.1c).

Because external gills are vulnerable to damage and are tempting morsels for carnivorous organisms, protective body

cavities for gills have evolved. Many mollusks, arthropods, and fishes have internal gills in such cavities.

Just as the gills of water breathers increase the surface area available for respiratory gas exchange, air-breathing vertebrates have enormous surface areas for gas exchange. Lungs are internal cavities for respiratory gas exchange with air. Their structure is quite different from that of gills (Figure 48.4b). Lungs have a large surface area because they are highly divided, and they are elastic so they can be inflated and deflated with air.

Most air-breathing invertebrates are insects, which have a unique respiratory gas exchange system consisting of a highly branched network of air-filled tubes called tracheae that branch through all the tissues of the insect's body. The terminal branches of these tubes are so numerous that they have an enormous surface area.

Ventilation and perfusion maximize partial pressure gradients

Fick's law of diffusion points to other possible adaptations besides increasing surface area that can increase respira-

A large surface area for the diffusion of respiratory gases is a common feature of animals.

torv gas exchange. Animals maximize the partial pressure gradients ($C_i - C_o/L$) that drive the diffusion of respiratory gases across their gas exchange membranes in several ways:

- Gill and lung membranes are very thin so that the path length for diffusion (L) is small.
- Breathing mechanisms ventilate the environmental side of the exchange surfaces so that they are exposed to fresh respiratory medium (air or water) with the highest possible partial pressure of O_2 and the lowest possible partial pressure of CO_2 .
- Circulatory systems perfuse the internal side of the exchange surfaces with a respiratory gas transport medium that helps maintain the lowest possible partial pressure of O_2 , and highest possible partial pressure of CO_2 , on the inside of the exchange membranes.

Air sacs

An animal's gas exchange system is made up of its gas exchange surfaces and the mechanisms it uses to ventilate and perfuse those surfaces. The following sections describe four gas exchange systems. First we look at the unique gas exchange system of insects. Then we describe two remarkably efficient systems: fish gills and bird lungs. Finally, we discuss mammalian lungs.

insect tracheae. Respiratory gases diffuse through air most of the way to and from every cell of an insect's body. This diffusion is achieved through a system of air tubes, or tracheae, that open to the outside environment through holes called spiracles in the sides of the abdomen (Figure 48.5a). The tracheae branch into even finer tubes, or tracheoles, until they end in tiny air capillaries (Figure 48.5c). In the insect's flight muscles and other highly active tissues, no mitochondrion is

more than a few micrometers away from an air capillary

Because the diffusion rate of oxygen is so much higher in air than in water, air capillaries enable insects to supply oxygen to their cells at high rates. Many insects metabolize at high rates, but their relatively simple gas exchange systems are able to provide them with the oxygen they need. However, the rate of diffusion in insect tracheae and air capillaries is limited by their small diameter (A) and by the length (L) of these dead-end airways, so insects must be relatively small animals.

Some species of insects that dive and stay underwater for long periods make use of an interesting variation on diffusion. These insects carry with them a bubble of air. A small bubble may not seem like a very large reservoir of oxygen, yet these insects can stay underwater almost indefinitely with their small air supplies. The secret has to do with the P_{O_2} in the bubble. When the insect dives, the air bubble contains about 80 percent nitrogen and 20 percent O_2 . As the insect consumes the O_2 in its bubble, the bubble shrinks a little. The bubble doesn't disappear, however, because it consists mostly of nitrogen, which the insect does not consume. When the P_{O_2} in the bubble falls below the P_{O_2} in the surrounding water, O_2 diffuses from the water into the bubble. For these small animals, the rate of O_2 dif-

The spiracles of the larva of a spinx moth are arranged down the side of the anima

The tracheal system extends throughout the body and opens to the exterior through spiracles.

A scanning electron micrograph shows a trachea dividing into smaller trachioles, which give rise to still finer air capillaries.

In insects, respiratory gases diffuse through a system of air tubes (tracheae) that open to the external environment through holes called spiracles.

fusion into the bubble is enough to meet their O_2 demand while they are underwater.

fish gills. The internal gills of fishes are supported by usually four gill arches on either side of the fish and lie between the mouth cavity and the protective opercular flaps (Figure 48. 6a). Water flows unidirectionally into the fish's mouth, over the gills, and out from under the opercular flaps, so that the gills are continuously bathed with fresh water. This constant flow of water moving over the gills maximizes the P_{O_2} on the external surfaces. On the internal side, the circulation of blood minimizes the P_{O_2} by sweeping the O_2 away as rapidly as it diffuses across.

The gills have an enormous surface area for gas exchange because they are so highly divided. Each gill consists of hundreds of leaf-shaped gill filaments (Figure 48.6i>). The upper and lower flat surfaces of each gill filament have rows of evenly spaced folds, or lamellae. The lamellae are the gas exchange surfaces. Their delicate structure minimizes the path length for diffusion of gases between blood and water. The surfaces of the lamellae consist of highly

854 CHAPTER FORTY-EIGHT

flattened epithelial cells, so the water and the red blood cells are separated by little more than 1 or 2 μm .

The flow of blood perfusing the inner surfaces of the lamellae, like the flow of water over the gills, is unidirectional. Afferent blood vessels bring blood to the gills, while efferent blood vessels take blood away from the gills (Figure i. Blood flows through the lamellae in the direction op-

Each gill arch supports two rows of gill filament

opposite to the flow of water over the lamellae. This counter-current flow maximizes the P_{50} gradient between water and blood, making gas exchange more efficient than it would be in a system using concurrent (parallel) flow (Figure 48.7).

Some fish, including anchovies, tuna, and certain species of sharks, ventilate their gills by swimming almost constantly with their mouths open. Most fish, however, ventilate the external surfaces of their gills by means of a two-pump mechanism that maintains a unidirectional and constant flow of water over the gills. The closing and contracting of the mouth cavity pushes water over the gills, and the opening and closing of the opercular flaps pulls water over the gills.

In summary, fish can extract an adequate supply of O_2 from meager environmental sources by maximizing the surface area for diffusion, minimizing the path length for diffusion, and maximizing oxygen extraction efficiency by means of constant, unidirectional, countercurrent flow of blood and water over the opposite sides of their gas exchange surfaces.

bird lungs. Birds can sustain extremely high levels of activity for much longer than mammals can—even at very high altitudes where mammals cannot even survive. Yet the lungs of a bird are smaller than the lungs of a

Lamellae

Red blood cells

similar-sized mammal. How can this be? Bird lungs have a unique structure that allows air to flow unidirectionally through the lungs, rather than having to flow in and out through the same airways, as it does in mammalian lungs.

In addition to lungs, birds have air sacs at several locations in their bodies. The air sacs are interconnected with the lungs and with air spaces (another unique feature of birds) in some of the bones (Figure 48.8). The air sacs receive inhaled air, but they are not gas exchange surfaces. The composition of air in an air sac does not change rapidly, as it would if O_2 were diffusing into the blood and CO_2 were diffusing into the air sac.

As in other air-breathing vertebrates, air enters and

leaves a bird's gas exchange system through a trachea

(commonly known as the windpipe), which divides into

smaller airways called bronchi (singular bronchus). In

air-breathing vertebrates other than birds,

the bronchi generate trees of branching

airways that become finer and finer until

they dead-end in clusters of microscopic, membrane-enclosed air sacs, where gases are exchanged. In bird lungs, however, there are no dead ends; air flows unidirectionally through the lungs. O_2 diffuses from water into the blood over the entire length of a lamella.

Blood flow through the lamellae is counter-current to the flow of water over the lamellae. tionally through the lungs.

GAS EXCHANGE IN ANIMALS 855

48.7 Countercurrent Exchange Is More Efficient than Concurrent Exchange

In these models of concurrent and countercurrent exchange, the numbers represent the oxygen saturation of blood and water, (a) In the concurrent exchanger, the percentages of saturation of blood and water reach equilibrium even before the water has flowed halfway across the exchange surface. (b) There is more complete exchange in the case of countercurrent flow because the water is always more saturated than the blood as it passes over the exchange surface, so that a gradient of O_2 saturation is always maintained.

avian lungs do. To make things even more puzzling, bird lungs contract during inhalation and expand during exhalation!

The puzzle of how birds breathe was solved by an experiment that placed small oxygen sensors at different locations in the air sacs and airways of birds. The bird could then be exposed to pure O_2 , and the progress of that single breath through the bird's gas exchange

In bird lungs, the bronchi divide into tubelike parabronchi (Figure 48.9). Running between the parabronchi are tiny airways called air capillaries. Air flows through the lungs in the parabronchi, but crosses between parabronchi through the air capillaries. The air capillaries are the gas exchange surfaces. They are tiny but numerous, so they provide an enormous surface area for gas exchange.

Another unusual feature of bird lungs is that they expand and contract less during a breathing cycle than mam-

Air capillaries carry air from a parabronchus, over blood capillaries where O_2 is absorbed, and out through other parabronchi.

856 CHAPTER FORTY-EIGHT

EXPERIMENT

Question: How does air flow through a bird's respiratory system?

METHOD Place oxygen sensors at different locations in a

bird's respiratory system. Give the bird one breath of pure oxygen, followed by a breath of normal air. Record when oxygen reaches different sensors.

RESULTS Breath 1

f

The breath of pure O_2 is inhaled directly to the posterior air sacs.

Bronchus

Trachea

During exhalation, the pure O_2 flows into the lungs.

f

During the next inhalation, the breath of pure O_2 flows from the lungs to the anterior air sacs.

Breath 2

Finally, during the next exhalation, the breath marked by pure O_2 is expelled.

Conclusion: Air travels through the lungs in one direction, from the posterior to the anterior air sacs. Two cycles of inhalation and exhalation are required for the air to travel through the bird's respiratory tract.

48.70 The Path of Air Flow through Bird Lungs *

The fresh air a bird takes in with one breath (blue) travels through the lungs in one direction, from the posterior to the anterior air sacs. Two cycles of inhalation and exhalation are required for the air to travel the full length of the bird's respiratory system.

This system could be followed by the oxygen sensors. This experiment showed that a single breath remains in the bird's gas exchange system for two cycles of inhalation and exhalation, and that the air sacs work as bellows maintaining a

continuous and unidirectional flow of fresh air through the lungs (Figure 48.10).

The advantages of the bird gas exchange system are similar to those of fish gills. Because the air sacs keep fresh air from the outside flowing unidirectionally and practically continuously over the gas exchange surfaces, the P_{O_2} on the environmental side of those surfaces is maximized. Furthermore, the unidirectional flow of air through the system makes possible a pattern of blood flow, to minimize the P_{O_2} on the internal side of the exchange surfaces.

It is now clear how birds can live over Mount Everest. A bird is able to supply its gas exchange surfaces with a continuous flow of fresh air that has a P_{O_2} close to that of the ambient air. Even when the P_{O_2} of the ambient air is only slightly above the P_{O_2} of the blood, O_2 can diffuse from air to blood. Next we will see why humans find it difficult to sustain even low levels of metabolic activity at such high altitudes.

tidal breathing in mammals. At the beginning of their evolution, lungs were dead-end sacs, and they remain so today in all air-breathing vertebrates except birds. Because lungs are dead-end sacs, ventilation cannot be constant and unidirectional, but must be tidal: Air flows in and out by the same route.

Figure 48.11 shows how we use our lung capacity in breathing (Figure 48.11). When we are at rest, the amount of air that moves in and out of the lungs during one normal breath is called the tidal volume (about 500 ml for an average human adult). We can breathe much more deeply and inhale more air than our resting tidal volume; the additional volume of air we can take in above normal tidal volume is our inspiratory reserve volume. Conversely, we can forcefully exhale more air than we normally do during a resting exhalation. This additional amount of air that can be forced out of the lungs is the expiratory reserve volume. But even after the most extreme exhalation possible, some air remains in the lungs. The lungs and airway cannot be collapsed completely; they always contain a residual volume. The total lung capacity is the sum of the residual volume, expiratory reserve volume, tidal volume, and inspiratory reserve volume.

Tidal breathing severely limits the partial pressure gradient available to drive the diffusion of O_2 from air into the blood. Fresh air is not moving into the lungs during half of the respiratory cycle; therefore, the average P_{O_2} of air in the lungs is considerably less than it is in the air outside the lungs. Furthermore, the incoming air mixes with the stale air that was not expelled by the previous exhalation. The lung volume that is not ventilated with fresh air is called dead space. This dead space consists of the residual volume and, depending on the depth of breathing, some or all of the expiratory reserve volume.

The scale in Figure 48.11 tells us that a tidal volume of 500 ml of fresh air mixes with up to 2,000 ml of stale air before reaching the gas exchange surfaces in our lungs. When the P_{O_2} in the ambient air is 150 mm Hg, the P_{O_2} of the air that reaches our gas exchange surfaces is only about 100

mm Hg. By contrast, the P_{O_2} in the water that bathes the lamellae of fish gills or in the air that flows through the air capillaries of bird lungs is the same as the P_c in the outside water or air.

In addition to reducing the partial pressure gradient, tidal breathing reduces the efficiency of gas exchange in another way: It does not allow countercurrent gas exchange between air and blood. Because air enters and leaves the gas exchange structures by the same route, there is no anatomical way that blood can flow countercurrent, or even cross current, to their flow.

Mammalian Lungs and Gas Exchange

To offset the inefficiencies of tidal breathing, mammalian lungs have some design features that maximize the rate of gas exchange: an enormous surface area, and a very short path length for diffusion. Mammalian lungs serve the respiratory needs of mammals well, considering the ecologies and lifestyles of these animals.

Air enters the lungs through the oral cavity or nasal passage, which join together in the pharynx (Figure 48.12). From the pharynx, the esophagus conducts food to the stomach and a single airway leads to the lungs. At the beginning of this airway is the larynx, or voice box, which houses the vocal cords. The larynx is the "Adam's apple" that you can see or feel on the front of your neck. The major airway, the trachea, has a diameter of about 2 cm. The thin walls of the trachea are prevented from collapsing by rings of cartilage that support them as air pressure changes during the breathing cycle. If you run your fingers

down the front of your neck just below your larynx, you can feel a couple of these rings of cartilage.

The trachea branches into two smaller bronchi, one leading to each lung. The bronchi branch repeatedly to generate a treelike structure of progressively smaller airways extending to all regions of the lungs (see Figure 48.12). As the branching of the bronchial tree continues to produce still smaller airways, the cartilage supports eventually disappear, marking the transition to bronchioles. The branching continues until the bronchioles are smaller than the diameter of a pencil lead, at which point tiny, thin-walled air sacs called alveoli begin to appear.

The alveoli are the sites of gas exchange. Because the airways only conduct air to and from the alveoli and do not themselves conduct gas exchange, their volume is physiologically small. The number of alveoli in human lungs is about 300 million. Even though each alveolus is very small, the combined surface area for diffusion of respiratory gases is about 70 m²—the size of a badminton court.

Each alveolus is made of very thin cells. Between and surrounding the alveoli are networks of the smallest of blood vessels, the capillaries, whose walls are also made up of exceedingly thin endothelial cells. Where capillary meets alveolus, very little space separates them (see Figure 48.12), so the length of the diffusion path between air and blood is less than 2 μ m. Even the diameter of a red blood cell is greater—about 7 μ m.

Respiratory tract secretions aid breathing

Mammalian lungs have two other important adaptations that do not directly influence their gas exchange properties:

858 CHAPTER FORTY-EIGHT

[The lungs lie within the thoracic cavity, which is bounded by the ribs and the diaphragm.]

Nasal passage Oral cavity

Ribs

| The bronchi are the major air passageways of the lungs. They lead to the bronchioles, which are finely branched.

Pleural membranes line the part of the thoracic cavity containing the lungs, so the lungs are in the pleural cavities.

The diagram traces the hierarchy of human respiratory structures from the lungs down to the minuscule alveoli.

the production of mucus and the production of surfactant.

A surfactant is a substance that reduces the surface tension of a liquid. Lung surfactant reduces the surface tension of the film of fluid lining the insides of the alveoli. What is surface tension and how does it affect lung function? Surface tension is a result of cohesion between the molecules of a liquid. Cohesion gives the surface of the liquid the properties of an elastic membrane. Surface tension is what allows some insects to walk on the surface of water (see Figure 2.16). A surfactant interferes with the cohesive forces that create surface tension. Detergent is a surfactant, and when added to water, it makes walking on water difficult for the water strider.

The thin, aqueous layer that lines the alveoli has surface tension, which must be overcome to inflate the lungs. Surface tension normally is reduced by surfactant molecules produced by certain cells in the alveoli. If a baby is born more than a month prematurely, however, these cells may not yet be producing surfactant. Such a premature baby has great difficulty breathing because an enormous effort is required to stretch the alveoli against the surface tension. This condition, known as respiratory distress syndrome, may cause the baby to die from exhaustion and suffocation. Common treatments have been to put the baby on a respirator to assist its breathing and to give the baby hormones to speed its lung development. A new approach, however, is to apply surfactant to the lungs via an aerosol.

Many cells lining the airways produce a sticky mucus that captures bits of dirt and microorganisms that are inhaled. This mucus must be continually cleared from the air-

ways. Other cells lining the airways have cilia (see Figure 47.2) whose beating moves the mucus with its trapped debris up toward the pharynx, where it is swallowed. This phenomenon, called the mucus escalator, can be adversely affected by inhaled pollutants. Smoking one cigarette a day can immobilize the cilia of the airways for hours. A smoker's cough results from the need to clear the obstructing mucus from the airways when the mucus escalator is out of order.

Lungs are ventilated by pressure changes in the thoracic cavity

As Figure 48.12 shows, human lungs are suspended in the thoracic cavity, which is bounded on the top by the shoulder girdle, on the sides by the rib cage, and on the bottom by a domed sheet of muscle, the diaphragm. The thoracic cavity is lined on the inside by the pleural membranes, which divide it into right and left pleural cavities enclosing each lung. Because the pleural cavities are closed spaces, any effort to increase their volume creates negative pressure—suction—inside them.

Negative pressure within the pleural cavities causes the lungs to expand as air flows into them from the outside. This is the mechanism of inhalation. The diaphragm contracts to begin an inhalation. This contraction pulls the diaphragm down, increasing the volume of the thoracic and pleural cavities (Figure 48.13). As pressure in the pleural cavities becomes more

negative, air moves into the lungs. Exhalation begins when the contraction of the diaphragm ceases. The diaphragm relaxes and moves up, and the elastic recoil of the lungs pushes air out through the airways. During tidal breathing, inhalation is an active process and exhalation is a passive process.

The diaphragm is not the only muscle that changes the volume of the pleural cavities. Between the ribs are two sets

of intercostal muscles. The external intercostal muscles expand the pleural cavities by lifting the ribs up and outward. The internal intercostal muscles decrease the volume of the thoracic cavity by pulling the ribs down and inward. When heavy demands are placed on the gas exchange system, such as during strenuous exercise, the external intercostal muscles increase the volume of air inhaled, making use of the inspiratory reserve volume, and the internal intercostal muscles increase the amount of air exhaled, making use of the expiratory reserve volume.

When the diaphragm is at rest between tidal breaths, the pressure in the pleural cavities is still slightly negative. This slight suction keeps the alveoli partly inflated. If the thoracic wall is punctured—by a knife wound, for example—air leaks into the pleural cavity, and the pressure from this air causes the lung to collapse. If the hole in the thoracic wall is not sealed, the breathing movements of the diaphragm and intercostal muscles pull air into the pleural cavity rather than into the lung, and ventilation of the alveoli in that lung ceases.

48.13 Into the Lungs and Out Again

Inhalation is an active process spurred by the contraction of the diaphragm. Exhalation generally is a passive process as the diaphragm relaxes. During inhalation, the negative pressure in the pleural cavity increases, expanding the elastic lung tissue and sucking air into the lungs. During exhalation, the negative pressure in the pleural cavity decreases, allowing the elastic lung tissue to recoil to create a positive pressure in the lungs and expel air.

860 CHAPTER FORTY-EIGHT

Blood Transport of Respiratory Gases

The circulatory system is the subject of the next chapter, but since two of the substances the blood transports are the respiratory gases (O_2 and CO_2), we must discuss blood here. The circulatory system uses a pump (the heart) and a network of blood vessels to transport blood and the substances it carries around the body. As O_2 diffuses across the gas exchange surfaces into the blood vessels, the circulating blood sweeps it away. As we have seen, this internal perfusion of the gas exchange surfaces minimizes the P_{pO_2} on the internal side and promotes the diffusion of O_2 across the surface at the highest possible rate. The blood then delivers this O_2 to the cells and tissues of the body.

The liquid part of the blood, the blood plasma, carries some O_2 in solution, but its ability to transport O_2 is quite limited. Blood plasma can carry only about 0.3 ml of oxygen per 100 ml, which is inadequate to support the metabolism of a person at rest. Fortunately, the blood also contains red blood cells, which are red because they are loaded with the oxygen-binding pigment hemoglobin. Hemoglobin increases the capacity of blood to transport oxygen by about 60-fold. There is quite a diversity of O_2 -binding pigments among the animals; there is even considerable diversity of hemoglobin molecules. The discussion that follows focuses on human hemoglobin.

Hemoglobin combines reversibly with oxygen

Red blood cells contain enormous numbers of hemoglobin

molecules. Hemoglobin is a protein consisting of four polypeptide subunits (see Figure 3.7). Each of these polypeptides surrounds a heme group—an iron-containing structure that can reversibly bind a molecule of O_2 .

As O_2 diffuses into the red blood cells, it binds to hemoglobin. Once O_2 is bound, it cannot diffuse back across the red cell plasma membrane. By mopping up O_2 molecules as they enter the red blood cells, hemoglobin maximizes the partial pressure gradient driving the diffusion of O_2 into the cells. In addition, it enables the red blood cells to carry a large amount of O_2 to the tissues of the body.

t

The normal P_{aO_2} of deoxygenated blood is 40 mm Hg. The P_{aO_2} of blood leaving the lungs is about 100 mm Hg.

100

75

250

~Y

lungs is about 100 mm Hg.

O_2

The ability of hemoglobin to pick up or release O_2 depends on the partial pressure of O_2 in its environment. When the P_{O_2} of the blood plasma is high, as it usually is in the lung capillaries, each molecule of hemoglobin can carry its maximum load of four molecules of O_2 . As the blood circulates through the rest of the body, it encounters lower P_{O_2} values. At these lower P_{O_2} values, the hemoglobin releases some of the O_2 it is carrying (Figure 48.14).

As you can see from the figure, the relation between P_{O_2} and the amount of O_2 bound to hemoglobin is not linear, but S-shaped (sigmoid). The sigmoid hemoglobin- O_2 binding curve reflects interactions between the four subunits of the hemoglobin molecule, each of which can bind one molecule of O_2 . At low P_{O_2} values, only one subunit will bind an O_2 molecule. When it does so, the shape of this subunit changes, causing an alteration in the quaternary structure of the whole hemoglobin molecule (see Chapter 3). This structural change makes it easier for the other subunits to bind a molecule of O_2 ; that is, their O_2 affinity is increased. Therefore a smaller increase in P_{O_2} is necessary to get most of the hemoglobin molecules to bind two O_2 molecules (that is, to become 50 percent saturated) than it was to get them to bind one molecule of O_2 (25 percent saturated). The influence of the binding of O_2 by one subunit on the O_2 affinity of the other subunits is called positive cooperativity, because

binding of the first molecule makes binding of the second easier, and so forth.

Once the third molecule of O_2 is bound, however, the relationship seems to change, as a larger increase in P_{O_2} is required to reach 100 percent saturation. This upper bend of the sigmoid curve is due to a probability phenomenon: The closer we get to having all subunits occupied, the less likely it is that a single O_2 molecule will find a place to bind. Therefore it takes a relatively large P_{O_2} to achieve 100 percent saturation.

This is a good place to mention the danger posed by carbon monoxide (CO), which can come from a faulty furnace or from combusting a fuel such as charcoal or kerosene without adequate ventilation. CO binds to hemoglobin with a higher affinity than does O_2 . Thus, CO destroys the ability of hemoglobin to transport and release O_2 to the tissues of the body. The victim loses consciousness and can die because the brain lacks O_2 .

100

48.74 The Binding of Oxygen to Hemoglobin Depends on the P_{O_2}

Hemoglobin in blood leaving the lungs is 100 percent saturated (four molecules of O_2 are bound to each hemoglobin). Most hemoglobin molecules will drop only one of their four O_2 molecules as they circulate through the body, and are still 75 percent saturated when the blood returns to the lungs. The steep portion of this oxygen-binding curve comes into play

when tissue P_{O_2} falls below the normal 40 mm Hg. At this point the hemoglobin will "unload" its oxygen reserves.

The O_2 -binding properties of hemoglobin help get O_2 to the tissues that need it most. In the lungs, where the P_{O_2} is about 100 mm Hg, the hemoglobin is 100 percent saturated. The P_{O_2} in blood returning to the heart from the body is usually about 40 mm Hg. You can see from Figure 48.14 that at this P_{O_2} , the hemoglobin is still about 75 percent saturated. This

means that as the blood circulates around the body, only about 1 of 4 O₂ molecules it carries is released to the tissues. That seems inefficient, but it is really quite adaptive, because the hemoglobin keeps 75 percent of its oxygen in reserve to meet peak demands.

When a tissue becomes starved of oxygen and its local P_{O2} falls below 40 mm Hg, the hemoglobin flowing through that tissue is on the steep portion of its sigmoid binding curve. That means that relatively small decreases in P_{O2} below 40 mm Hg will result in the release of lots of O₂ to the tissue. Thus the cooperativity of O₂ binding by hemoglobin is very effective in making O₂ available to the tissues precisely when and where it is needed most.

Myoglobin holds an oxygen reserve

Muscle cells have their own oxygen-binding molecule, myoglobin. Myoglobin consists of just one polypeptide chain associated with an iron-containing ring structure that can bind one molecule of oxygen. Myoglobin has a higher affinity for O₂ than hemoglobin does (see Figure 48.15), so it picks up and holds oxygen at P_{O2} values at which hemoglobin is releasing its bound O₂.

Myoglobin provides a reserve of oxygen for the muscle cells for times when metabolic demands are high and blood flow is interrupted. Interruption of blood flow in muscles is common because contracting muscles constrict blood vessels. When tissue P_{O2} values are low and hemoglobin can no longer supply more O₂, myoglobin releases its bound O₂. Diving mammals such as seals have high concentrations of myoglobin in their muscles, which is one reason they can stay underwater for so long. (We will learn more about adaptations for diving in the next chapter.) Even in nondiving animals, muscles called on for extended periods of work frequently have more myoglobin than muscles that

48.15 Oxygen-Binding Adaptations

Evolution has adapted the oxygen-binding properties of different hemoglobins and of myoglobin. The hemoglobin of llamas, for example, is adapted for binding oxygen at high altitudes, where P_{O2} is low.

are used for short, intermittent periods. This is one of the reasons for the difference in appearance between fast-twitch and slow-twitch muscle (see Figure 47.12).

The affinity of hemoglobin for oxygen is variable

Various factors influence the oxygen-binding properties of hemoglobin, thereby influencing oxygen delivery to tissues. In this section we examine three of these factors: the chemical composition of the hemoglobin, pH, and the presence of 2,3 diphosphoglyceric acid.

hemoglobin composition. As we noted above, there is more than one type of hemoglobin. The chemical composition of the polypeptide chains that form the hemoglobin molecule varies. The normal hemoglobin of adult humans has two each of two kinds of polypeptide chains—two alpha chains and two beta chains—and the oxygen-binding characteristics shown in Figure 48.14.

Before birth, the human fetus has a different form of hemoglobin, consisting of two alpha chains and two gamma chains. The functional difference between these two types of hemoglobin is that the fetal hemoglobin has a higher affinity for O_2 . Therefore, the hemoglobin- O_2 binding curve of fetal hemoglobin is shifted to the left in comparison to the curve for adult hemoglobin (Figure 48.15). You can see from these curves that if both types of hemoglobin are at the same P_{O_2} , the fetal hemoglobin will pick up oxygen released by the adult hemoglobin. This difference in O_2 affinities facilitates the transfer of O_2 from the mother's blood to the blood of the fetus in the placenta.

Llamas and vicunas are mammals native to high altitudes in the Andes Mountains of South America. In the natural habitat of these animals, more than 5,000 m above sea

862 CHAPTER FORTY-EIGHT

Lowered pH decreases the oxygen-binding affinity of hemoglobin; more oxygen is then released to tissues.

48.16 The Oxygen-Binding Properties of Hemoglobin Can Change

Changes in pH affect the oxygen-binding capacity of hemoglobin.

level, the P_{O_2} is below 85 mm Hg, and the P_{O_2} in their lungs is about 50 mm Hg. Thus, the hemoglobins of these animals must be able to pick up O_2 in an environment that has a low P_{O_2} . The hemoglobins of llamas and vicunas have oxygen-binding curves to the left of hemoglobins of most other mammals—in other words, their hemoglobin can become saturated with O_2 at lower P_{O_2} values than those of other animals can.

pH. The oxygen-binding properties of hemoglobin are influenced by physiological conditions. The influence of pH on the function of hemoglobin is known as the Bohr effect. As the blood plasma picks up acidic metabolites such as lactic acid, fatty acids, and CO_2 (which combines with water to form carbonic acid) from the tissues, its pH falls. When this happens, the oxygen-binding curve of hemoglobin shifts to the right (Figure 48.16). This shift means that the hemoglobin will release more O_2 to the tissues—another way that O_2 is supplied where and when it is most needed.

2,3 diphosphoglyceric acid. 2,3 diphosphoglyceric acid (DPG) is a metabolite in the glycolytic pathway. Mammalian red blood cells have a high concentration of DPG, an important regulator of hemoglobin function. DPG⁻, reversibly combines with deoxygenated hemoglobin and ν^{\wedge} changes the shape of the hemoglobin such that it has a lower affinity for O_2 . The result is that at any P_{O_2} , hemoglobin releases more of its bound O_2 than it otherwise would. In other words, DPG shifts the oxygen-binding curve of mammalian hemoglobin to the right. When humans go to high altitudes, or when they cease being sedentary and begin to exercise, the level of DPG in their red blood cells goes up and makes it easier for the hemoglobin to deliver more O_2 to the tissues. The reason that fetal hemoglobin has a left-shifted hemoglobin- O_2 binding curve is that it has a lower affinity for DPG than does adult hemoglobin.

Llamas and humans employ opposite adjustments of hemoglobin function as adaptations for life at high altitudes. The llama's hemoglobin has a left-shifted oxygen-binding curve, which means that it can become 100 percent saturated with O_2 at the low P_{O_2} values at high altitudes. As a consequence, the llama's tissues must operate at a lower P_{O_2} . By contrast, human hemoglobin achieves, through acclimation, a right-shifted oxygen-binding curve. The result is that human

hemoglobin never becomes fully saturated with O_2 at high altitudes, but more of the O_2 carried by that hemoglobin is released to the tissues.

Carbon dioxide is transported as bicarbonate ions in the blood

Delivering O_2 to the tissues is only half of the respiratory function of the blood. The blood also must take carbon dioxide, a metabolic waste product, away from the tissues. CO_2 is highly soluble and readily diffuses through cell membranes, moving from its site of production in a cell into the blood, where the partial pressure of CO_2 is lower. However, very little dissolved CO_2 is transported by the blood. Most CO_2 produced by the tissues is transported to the lungs in the form of the bicarbonate ion HCO_3^- . How and where CO_2 is converted to HCO_3^- , is transported, and then is converted back to CO_2 is an interesting story.

When CO_2 dissolves in water, some of it slowly reacts with the water molecules to form carbonic acid (H_2CO_3), some of which then dissociates into a proton (H^+) and a bicarbonate ion (HCO_3^-). This reversible reaction is expressed as follows:

In the blood plasma, the reaction between CO_2 and H_2O proceeds slowly. But it is a different story in the endothelial cells of the capillaries and the red blood cells, where the enzyme carbonic anhydrase speeds up the conversion of CO_2 to H_2CO_3 . The newly formed carbonic acid dissociates and the resulting bicarbonate ions enter the plasma in exchange for Cl^- (Figure 48.17). By converting CO_2 to H_2CO_3 , carbonic anhydrase reduces the partial

pressure of CO_2 in these cells and in the plasma, facilitating the diffusion of CO_2 from tissue cells to endothelial cells, plasma, and red blood cells. Most CO_2 is transported by the blood plasma as bicarbonate ion produced in endothelial cells and red blood cells. Some CO_2 is also carried in chemical combination with deoxygenated hemoglobin as carboxyhemoglobin.

In the lungs, the reactions involving CO_2 and bicarbonate ions are reversed. CO_2 diffuses from the pulmonary capillaries to the alveolar air and is exhaled. Since the partial pressure of CO_2 in the alveoli is less than the partial pressure in the plasma and in the endothelial cells, CO_2 leaves the plasma and the endothelial cells and enters the alveoli. As the partial pressure in the plasma falls, CO_2 diffuses from the red blood cells into the plasma and from there into the endothelial cells and into the alveoli. As the partial pressure of CO_2 in the red blood cells falls, more HCO_3^- is converted into CO_2 , and more HCO_3^- moves into the red blood

cells from the plasma. Remember that an enzyme like carbonic anhydrase only speeds up a reversible reaction; it does not determine its direction. Direction is determined by concentrations of reactants and products (see Chapter 6).

Regulating Breathing to Supply O_2

We must breathe every minute of our lives, but we don't worry about our need to breathe, or even think about it very often. Breathing is an autonomic function of the nervous system. The breathing pattern easily adjusts itself around other activities (such as speech and eating), and breathing rates change to match the metabolic demands of our bodies. In this section we examine how the regular breathing cycle is generated and controlled.

Breathing is controlled in the brain stem

The autonomic nervous system maintains breathing and modifies its depth and frequency to meet the demands of the body for O_2 supply and CO_2 elimination. Breathing ceases if the spinal cord is severed in the neck region, showing that the breathing pattern is generated in the brain. If the brain stem is cut just above the medulla, the segment of the brain stem just above the spinal cord, an irregular breathing pattern remains (Figure 48.18).

Groups of neurons within the medulla increase their firing rates just before an inhalation begins. As more and more of these neurons fire—and fire faster and faster—the diaphragm contracts. Suddenly the neurons stop firing, the diaphragm relaxes, and exhalation begins. Exhalation is

usually a passive process that depends on the elastic recoil of the lung tissues. When breathing demand is high, however, as during strenuous exercise, not only are the intercostal muscles recruited, which increases both the inhalation and the exhalation volumes. Brain areas above the medulla modify breathing to accommodate speech, ingestion of food, coughing, and emotional states.

Normal breathing requires an intact brain stem.

•n/W\w\

If the brain stem is cut below the pons but above the medulla, breathing continues but is irregular.

Mr

Medulla

Spinal cord

If the spinal cord in the neck is severed, breathing ceases.

48.18 The Brain Stem Generates and Controls Breathing Rhythm

Severing the brain stem at different levels reveals that the basic breathing rhythm is generated in the medulla and modified by neurons in or above the pons.

864 CHAPTER FORTY-EIGHT

An override reflex prevents the breathing muscles from overdistending and damaging the lung tissue. This reflex, which is called the Hering-Breuer reflex, begins with stretch receptors in the lung tissue. When stretched, these receptors send impulses to the medulla that inhibit the inhalation neurons.

Regulating breathing requires feedback information

When the P_{O_2} and the P_{CO_2} in the blood change, the breathing rhythm changes to return these values to normal levels. We should therefore expect the blood partial pressure of one or both of these gases to provide feedback information to the breathing rhythm generator. Experiments in which subjects breathe gases with different P_{O_2} and P_{CO_2} make it possible to measure the effect of these changes on breathing (Figure 48.19). In these experiments, it is assumed that the P_{O_2} or P_{CO_2} in inhaled air will be reflected in the blood. The conclusion from such experiments is that humans and other mammals are remarkably insensitive to falling blood levels of O_2 , but very sensitive to increases in the CO_2 of the blood.

Where are gas partial pressures in the blood sensed? The major site of CO_2 sensitivity is an area on the ven-

tral surface of the medulla, not far from the groups of neurons that generate the breathing rhythm. Sensitivity to O_2 in the blood resides in nodes of tissue on the large blood vessels leaving the heart: the aorta and the carotid arteries (Figure 48.20). These carotid and aortic bodies receive enormous supplies of blood, and they contain chemoreceptor nerve endings. If the blood supply to these structures decreases, or if the P_{O_2} of the blood falls dramatically, the chemoreceptors are activated and send impulses to the breathing control center. Although we are not very

Chapter Summary

Respiratory Gas Exchange

► Most cells require a constant supply of O_2 and continuous removal of CO_2 . These respiratory gases are exchanged between the body fluids of an animal and its environment by diffusion.

► In aquatic animals, gas exchange is limited by the low diffusion rate and low amount of oxygen in water. Aquatic animals face a double bind in that the amount of oxygen in water decreases, but their metabolism and the amount of work required to move water over gas exchange surfaces increase, as water temperature rises. Review Figure 48.2

Respiratory Adaptations for Gas Exchange

► The evolution of large animals with high metabolic rates required the evolution of adaptations to maximize the rates of diffusion of respiratory gases between animals and their environments. These adaptations involve increasing surface areas

for gas exchange and maximizing partial pressure gradients across those exchange surfaces by decreasing their thickness, ventilating the outer surface with respiratory

GAS EXCHANGE IN ANIMALS 865

medium, and perfusing the inner surface with blood. Review Figure 48.4

- Insects distribute air throughout their bodies in a system of tracheae, tracheoles, and air capillaries. Review Figure 48.5

- ▶ Fish have maximized their rates of gas exchange by having large gas exchange surface areas that are ventilated continuously and unidirectionally with fresh water. Countercurrent blood flow helps increase the efficiency of gas exchange. Review Figures 48.6, 48.7

- ▶ The gas exchange system of birds includes air sacs that communicate with the lungs but are not used for gas exchange. Air flows unidirectionally through bird lungs in parabronchi. Gases are exchanged in air capillaries that run between parabronchi. Review Figures 48.8, 48.9

- ▶ Each breath of air remains in the bird respiratory system for two breathing cycles. The air sacs work as bellows to supply the air capillaries with a continuous, unidirectional flow of fresh air. Review Figure 48.10

- ▶ Breathing in vertebrates other than birds is tidal and is therefore less efficient than gas exchange in fishes or birds. Even though the volume of air exchanged with each breath can vary considerably, the inhaled air is always mixed with stale air. Review Figure 48.11

Mammalian Lungs and Gas Exchange

- ▶ In mammalian lungs, the gas exchange surface area provided by the millions of alveoli is enormous, and the diffusion path length between the air and perfusing blood is very short. Review Figure 48.12

- ▶ Surface tension in the alveoli would make their inflation difficult if the lungs did not produce surfactant.

- ▶ Inhalation occurs when contractions of the diaphragm and the intercostal muscles create negative pressure in the thoracic cavity. Relaxation of the diaphragm and some intercostal muscles and contraction of other intercostal muscles increases pressure in the thoracic cavity and causes exhalation. Review Figure 48.13

Blood Transport of Respiratory Gases

- ▶ Oxygen is reversibly bound to hemoglobin in red blood cells. Each molecule of hemoglobin can carry a maximum of four molecules of oxygen. Because of positive cooperativity, the affinity of hemoglobin for oxygen depends on the P_{O_2} to which the hemoglobin is exposed. Therefore, hemoglobin gives up oxygen in metabolically active tissues and picks up oxygen as it flows through respiratory exchange structures. Review Figure 48.14

- ▶ Myoglobin has a very high affinity for oxygen and serves as an oxygen reserve in muscle.
- ▶ There is more than one type of hemoglobin. Fetal hemoglobin has a higher affinity for oxygen than does maternal hemoglobin, allowing fetal blood to pick up oxygen from the maternal blood in the placenta. Review Figure 48.15
- ▶ The affinity of hemoglobin for oxygen is decreased by the presence of hydrogen ions or 2,3 diphosphoglyceric acid. Review Figure 48.16
- ▶ Carbon dioxide is carried in the blood principally as bicarbonate ions. Review Figure 48.17

Regulating Breathing to Supply O_2

- ▶ The breathing rhythm is an autonomic function generated by neurons in the medulla of the brain stem and modulated by higher brain centers. Review Figure 48.18
- ▶ The most important feedback stimulus for breathing is the level of CO_2 in the blood. Review Figure 48.19
- The breathing rhythm is sensitive to feedback from chemoreceptors on the ventral surface of the brain stem and in the carotid and aortic bodies on the large vessels leaving the heart. Review Figure 48.20

For Discussion

1. A species of fish that lives in Antarctica has no hemoglobin. What anatomical and behavioral characteristics would you expect to find in this fish, and why is its distribution limited to the waters of Antarctica?
2. Blood banks store whole blood for a much shorter period than they store blood plasma. The reason is that when blood that has been stored for too long is infused into a patient, it can actually decrease the oxygen availability to the patient's tissues. Why is this so? Explain in terms of the different physiological functions of 2,3 diphosphoglyceric acid.
3. Explain how llamas and humans can have opposite adaptations for maximizing gas transport at high altitudes.
4. In the disease emphysema, the fine structures of alveoli break down, resulting in the formation of larger air cavities in the lungs. Also, the tissue of the lungs becomes fibrotic and less elastic. Explain at least two reasons why patients with emphysema have a low tolerance for exercise.
5. The disease called "the bends" occurs in scuba divers (persons who spend time underwater by breathing pressurized air) who have come too quickly to the surface after spending an extended period in deep water. The cause of the bends is tiny bubbles of nitrogen coming out of solution in the blood plasma. Seals spend much more time underwater and at deeper depths than scuba divers, yet they do not suffer the bends. Why?

Circulatory Systems

Your heart is a little bigger than

your fist. This mass of muscle pumps about 200 ml of blood to your lungs and an equal amount to the rest of the organs of your body with each beat, and when you are at rest, it beats about once each second. Even when you are at rest, your heart pumps your total blood volume through your lungs and around your body about once each minute.

Circulating blood has many functions, such as delivery of oxygen and nutrients to cells, removal of waste products of metabolism, and distribution of heat and hormones. It is not surprising, therefore, that when you work or exercise, your heart rate and the amount of blood your heart pumps

each minute go up as much as three or four times to match the increasing metabolic demands. Because blood flow can be redistributed to different tissues and organs depending on their needs, blood flow to your active muscles might increase more than 25-fold during exercise.

It makes sense that working muscles should get a greater blood supply. Consider, however, the cardiovascular responses of a seal searching for and pursuing prey underwater for over half an hour. The seal's response to this underwater exercise is very different from yours. Its heart slows dramatically, from about 150 beats per minute to 20, its cardiac output falls proportionally, and blood flow to the muscles propelling its swimming falls practically to zero. Blood flow to the heart is less than a third what it was before the dive began. Only blood flow to its nervous system is maintained at pre-dive levels. Because the circulatory system of the seal responds differently during exercise than yours does, the seal is able to conserve its oxygen supplies and remain underwater for long periods. By the end of this chapter, you will understand the adaptations of circulatory systems that enable you to match blood supply with demand in your exercising muscles and enable the seal to decrease its utilization of oxygen during long dives.

We begin this chapter by contrasting the open and closed circulatory systems of invertebrates. Then we discuss the evolution, structure, and function of vertebrate circulatory systems, going

Champion Divers

A harbor seal (*Phoca vitulina*) can be active underwater for 30 minutes or more without coming to the surface to breathe.

from the two-chambered hearts and single blood circuits of fishes to the four-chambered hearts and double blood circuits of birds and mammals. Taking the human heart as a model, we explore the mechanics of the beating heart and the events of the cardiac cycle that pump blood around the body.

After the heart, we turn to the characteristics of the vascular system: the arteries, capillaries, and veins. We explain how materials are exchanged between the blood and the tissue fluids. The third component of a circulatory system is the blood, and we describe the features of this fluid tissue. The chapter ends with a discussion of the hormonal and neural control and regulation of the human circulatory system and an explanation of the diving adaptations of marine mammals.

Circulatory Systems: Pumps, Vessels, and Blood

A circulatory system consists of a pump (heart), a fluid (blood) that can transport materials, and a series of connected blood vessels through which the fluid can be pumped around the body. Heart, blood, and vessels are also known as a cardiovascular system (from the Greek *kardia*, "heart," and the Latin *vascidum*, "small vessel"). In this sec-

Tentacle

(a) Cnidarian (Hydra)

Pharynx

The gastrovascular cavity of a flatworm, *Planaria*, extends into all regions of the animal's flattened body.

The gastrovascular cavity of a cnidarian, *Hydra*, extends into the tentacles. No cell of the hydra is more than one cell away from either the gastrovascular cavity or the external medium.

49.1 Gastrovascular Cavities

In small aquatic animals without circulatory systems, a gastrovascular cavity serves the metabolic needs of the innermost cells of the body.

tion, we compare the circulatory systems of different groups of animals.

Some simple aquatic animals do not have circulatory systems

A circulatory system is unnecessary if the cells of an organism are close enough to the external environment that nutrients, respiratory gases, and wastes can diffuse between the cells and the environment. Small aquatic invertebrates have structures and body shapes that permit direct exchanges -between cells and environment. The hydra, a cnidarian, is a good example (see Figure 42.1a). All cells of the hydra are in contact with, or very close to, the water that either surrounds the

animal or circulates through its gastrovascular cavity, a dead-end sac that serves both for digestion ("gastro-") and for transport ("vascular") (Figure 49.1a). The cells of some other invertebrates are served by highly branched gastrovascular systems, and many have flattened body shapes that maximize the surface area of the animal that is in contact with the external environment (Figure 49.1b). •

Large surface-to-volume ratios and branched gastrovascular systems cannot satisfy the needs of larger animals with many layers of cells. The cells of these animals are surrounded by internal, but extracellular, fluids—commonly called tissue fluids. Circulatory systems carry materials to and from all regions of the body to maintain the optimum composition of the tissue fluids, which in turn serve the needs of the cells. Terrestrial animals require circulatory systems because none of their cells are bathed by an external aqueous medium, and all their cells must be served by tissue fluids.

Open circulatory systems move tissue fluid

The simplest circulatory systems squeeze tissue fluid through intercellular spaces and the animal moves. In these open circulatory systems, there is no distinction between tissue fluid and blood. Usually a muscular pump, or heart, assists the distribution of the fluid. The contractions of the heart propel the tissue fluid through vessels leading to different regions of the body, but the fluid leaves those vessels to trickle through the tissues and eventually return to the heart. In the arthropod shown in Figure 49.2a, the fluid returns to the heart through y-shaped holes called ostia. In the mollusk in Figure 49.2b, open vessels aid in the return of tissue fluid to the heart.

Closed circulatory systems circulate blood through tissues

In a closed circulatory system, a system of vessels keeps circulating blood separate from the tissue fluid. Blood is pumped through this vascular system by one or more muscular hearts, and some components of the blood never leave the vessels.

In arthropods, tissue fluid reenters the heart through the ostia.

Anterior

Hearts

Ventral vessel

49.3 A Closed Circulatory System

In a closed circulatory system, blood is confined to the blood vessels, kept separate from the tissue fluid, and pumped by one or more muscular hearts. The earthworm, with large dorsal and ventral blood vessels and a branching network of smaller vessels, exemplifies this type of system.

A simple example of a closed circulatory system is that of the earthworm/an annelid (see Figure 31.23). One large blood vessel on the ventral side of the earthworm carries blood from its anterior end to its posterior end. Smaller vessels branch off and transport the blood to even smaller vessels serving the tissues in each segment of the worm's body. In the smallest vessels, respiratory gases, nutrients, and metabolic wastes diffuse between the blood and the tissue fluid. The blood then flows from these vessels into larger vessels that lead into one large vessel on the dorsal side of the worm. The dorsal vessel carries the blood from the posterior to the anterior end of the body. Five pairs of vessels connect the large dorsal and ventral vessels in the anterior end, thus completing the circuit (Figure 49.3). The dorsal vessel and the five connecting vessels serve as hearts for the earthworm; their contractions keep the blood circulating. The direction of circulation is determined by one-way valves in the dorsal and connecting vessels.

Closed circulatory systems have several advantages over open systems!

- ▶ Blood can flow more rapidly through vessels than through intercellular spaces, and therefore can transport nutrients and wastes to and from tissues more rapidly.
- ▶ By changing resistances in the vessels, closed systems can selectively direct blood to specific tissues.
- ▶ Cellular elements and large molecules that aid in the transport of hormones and nutrients can be kept within the vessels.

Overall, closed circulatory systems can support higher levels of metabolic activity, especially in larger animals. How, then, do highly active insect species achieve high levels of metabolic output with their open cir-

culatory systems? One answer to this question can be found in Chapter 48: Insects do not depend on their circulatory systems for respiratory gas exchange (see Figure 48.5).

Vertebrate Circulatory Systems

Vertebrates have closed circulatory systems and hearts with two or more chambers. Valves between the chambers, and between the chambers and the vessels, prevent the back-flow of blood when the heart contracts.

As we explore the features of the circulatory systems of the different classes of vertebrates, a general evolutionary theme will become apparent: there is a progressively more complete separation of the circulation of blood to the gas exchange organ from the circulation of blood to the rest of the body. In fishes, blood is pumped from the heart to the gills and then to the tissues of the body and back to the heart. In birds and mammals, blood is pumped from the heart to the lungs and back to the heart in a pulmonary circuit, and then from the heart to the rest of the body and back to the heart in a systemic circuit. We will trace the evolution of the separation of the circulation into two circuits.

The closed vascular system of vertebrates includes arteries that carry blood away from the heart and veins that carry blood back to the heart. Arterioles are small arteries, and venules are small veins. Capillaries are tiny, thin-walled vessels that permit the exchange of materials between the blood and the tissue fluid only across capillary walls.

Fishes have two-chambered hearts

The fish heart has two chambers. A less muscular chamber, called the atrium, receives blood from the body and pumps it into a more muscular chamber, the ventricle. The ventricle pumps the blood to the gills, where gases are exchanged. Blood leaving the gills collects in a large dorsal artery, the aorta, which distributes blood to smaller arteries and arterioles leading to all the organs and tissues of the body. In the tissues, blood flows through beds of tiny capillaries, collects in venules and veins, and eventually returns to the heart.

Gills

■ Oxygenated blood

1 Deoxygenated blood

Fishes have a heart with two chambers: a single atrium and a single ventricle.

Aorta

Systemic capillaries

Most of the pressure imparted to the blood by the contraction of the ventricle is dissipated by the high resistance of the narrow spaces through which blood flows in the

CIRCULATORY SYSTEMS 869

gills. As a result, blood entering the aorta of the fish is under low pressure, limiting the capacity of the fish circulatory system to supply the tissues with oxygen and nutrients. This limitation on arterial blood pressure does not seem to hamper the performance of many rapidly swimming species, such as tuna and marlin.

The evolutionary transition from breathing water to breathing air had important consequences for the vertebrate circulatory system. An example of how the system changed to serve a primitive lung is seen the African lung-fish. These fish are periodically exposed to water with low oxygen content or to situations in which their aquatic environment dries up. Their adaptation for dealing with these conditions is an outpocketing of the gut that serves as a lung. The lung contains many thin-walled blood vessels, so blood flowing through those vessels can pick up oxygen from air gulped into the lung.

How does the circulatory system take advantage of this new organ? The last pair of gill arteries is modified to carry blood to the lung, and a new vessel carries oxygenated blood from the lung back to the heart. In addition, two other gill arches have lost their gills, and their blood vessels deliver blood from the heart directly to the dorsal aorta. Because a few of the gill arches retain gills, the African lung-fish can breathe either air or water.

Gills

The lungfish heart has two atria, one receiving oxygenated blood from the lung and one deoxygenated blood from the body.

Lung

The lungfish heart has adaptations that partially separate the flow of its blood into pulmonary and systemic circuits. Unlike other fishes, the lungfish has a partly divided atrium; the left side receives oxygenated blood from the lungs, and the right side receives deoxygenated blood from the other tissues. These two bloodstreams stay mostly separate as they flow through the ventricle and the large vessel leading to the gill arches, so that the oxygenated blood goes to the gill arteries leading to the dorsal aorta, and the deoxygenated blood goes to the arches with functional gills and to the lung.

Amphibians have three-chambered hearts

Pulmonary and systemic circulation are partly separated in adult amphibians. A single ventricle pumps blood to the lungs and to the rest of the body. Two atria receive blood returning to the heart. One receives oxygenated blood from the lungs, and the other receives deoxygenated blood from the body.

Because both atria deliver blood to the same ventricle, the oxygenated and deoxygenated blood could mix so that blood going to the tissues would not carry a full load of oxygen. Mixing is limited, however, because anatomical features of the ventricle direct the flow of deoxygenated blood from the right atrium to the pulmonary circuit and the flow of oxygenated blood from the left atrium to the aorta.

Lung

■ Oxygenated TM blood

~| Deoxygenated LJ blood

j Mixed blood

Right atrium

In adult amphibians, the

pulmonary and systemic circuits are partially separated. The heart has three chambers.

The advantage of this partial separation of pulmonary and systemic circulation is that the high resistance of the gas exchange organ no longer lies between the heart and the tissues. Therefore, the amphibian heart delivers blood to the aorta, and hence to the body, at a higher pressure than the fish heart does.

Reptiles have exquisite control of pulmonary and systemic circulation

Turtles, snakes, and lizards are commonly said to have three-chambered hearts, while crocodilians (crocodiles and alligators) are said to have four-chambered hearts. But this statement is an oversimplification. The hearts of all these animals have two separate atria and a ventricle that is divided in a complex way so that mixing of oxygenated and deoxygenated blood is minimized.

The most important and unusual feature of reptilian and crocodilian hearts is their ability to alter the distribution of blood going to the lungs and to the rest of the body. Consider the behavior, ecology, and physiology of these animals. Despite the common image of turtles as being slow and plodding, reptiles and crocodilians can be fast, active, powerful animals. They can also be inactive for long periods of time, during which they have metabolic rates much lower than the resting metabolic rates of birds and mammals. The enormous range of metabolic demands in these animals means that they do not have to breathe continuously. Some species are also accomplished divers and spend long periods underwater where they cannot breathe.

To understand the wonderful adaptations of the reptilian and crocodilian hearts, you have to realize that there is no benefit in sending blood to the lungs when an animal is not breathing. The hearts of these animals circulate blood through their lungs and then to the rest of their bodies when they are breathing, but when they are not breathing, they can bypass the lung circuit and pump all the blood around the body. How do they accomplish this switching?

870 CHAPTER FORTY-NINE

Reptiles have two aortas instead of one. This simplified representation of reptilian cardiovascular anatomy shows that the right aorta can receive blood from either the right side or the left side of the ventricle:

■ Oxygenated blood

~| Deoxygenated blood

I Mixed blood

Lung

The reptilian ventricle is partly divided by a septum to direct oxygenated blood to the body and deoxygenated blood to the lungs.

Right aorta

When the animal is breathing air, two factors cause blood from the right side of the ventricle to go preferentially into the pulmonary circuit rather than into the systemic circuit. First, the resistance in the pulmonary circuit is lower than that in the systemic circuit. Second, there is a slight asynchrony in the timing of ventricular contraction, so the blood in the right side of the ventricle tends to be ejected slightly before the blood in the left side. As the ventricle contracts, the deoxygenated blood in the right side of the ventricle moves first into the lung circuit. When the oxygenated blood in the left side of the ventricle starts to move, it encounters resistance in the lung circuit, which is already filled with the deoxygenated blood from the right side. Therefore the blood from the left side tends to flow into the two aortas.

When the reptile stops breathing, blood flow is rerouted by constriction of vessels in the lung circuit. As resistance in the lung circuit increases, the blood from the right side of the ventricle tends to be directed into one of the aortas. As a result, blood from both sides of the ventricle flows through the aortas to the systemic circuit.

The ability of snakes, lizards, and turtles to redirect blood flow from the lung circuit to the systemic circuit depends on the incomplete division of their ventricles. Crocodilians have true four-chambered hearts with completely divided ventricles. Yet the crocodilians have not lost the ability to shunt blood from the lung circuit when they are not breathing. The crocodilians have one aorta originating in the left ventricle and one aorta originating in the right ventricle. However, a short

channel connects these two aortas just after they leave the heart.

Because the crocodilians' ventricles are separate, they can generate different pressures when they contract. When the animal is breathing, the pressure in the left ventricle and the left aorta is higher than the pressure in the right ventricle. This higher pressure is communicated through the connecting channel to the right aorta, and this high back pressure prevents right-ventricle blood from entering that aorta. As a result, both aortas carry blood from the left ventricle, and the blood from the right ventricle flows to the lung circuit.

■ Oxygenated blood

I Deoxygenated L i blood

J Mixed blood

Lung

Crocodilians have completely divided ventricles, but they still have the ability to alter the distribution of blood to the pulmonary and systemic circuits because of a connection between two of the major vessels leaving the heart.

Aorta from right ventricle

Aorta from left ventricle

When a crocodilian is not breathing, constriction of vessels in the lung circuit increases the resistance in that circuit. As a result, pressure builds up in the right ventricle to a level that exceeds the back pressure in the right aorta. Under these conditions, blood from both ventricles flows through the two aortas and the systemic circuit, and little blood flows into the lung circuit.

You can now appreciate the fact that reptilian and crocodilian hearts are not primitive. Rather, these hearts and their major vessels are highly adapted to operate efficiently over a wide range of metabolic demands.

Birds and mammals have fully separated pulmonary and systemic circuits

The four-chambered hearts of birds and mammals completely separate their pulmonary and systemic circuits.

Right ventricle

Systemic

► Oxygenated and deoxygenated blood cannot mix, and therefore the systemic circuit is always receiving blood with the highest oxygen content.

► Respiratory gas exchange is maximized because the blood with the lowest oxygen content and highest CO₂ content is sent

to the lungs.

► Separate systemic and pulmonary circuits can operate at different pressures.

The tissues of birds and mammals have high nutrient demands and thus a very high density of the smallest vessels, the capillaries. Many small vessels present lots of resistance to the flow of blood. Therefore, high pressure is re-

quired in the systemic circuits of birds and mammals. Their pulmonary circuits do not have as many capillaries and as high resistances as their systemic circuits, so the pulmonary circuits of birds and mammals can run at lower pressures. „ ^ _ -

The Human Heart: Two Pumps in One

Like all other mammalian hearts, the human heart has four chambers: two atria and two ventricles (Figure 49.4). The atrium and ventricle on the right side of your body are called the right atrium and right ventricle. They can be thought of as the right heart. The atrium and ventricle on the left side of your body are called the left atrium and left ventricle. They can be thought of as the left heart. The right heart pumps blood through the pulmonary circuit, and the left heart pumps blood through the systemic circuit. ^

valves between the atria and ventricles, the atrioventricular valves, prevent backflow of blood into the atria when the ventricles contract. The pulmonary valve and the aortic valve are situated between the ventricles and the arteries, ^^^^AP prevent the backflow of blood into the ventricles.

In what follows, we'll first focus on the flow of blood through the heart and through the body. Then we'll exam-

Let's follow the circulation of the blood through the heart, starting in the right heart. The right atrium receives deoxygenated blood from the superior vena cava and the infe-

§JThe right ventricle pumps the blood into the pulmonary circuit.

rior vena cava (see Figure 49.4), large veins that collect blood from the upper and lower body, respectively. The veins of the heart itself also drain into the right atrium. From the right atrium, the blood flows into the right ventricle. Most of the filling of the ventricle is due to passive flow while the heart is relaxed between beats. Just at the end of this period of ventricular filling, the atrium contracts and adds a little more blood to the ventricular volume. The right ventricle then contracts, pumping blood into the pul-

monarily~artery, which transports the blood

g-

The pulmonary veins lead oxygenated blood from the lungs to the left atrium, from which the blood enters the left ventricle. As with the right side of the heart, most left ventricular filling is passive, and ventricular volume is topped off by contraction of the atrium just at the end of the period of filling.

The walls of the left ventricle are powerful muscles that contract around the top with a wringing motion starting from the bottom. When pressure in the left ventricle is high enough to push open the aortic valve, the blood rushes into the aorta to begin its circulation throughout the body and eventually back to the right atrium. In Figure 49.4, observe that the left ventricle is more massive than the right ventricle. Because there are many more arterioles and capillaries in the systemic circuit than in the pulmonary circuit, resistance is higher in the systemic circuit, and the left ventricle must squeeze with greater force than the right, even though both are pumping the same volume of blood.

Figure 49.4 The Human Heart and Circulation

In the human heart, blood flows from right heart to lungs to left heart to body. The atrioventricular valves prevent blood from flowing back into the atria when the ventricles contract. The pulmonary and aortic valves prevent blood from flowing back into ventricles from the arteries when the ventricles relax.

The pumping of the heart—the contraction of the two atria followed by the contraction of the two ventricles, and then relaxation—is the cardiac cycle. Contraction of the ventricles is called systole, and relaxation of the ventricles is diastole (Figure 49.5). Just at the end of diastole, the atria contract and top off the volume of blood in the ventricles. The sounds of the cardiac cycle, the "lub-dub" heard through a stethoscope placed on the chest, are created by the slamming shut of the heart valves. The shutting and opening of these valves is simply a mechanical event resulting from pressure differences on the two sides of the valves. As the ventricles begin to contract, the pressure in the ventricles rises above the pressure in the atria, and the atrioventricular valves close ("lub"). When the ventricles begin to relax, the high back pressure in the aorta and pulmonary arteries causes the aortic and pulmonary valves to bang shut ("dub"). Defective valves produce the sounds of heart murmurs. For example, if an atrioventricular valve is defective, blood will flow back into the atrium with a "whoosh" sound following the "lub."

The cardiac cycle can be felt in the pulsation of arteries such as the one that supplies blood to your hand. You can feel your pulse by placing two fingers from one hand

49.5 The Cardiac Cycle

The rhythmic contraction (systole) and relaxation (diastole) of the ventricles is called the cardiac cycle.

lightly over the wrist of the other hand just below the thumb. During systole, blood surges through the arteries of your arm and hand, and you can feel the surge as a pulsing of the artery in your wrist.

Blood pressure changes associated with the cardiac cycle can be measured in the large artery in your arm by using an inflatable pressure cuff called a sphygmomanometer and a stethoscope (Figure 49.6). This method measures the minimum pressure necessary to compress an artery so that blood does not flow through it at all (the systolic value) and the minimum pressure that permits intermittent flow through the artery (the diastolic value). In a conventional blood pressure reading, the systolic value is placed over the diastolic value. Normal values for a young adult might be 120 mm of mercury (Hg) during systole and 80 mm Hg during diastole, or 120/80.

The heartbeat originates in the cardiac muscle

Cardiac muscle, as we saw in Chapter 47, has some unique properties that allow it to function as an effective pump. First, the cardiac muscle cells are in electrical continuity with each other. Gap junctions enable action potentials to spread rapidly from one cell to the next. Because a spreading action potential stimulates contraction, large groups of cardiac muscle cells contract in unison. This coordinated contraction is important for pumping blood.

"Lub": The ventricles contract, the atrioventricular valve shuts, and pressure in the ventricles builds up until the aortic and pulmonary valves open.

"Dub": The ventricles relax; pressure in the ventricles falls at the end of systole, and since pressure is higher in the aorta, the aortic and pulmonary valves slam shut.

Pulsing sounds

Pulsing sound gives way to smooth "whoosh" of blood flow

Pressure in the cuff is increased to close both the arteries and veins. No sound is audible.

Pressure in the cuff is gradually lowered until the sound of a pulsing flow of blood through the constriction in the artery during systole is heard. At this time, pressure in the cuff is just below the peak systolic pressure in the artery.

Pressure is further lowered until the sound becomes continuous when the artery remains open for an entire cardiac cycle. The cuff is just below the diastolic pressure in the artery at this time. Blood pressure in this person is 120/70.

49.6 Measuring Blood Pressure

Blood pressure in the major artery of the arm can be measured with an inflatable pressure cuff called a sphygmomanometer.

Second, some cardiac muscle cells have the ability to initiate action potentials

system. These cells stimulate neighboring cells to contract, thereby acting as pacemakers. The important characteristic of a pacemaker cell is that its resting membrane potential gradually becomes less negative until it reaches the threshold voltage for initiating an action potential (Figure 49.7).

Sympathetic autonomic activity increases the heart rate.

Parasympathetic autonomic activity slows the heart rate.

Time

49.7 The Autonomic Nervous System Controls Heart Rate

The resting potentials of the pacemaker cells spontaneously generate action

potentials. Signals from the two divisions of the autonomic nervous system raise and lower the heart rate, respectively.

These action potentials look different from the neuronal action potentials you saw in Chapter 41 because the depolarization is due primarily to the opening of voltage-gated calcium channels rather than voltage-gated sodium channels.

Like neurons, cardiac muscle regularizes in part by opening potassium channels. The potassium channels in cardiac pacemaker cells, however, are unique. After an action potential, they open, causing the membrane potential to fall to its most negative level. Then they gradually close, and as they do so, the membrane potential becomes less negative—it slowly depolarizes. Sodium and calcium channels contribute to this gradual depolarization between action potentials. When membrane potential reaches threshold for the voltage-gated calcium channels, another action potential occurs.

The nervous system controls the heartbeat (speeds it up or slows it down) by influencing the rate at which pacemaker cells gradually depolarize between action potentials. Acetylcholine released by parasympathetic nerve endings onto the pacemaker cells slows their rate of depolarization and thereby

lowers heart rate. No

by sympathetic nerve endings onto the pacemaker cells increases their rate of depolarization and thereby speeds the heart rate (see Figure 49.7).

Under normal circumstances, the heartbeat originates from pacemaker cells located at the junction of the superior vena cava and right atrium, in the sinoatrial node (Figure 49.8). An action potential spreads from the sinoatrial node across the atrial walls, causing the two atria to contract in unison. Since there are no gap junctions between the atria and the ventricles, however, this depolarization does not

QRS

QRS

"

QRS

Besides detecting rhythmic irregularities in the heartbeat (arrhythmias), EKGs can detect damage to the heart muscle (infarctions) or decreased blood supply to the heart muscle (ischemias) by changes in the size and shape of the EKG curves.

The action potential initiated in the atria passes to the ventricles through another node of modified cardiac muscle cells, the atrioventricular node. The atrioventricular node passes the action potential on to the ventricles via modified muscle fibers called the bundle of His. The bundle of His divides into right and left branches, which connect with Purkinje fibers that branch throughout the ventricular muscle.

The timing of the spread of the action potential from atria to ventricles is important. The atrioventricular node imposes a short delay in the spread of the action potential from atria to ventricles. Then the action potential spreads very rapidly throughout the ventricles, causing them to contract. Thus the atria contract before the ventricles do, so the blood passes progressively from the atria to the ventricles to the arteries.

(c)

49.9 The Electrocardiogram

An EKG can be used to monitor heart function.

The EKG records the electrical activity of the heart

Electrical events in the cardiac muscle during the cardiac cycle can be recorded by electrodes placed on the surface of the body. Such a recording is called an electrocardiogram, or EKG ("EKG" because the Greek word for heart is kardia, but "ECG" is also used). The EKG is an important tool for diagnosing heart problems.

The action potentials that sweep through the muscles of the atria and the ventricles before they contract are such massive, localized electrical events that they cause electric currents to flow outward from the heart to all parts of the body. Electrodes placed on the surface of the body at different locations—usually on the wrists and ankles—detect those electric currents at different times and therefore register a voltage difference. The appearance of the EKG depends on the exact placement of the electrodes used for the recording. Electrodes placed on the right wrist and left ankle produced the normal EKG shown in Figure 49.9a. The waves of the EKG are designated P, Q, R, S, and T, each letter representing a particular event in the cardiac muscle.

The EKG is used by cardiologists (heart specialists) to diagnose heart problems. Figure 49.9b shows some abnormal EKGs that result from different problems. For patients who have had heart attacks, it is possible to determine which region of the heart has been damaged by placing electrodes at

different locations on the chest. Comparing EKGs from the different electrodes tells the cardiologist which region of the heart is behaving abnormally.

The Vascular System: Arteries, Capillaries, and Veins

Blood circulates throughout the body in a system of blood vessels: arteries, capillaries, and veins. Arteries receive blood from the heart; accordingly, they withstand high pressures. Arteries are important in controlling blood pressure and in the distribution of blood to different organs. Veins, return blood to the heart at low pressures and serve as blood reservoir. Capillaries are the site of all exchanges between the blood and the internal environment. In this section, we see how the structure of each of these vessel types supports its functions. In addition to arteries, capillaries, and veins, we consider another set of vessels, the lymphatic vessels, which return tissue fluid to the blood.

Arteries and arterioles have abundant elastic and muscle fibers

The walls of the large arteries have many elastic fibers that enable them to withstand high pressures (Figure 49.10). These elastic fibers have another important function as

Arteries have lots of elastic fibers and muscle fibers, allowing them to withstand high pressures.

, A^{***}

[r7!^ 49.10 Anatomy of Blood Vessels

The anatomical characteristics of blood vessels match their functions. The total cross-sectional area of capillaries is greater than that of any other class of vessels, and they are more permeable, a characteristic that suits them for their function of exchange of nutrients and wastes with the tissue fluids.

876 CHAPTER FORTY-NINE

well: During systole, they are stretched, and thereby store some of the energy imparted to the blood by the heart. During diastole, they return this energy by squeezing the blood and pushing it forward. As a result, even though the flow of blood through the arterial system pulsates, it is smoother than it would be through a system of rigid pipes.

Smooth muscle cells in the arteries and arterioles make the diameter of these vessels variable. When their diameter changes, their resistance to blood flow changes as well, and the amount of blood flowing through them changes as a result. By influencing the contraction of the smooth muscle in the walls of arteries and arterioles, neural and hormonal mechanisms can control the distribution of blood to the different tissues of the body as well as central blood pressure. The arteries and arterioles are referred to as the resistance vessels because their resistance varies.

Materials are exchanged between blood and tissue fluid in the capillaries

Beds of capillaries lie between arterioles and venules. No cell of the body is more than a couple of cell diameters away from a

capillary. The needs of the cells are served by the exchange of materials between blood and tissue fluid across the capillary walls. Capillaries have thin, permeable walls, and blood flows through them slowly, facilitating this exchange (Figure 49.11).

To anyone who has played with a garden hose, it may seem strange that blood flows through the large arteries rapidly at high pressures, but when it reaches the small capillaries, the pressure and rate of flow decrease. When you restrict the diameter of a garden hose by placing your thumb over the opening, the pressure in the hose increases, which in turn

increases the velocity of the water spraying out of the hose.

This puzzle is solved by two more pieces of information.

First, arterioles are highly branched. When one is restricted, blood flows into other branches, so pressure does not build

,

f

,

V

Red blood cells must pass through capillaries in single file.

49.7 A Narrow Lane

Capillaries have a very small diameter, and blood flows through them slowly.

f

up quickly. Second, each arteriole gives rise to many, many

capillaries. Even though each capillary has a diameter so small that red blood cells must pass through in single file (see Figure 49.11), there are so many capillaries that their total cross-sectional area is much greater than that of any other class of vessel. As a result, all of the capillaries together have a much greater capacity for blood than do the arterioles. Returning to our garden hose analogy, if we connect the hose to many junctions leading to small irrigation tubes, the pressure and the flow in each of the irrigation tubes will be quite low.

Materials are exchanged in capillary beds by filtration, osmosis, and diffusion

The walls of capillaries are made of a single layer of thin endothelial cells. In most tissues of the body other than the brain, these tubes of endothelial cells have tiny holes called fenestrations. Surrounding the endothelial cells is a very permeable basal lamina. So, capillaries are leaky. They are permeable to water, to some ions, and to some small molecules, but not to large molecules such as proteins. Blood pressure therefore tends to squeeze water and some solutes out of the capillaries, and into the surrounding intercellular spaces. This process is called filtration. The large molecules that cannot cross the capillary wall create a difference in osmotic potential (also called osmotic pressure) between the plasma and the tissue fluid, which tends to draw water back into the capillary.

Recent research suggests that bicarbonate ions in the capillary plasma are an important contributor to the osmotic attraction of water back into the capillary. As we saw in Chapter 48, CO_2 diffuses into the plasma as the blood flows through the capillary. The conversion of this CO_2 to

bicarbonate ions is catalyzed by the enzyme carbonic anhydrase. Therefore, there is a rise in bicarbonate concentration as blood flows through the capillary, and this increased concentration contributes to the resorption of water from the tissue fluid.

Blood pressure is highest on the arterial side of a capillary bed and steadily decreases as the blood flows to the venous side. Therefore, more water is squeezed out of the capillaries on the arterial side of the bed. The osmotic potential is pulling water back into the capillary rises as blood flows toward the venous side. Gradually, osmotic potential becomes dominant.

The dominant force, pulling water back into the plasma. The interaction of these two opposing forces— blood pressure and osmotic potential—

π versus osmotic potential—determines the net flow of water $\Delta \pi$ between the plasma and the tissue fluid (Figure 49.12). The balance between blood pressure and osmotic potential changes if the blood pressure in the arterioles or the permeability of the capillary walls changes. Such a change leads to the inflammation that accompanies injuries to the skin or allergic reactions. A major mediator of inflammation is a hormone called histamine that is released mainly by white blood cells, called mast cells, that move to the damaged tissue (see Chapter 41). Histamine relaxes the smooth muscle of the arterioles, thus increasing blood flow to the damaged tissue and increasing pressure in the capillaries.

Fluid is squeezed out of the capillary by blood pressure.

Fluid is pulled back into the capillary by osmotic potential.

49.12 A Balance of Opposite Forces

Blood pressure and osmotic attraction (both expressed as millimeters of mercury, mm HG) control the exchange of fluids between blood vessels and intercellular space.

Histamine also increases the permeability of the capillaries,

CIRCULATORY SYSTEMS 877

The capillaries in different tissues, however, are differentially selective as to the sizes of molecules that can pass through them. In all auxiliaries. $Q : \text{CO}^+$, glucose, lactate, and small ions such as Na^+ and Cl^- can cross. The capillaries of the brain do not have fenestrations, and therefore not much else can pass through them unless it is a lipid-soluble substance such as alcohol. This high selectivity of brain capillaries is known as the blood-brain barrier (see Chapter 44).

In other tissues, the capillaries are much less selective. Such capillaries are found in the digestive tract, where nutrients are absorbed, and in the kidneys, where wastes are filtered. Some capillaries have large gaps that permit the movement of even larger substances, such as red blood cells. These capillaries are found in the bone marrow, spleen, and liver. Substances move across many capillary walls by endocytosis (see Chapter 5).

Lymphatic vessels return tissue fluid to the blood

The tissue fluid that accumulates outside the capillaries contains water and small molecules, but no red blood cells, and less protein than there is in blood. A separate system of vessels—the lymphatic system—returns tissue fluid to the blood.

After entering the lymphatic vessels, the tissue fluid is called lymph. Fine lymphatic capillaries merge progressively into larger and larger vessels and end in a major vessel—the thoracic duct—that empties into the superior vena cava, returning blood to the heart (see Figure 19.1). Lymphatic vessels have one-way valves that keep the lymph flowing toward the thoracic duct. The force propelling the lymph is pressure on the lymphatic vessels from the contractions of nearby skeletal muscles.

Mammals and birds have lymph nodes along the major lymphatic vessels. Lymph nodes are an important component of the defensive machinery of the body (see Chapter 19). They are a major site of lymphocyte production and of

so that more water leaves the vessels. The accumulation of the phagocytic action that removes microorganisms and

fluid in the intercellular spaces causes the tissue to swell, a condition known as edema. The use of drugs called antihistamines can alleviate inflammation and allergic reactions.

The loss of water from capillaries increases if the protein content of the blood decreases, as is seen in cases of liver failure due to alcoholism or liver disease. The liver is the major producer of blood proteins. If it fails, blood protein levels fall. With a lower protein concentration in the plasma, there is less of an osmotic potential to pull water back into the capillaries. The result is that tissue fluid builds up, swelling the abdomen and the extremities.

Which specific small molecules can cross a capillary wall depends on the architecture of the capillary, the type of substance, and the concentration gradient of the substance between the blood and the tissue fluid. Capillary walls consist of the plasma membranes of endothelial cells and, as mentioned, may have actual holes (fenestrations) in them. Therefore, lipid-soluble substances and many small solute molecules can pass through them from an area of higher concentration to one of lower concentration (see Chapter 5).

Other foreign materials from the circulation. The lymph nodes also act as mechanical filters. Particles become trapped there and are digested by the phagocytes that are abundant in the nodes.

Lymph nodes swell during infection. Some of them, particularly those on the sides of the neck or in the armpits, become noticeable when they swell. The nodes also trap metastasized cancer cells—that is, those that have broken free of the original tumor. Because such cells may start additional tumors, surgeons often remove the neighboring lymph nodes when they excise a malignant tumor.

Blood flows back to the heart through veins

The pressure of the blood flowing from capillaries to venules is extremely low, and is insufficient to propel blood back to the heart. Blood tends to accumulate in veins, and the walls of veins are more expandable than the walls of arteries. As much as 80 percent of the total blood volume may be in the veins at any one time. Because of their high capacity to store blood, veins are sometimes called blood reservoirs.

878 CHAPTER FORTY-NINE

Blood must be returned from the veins to the heart so that circulation can continue. If the veins are above the level of the heart, gravity helps blood flow, but below the level of the heart, gravity.

If too much blood remains in the veins, then too little blood returns to the heart, and thus too little blood is pumped to the brain; a person may faint as a result. Fainting is self-correcting: if a person falls, thereby moving out of the position in which gravity caused blood to accumulate in the lower body. But means other than fainting also move blood from the tissues back to the heart.

The most important of the forces that propel venous and lymphatic return from the regions of the body below the heart is the squeezing of the vessels by the contractions of skeletal muscles. As muscles contract, the vessels are compressed, and the blood is squeezed through them. Blood flow might be temporarily obstructed during a

■ Δ

a***

prolonged muscle contraction, but with relaxation of the muscles the blood is free to move again.

One-way valves within the veins prevent the backflow of blood. Thus whenever a vein is squeezed, blood is propelled forward toward the heart (Figure 49.13). As we have already noted, the lymphatic vessels have similar one-way valves.

Gravity causes blood accumulation in veins and edema. The back pressure that builds up in the capillaries when blood

accumulates in the veins shifts the balance between blood pressure and osmotic potential so that there is a net movement of fluid into the intercellular spaces. That is why you have trouble putting your shoes back on after you sit for a long time with your shoes off, such as on an airline flight. In persons with very expandable veins, the veins can become so stretched that the valves can no longer prevent backflow. This condition produces (microscopic) (swollen) veins. Draining of these veins is highly desirable and can be aided by wearing support hose and periodically elevating the legs above the level of the heart.

During exercise, the squeezing action of muscles on veins speeds blood toward the heart to be pumped to the lungs and then to the respiring tissues. As an animal runs, its legs act as auxiliary vascular pumps, returning blood to the heart from the veins of the lower body. As a greater volume of blood is returned to the heart, the heart contracts more forcefully, and its pumping action becomes more effective. This strengthening of the heartbeat is due to a property of cardiac muscle cells referred to as the Frank-Starling law: If the cells are stretched, as they are when the volume of returning blood increases, they contract more forcefully. This principle holds (within a certain range) whenever venous return increases, by any mechanism.

The actions of breathing also help return venous blood to the heart. The ventilatory muscles create suction that pulls air into the lungs (see Chapter 48), and this suction also pulls blood and lymph toward the chest, increasing venous return to the right atrium.

Some smooth muscles in the walls of veins move venous blood back to the heart by constricting the veins and moving

or

or?

Contractions of skeletal muscles squeeze the veins.

Muscle contracts

Valve closed 111 Valve open

\\

This squeezing moves the blood in the veins toward the heart because of one-way valves that prevent backflow.

Muscle relaxes

Valve open

Valve closed

Blood is propelled forward by muscle contractions and, possibly, by gravity.

Back pressure is due to contractions of atria, contractions of muscles, and, possibly, gravity.

49.73 One-Way Flow

Veins have valves that prevent blood from flowing backward.

ing the blood forward. These muscles are rare in most veins and are totally absent from lymphatic vessels in humans. They do not play a major role in venous return. However, in the largest veins closest to the heart, contraction of smooth muscles at the onset of exercise can suddenly increase venous return and stimulate the heart in accord with the Frank-Starling law, thus increasing cardiac output.

Will you die of cardiovascular disease?

Cardiovascular disease is by far the largest single killer in the United States and Europe; it is responsible for about half of all deaths each year. The immediate cause of most of these deaths is heart attack or stroke, but those events are the end result of a disease called atherosclerosis (hardening of the arteries) that begins many years before symptoms are detected. Hence atherosclerosis is called the "silent killer." What is atherosclerosis, and how can it be prevented?

Healthy arteries have a smooth internal lining of endothelial cells (Figure 49. 14a). This lining can be damaged by chronic high blood pressure, smoking, a high-fat diet or microorganisms. Deposits called atheromas begin to form at sites of endothelial damage. First the endothelial cells at the damaged site swell and proliferate; then they are joined by smooth muscle cells migrating from below. Lipids, espe-

^

(fl)

Thrombus

(b)

daily cholesterol, are deposited in these cells, so the plaque becomes fatty. Fibrous connective tissue invades the plaque and, along with deposits of calcium, makes the artery wall less elastic; this process is what gives us the terms "atherosclerosis" and "hardening of the arteries." The growing plaque narrows the artery and causes turbulence in the blood flowing over it. Blood platelets (discussed later in this chapter) stick to the plaque and initiate the formation of a blood clot, called a thrombus, which further blocks the artery (Figure 49. 14b).

The blood supply to the heart itself flows through the coronary arteries. These arteries are highly susceptible to atherosclerosis; as they narrow, blood flow to the heart muscles decreases. Chest pains and shortness of breath during mild exertion are symptoms of this condition. A person with atherosclerosis is at high risk of forming a thrombus in a coronary artery. This condition, called coronary thrombosis, can totally block the vessel, causing a heart attack, or coronary infarction.

~~. A piece of a thrombus that breaks loose, called an embolus,

is likely to travel to and become lodged in a vessel of

smaller diameter, blocking its flow (a condition referred to

as an embolism). Arteries already narrowed by plaque for-

V-tT ^

mation are likely places for an embolus to lodge. An embolism in an artery in the brain causes the cells fed by that artery to die. This event is called a stroke. The specific damage resulting from a stroke, such as memory loss, speech impairment, or paralysis, depends on the location of the blocked artery.

The most important approach to cardiovascular disease is prevention, not treatment. Probably the most important determinant of whether or not you will get atherosclerosis is your genetic predisposition. Environmental risk factors also play a large role, however, and if you do have a genetic predisposition to atherosclerosis, it is even more important to minimize environmental risk factors. These factors include high-fat and high-cholesterol diets, smoking, a sedentary lifestyle, hypertension (high blood pressure), obesity,

and certain medical conditions such as diabetes. Changes in diet and behavior can prevent and reverse atherosclerosis and help fend off the silent killer.

Blood: A Fluid Tissue

Blood is classified as a connective tissue: it has cellular ele-

ments suspended in an extracellular matrix of complex, yet specific, composition. The unusual feature of blood is that the extracellular matrix is a liquid, so blood is a fluid tissue.

The cells of the blood can be separated from the fluid matrix, called plasma, by centrifugation (Figure 49.15). If a 100-ml sample of blood is spun in a centrifuge, all the cells move to the bottom of the tube, leaving the straw-colored, clear plasma on top. The packed volume, or hematocrit, is the percentage of the blood volume made up by cells. Normal hematocrit is about 38 percent for women and 46 percent for men, but these values can vary considerably. They are usually higher, for example, in people who live and work at high altitudes because the low oxygen concentrations at high altitudes stimulate the production of more red blood cells.

In this section, we consider two classes of cellular elements in blood: the red blood cells and the platelets, which are pinched-off fragments of cells. We have already studied the other important class of blood cells—white blood cells, or leucocytes—in Chapter 19. Finally, we take a closer look at the content of plasma.

Red blood cells transport respiratory gases

Most of the cells in the blood are erythrocytes, or red blood cells. Mature red blood cells are biconcave, flexible discs packed with hemoglobin. Their function is to transport the respiratory gases. Their shape gives them a large surface area for gas exchange, and their flexibility enables them to squeeze through narrow capillaries. There are about 5 to 6 million red blood cells per milliliter of blood.

49.15 The Composition of Blood

Blood consists of a complex aqueous solution, numerous cell types, and cell fragments.

Red blood cells are generated by special cells in the bone marrow called stem cells, particularly in the bone marrow of the ribs, breastbone, pelvis, and vertebrae. Red blood cell production is controlled by a hormone, erythropoietin, which is released by cells in the kidney in response to insufficient oxygen (hypoxia) in the tissues (Figure 49.16a). Many tissues respond to hypoxia by expressing a transcription factor called hypoxia-inducible factor 1 (HIF-1). In the kidney, HIF-1 activates the gene encoding erythropoietin. Cells in the kidney produce erythropoietin, which stimulates the stem cells to produce red blood cells.

Under normal conditions, your bone marrow produces about 2 million red blood cells every second. The developing, immature red blood cells divide many times while still in the bone marrow, and during this time they produce hemoglobin. When the hemoglobin content of a red blood cell

approaches about 30 percent, its nucleus, endoplasmic reticulum, Golgi apparatus, and mitochondria begin to break down. This process is almost complete when the new red blood cell squeezes between the endothelial cells of capillaries in the bone marrow and enters the circulation.

Each red blood cell circulates for about 120 days and then breaks down. As it gets older, its membrane becomes less flexible and more fragile. Therefore, old red blood cells frequently rupture as they bend to fit through narrow capillaries. One place where they are really squeezed is in the

spleen, an organ that sits near the stomach in the upper left side of the abdominal cavity. The spleen has many venous cavities, or sinuses, that serve as a reservoir for red blood cells, but to get into the sinuses, the red blood cells must squeeze between spleen cells. Old red blood cells are likely to be ruptured by this squeezing and when they are, their remnants are broken down by macrophages.

Platelets are essential for blood clotting

Besides producing red blood cells, the stem cells in the bone marrow produce the leukocytes and cells called megakaryocytes. Megakaryocytes are large cells that remain in the bone marrow and continually break off cell fragments called platelets (Figure 49.16/). A platelet is just a tiny fragment of a cell, but it is packed with enzymes and chemicals necessary for its function: sealing leaks in blood vessels and initiating blood clotting.

Damage to a blood vessel exposes collagen fibers. When a platelet encounters collagen fibers, it is activated. It swells, becomes irregularly shaped and sticky, and releases chemicals that activate other platelets and initiate the clotting of

bloodr The sticky platelets form a plug at the damaged site, and the subsequent clotting forms a stronger patch on the vessel.

~The~doTtmg of blood requires many steps and many clotting faejp rs. The absence oi any one o\ these factors can impair clotting and cause excessive bleeding. Because the lixejj^njduces most of the clotting factors, liver diseases such as he4^aiiis_ and cirrhosis can result in exce ssive

bleeding. The sex-linked trait hemophilia (see Chapter 10) is an example of a genetic inability tevp roduce one o f the clotting factors.

Blood clotting factors participate in a cascade of steps that activate other substances circulating in the blood. The cascade begins with cell damage and-plaJ£leLac±Lvation and leads to the con version of an inactive circulating enzyme, prothrombin, to its activ e form, thrombi n. Thrombin causes olecules of a plasma protein called fibrinogen to polymerize and form fibrin threads. The fibrin threads form the meshw ork that clo ts the blood, seals the vessel, and provides a scaffold for the formation of scar tissue (Figure 49.17).

Platelets

Plasma is a complex solution

Plasma, the clear straw-colored liquid portion of the blood, contains gases, ions, nutrient molecules, proteins, and other molecules, such as nonprotein hormones. Most of the ions are Na^+ and Cl^- (hence the salty taste of blood), but many other ions are also present. Nutrient molecules in plasma include glucose, amino acids, lipids, cholesterol, and lactic acid.

The circulating proteins in plasma have many functions. We have just noted proteins that function in blood clotting; others of interest include albumin, which is partly responsible for the osmotic potential in capillaries that prevents a massive loss of water from plasma to intercellular spaces; antibodies (the immunoglobulins); hormones; and various carrier molecules, such as transferrin, which carries iron from the gut to where it is stored or used.

(f)

An injury to the lining of a blood vessel exposes collagen fibers; platelets adhere and become sticky.

882 CHAPTER FORTY-NINE

Plasma is very similar to tissue fluid in composition, and most of its components move readily between these two fluid compartments of the body. The main difference between the two fluids is the higher concentration of proteins in the plasma.

Precapillary sphincters can shut off blood supply to the capillary bed.

Control and Regulation of Circulation

Arteriole - Capillary —

Muscle fibers (cells).

The circulatory system is controlled and regulated by neural and hormonal mechanisms at both the local and systemic levels. Every tissue requires an adequate supply of blood that is saturated with oxygen, carries essential nutrients, and is relatively free of waste products. The nervous system cannot monitor and control every capillary bed in the body. Instead, each tissue regulates its own blood flow through autoregulatory mechanisms that cause the arterioles to constrict or dilate.

The autoregulatory actions of every capillary bed in every tissue influence the pressure and composition of the arterial blood leaving the heart. If many arterioles suddenly dilate, for example, allowing blood to flow through many more capillary beds, arterial blood pressure falls. If all the newly filled capillary beds contribute metabolic waste products to the blood at one time, the concentration of wastes in the blood returning to the heart increases. Thus events in all the capillary beds throughout the body produce

the combined effects on arterial blood pressure and blood composition. The nervous and endocrine systems respond to these changes by changing the heart rate, and blood distribution to match the metabolic needs of the

body.

Autoregulation matches local flow to local need

The autoregulatory mechanisms that adjust the flow of blood to a tissue are part of the tissue itself, but they can be influenced by the nervous system and certain hormones.

The amount of blood that flows through a capillary bed is controlled by the degree of contraction of the smooth muscle of the arteries and arterioles feeding that bed. The flow of blood in a typical capillary bed is diagrammed in Figure 49.18. Blood flows into the bed from an arteriole. Smooth muscle "cuffs," or precapillary sphincters, on the arteriole can completely shut off the supply of blood to the capillary bed. When the precapillary sphincters are relaxed and the arteriole is open, the arterial blood pressure pushes blood into the capillaries.

Autoregulation depends on the sensitivity of the smooth muscle to its chemical environment. Low O_2 concentrations and high CO_2 concentrations cause the smooth muscle to relax, thus increasing the supply of blood, which brings in more O_2 and carries away CO_2 . Increases in other by-products of metabolism, such as lactate, hydrogen ions, potassium, and adenosine, promote increased blood flow through

Venule

Throughfare channel

Blood flow through a capillary bed is controlled by the constriction of smooth muscle in the arteries and arterioles.

49.78 Local Control of Blood Flow

Low O_2 concentrations or high levels of metabolic by-products cause the smooth muscle of the arteries and arterioles to relax, thus increasing the supply of blood to the capillary bed.

the same mechanism. Hence, activities that increase the metabolism of a tissue also increase blood flow to that tissue.

Arterial pressure is controlled and regulated by hormonal and neural mechanisms

The same smooth muscle of arteries and arterioles that responds to autoregulatory stimuli also responds to signals from the endocrine and central nervous systems. Most arteries and arterioles are innervated by the autonomic nervous system, particularly the sympathetic division. Most sympathetic neurons release norepinephrine, which causes the smooth muscle cells to contract. This constricts the vessels and reduces blood flow. An exception is found in skeletal muscle, in which specialized sympathetic neurons release epinephrine, causing the smooth muscle of the arterioles to relax and the vessels to dilate, increasing blood flow to the muscle, especially during exercise.

Hormones also can cause arterioles to constrict or dilate.

Angiotensin II

Angiotensin II, which has actions similar to those of norepinephrine, is released from the adrenal medulla during exercise

sympathetic activation—the fight-or-flight response. Angiotensin, produced when blood pressure in the kidneys falls, causes arterioles to constrict. Vasopressin, released by the posterior pituitary when blood pressure falls, has similar effects (Figure 49.19). These hormones influence arterioles located for the most part in peripheral tissues (extremities) or in tissues whose functions need not be maintained continuously, (such as the gut). By reducing blood flow in those arterioles, the hormones increase central blood pressure and blood flow to essential organs such as the heart, brain, and kidneys.

49.19 Hormonal Control of Blood Pressure through Vascular Resistance

A drop in arterial pressure reduces blood flow to tissues, resulting in local accumulation of metabolic wastes. This change in the extracellular environment stimulates autoregulatory opening of the arteries, which would lead to a further decrease in central blood pressure if not prevented by the negative feedback mechanisms shown in this diagram, which work by promoting the constriction of arteries in less essential tissues.

Arterial pressure rises

The autonomic nervous system activity that controls heart rate and constriction of blood vessels originates in cardiovascular centers in the medulla of the brain stem. Many inputs converge on this central integrative network and influence the commands it issues via parasympathetic and sympathetic nerves (Figure 49.20). Of special importance is information about changes in blood pressure from stretch receptors in the walls of the great arteries leading to the brain—the aorta and the carotid arteries.

^k

Increased activity in the stretch receptors indicates rising blood pressure and inhibits sympathetic nervous system output. As a result, the heart slows, and arterioles in peripheral tissues dilate. If pressure in the great arteries falls, the activity of the stretch receptors decreases, stimulating sympathetic output. As a result, the heart beats faster, and the arterioles in peripheral tissues constrict. When arterial pressure falls, the change in stretch receptor activity also causes the

hypothalamus to release vasopressin, which helps increase blood pressure by stimulating peripheral arterioles to constrict.

You experience the action of the aortic and carotid stretch receptors when you get up each morning. While you are lying down, your blood pressure is rather evenly distributed from head to toe, but when you get up gravity pulls blood to the lower part of your body. Blood return to the heart decreases, and therefore cardiac output decreases. As a result, the pressure in the aorta and the carotid arteries falls. This change is detected by the carotid and aortic stretch receptors, which initiate corrective responses within two heartbeats. Now imagine the change in blood pressure detected by the carotid stretch receptors in the giraffe in the cover of this book when it raises and lowers its head. The giraffe has a much larger heart than would be expected for a mammal of its size because of the need to generate blood pressure sufficient to pump blood against gravity to a height more than 3 m above its heart.

49.20 Regulating Blood Pressure

The autonomic nervous system controls heart rate in response to information about blood pressure and blood composition that is integrated by regulatory centers in the medulla.

884 CHAPTER FORTY-NINE

Other information that causes the medullary regulatory system to increase heart rate and blood pressure comes from chemoreceptors in the carotid and aortic bodies. These nodules of modified smooth muscle tissue respond to inadequate O₂ supply. If arterial blood flow slows or the O₂ content of the arterial blood falls drastically, these receptors are activated and

send signals to the regulatory center. The regulatory center also receives input from other brain areas. Emotions or the anticipation of intense activity, as at the start of a race, can cause the center to increase heart rate and blood pressure.

Control and regulation in the cardiovascular system begins with the local autoregulatory mechanisms that cause dilation of local arterioles and precapillary sphincters when a tissue needs more oxygen or has accumulated wastes. As more blood flows into the tissues, the central blood pressure falls, and the composition of the blood returning to the heart reflects the exchanges that are occurring in the tissues. Changes in central blood pressure and blood composition are sensed, and both endocrine and central nervous system responses are activated to return blood pressure and composition to normal. Thus circulatory functions are matched to the regional and overall needs of the body.

Cardiovascular control in diving mammals conserves oxygen

We began this chapter with the observation that when a seal begins underwater activity, its heart rate slows and blood flow to all of its tissues except its brain drops dramatically. This "diving reflex" of marine mammals is in stark contrast to our Increase in heart rate and blood flow when we begin exercise. The obvious difference between the situation of the seal and the human is that the human has access to atmospheric oxygen during exercise and the diving seal does not.

The adaptations of the seal that enable it to remain underwater for a long time are several. The seal's oxygen storage capacity is about twice ours due to greater blood volume, the greater oxygen carrying capacity of its blood, and more myoglobin in its muscles. That is not sufficient, however, to explain dives of half an hour or more. The most important adaptation is the diving reflex, which is a slowing of the heart (Figure 49.21) and a constriction of major blood vessels going to all tissues except certain critical ones such as the nervous system, the heart, and the eyes. Central blood pressure remains high, but blood flow to the tissues decreases. This reduced blood flow has two effects: one is to switch the tissue to glycolytic (anaerobic) metabolism, and the other is to suppress the metabolism of the tissue.

While diving, the seal accumulates lactic acid in its muscles, which constitutes an "oxygen debt" to be paid back through elevated metabolism after the dive ends. But the total metabolic "payback" is much less than the metabolism that would have occurred over the same period of time had the seal not dived. The diving reflex caused the seal to be

49.21 The Diving Reflex

When a marine mammal dives, its heart rate slows and the arteries to most of its organs constrict, so almost all blood flow and available oxygen goes to the animal's heart and brain. These adaptations enable some seals to remain underwater for up to an hour.

hypometabolic (below the basal metabolic rate) during the dive. Hypometabolism, increased oxygen stores, and a high

capacity for anaerobic metabolism make it possible-for the seal to perform amazing feats.

Chapter Summary

Circulatory Systems: Pumps, Vessels, and Blood

- ▶ The metabolic needs of the cells of small aquatic animals are met by direct exchange of materials with the external medium. The metabolic needs of the cells of larger animals are met by a circulatory system that transports nutrients, respiratory gases, and metabolic wastes throughout the body. Review Figure 49.1
- ▶ In open circulatory systems the blood or tissue fluid leaves vessels and percolates through tissues. Review Figure 49.2
- ▶ In closed circulatory systems the blood is contained in a system of vessels. Review Figure 49.3

Vertebrate Circulatory Systems

- ▶ The circulatory systems of vertebrates consist of a heart and a closed system of vessels containing blood that is separate from the tissue fluid. Arteries and arterioles carry blood from the heart; capillaries are the site of exchange between blood and tissue fluid; venules and veins carry blood back to the heart.
- ▶ The vertebrate heart evolved from two chambers in fishes to three in amphibians and reptiles and four in crocodilians, mammals, and birds. This evolutionary progression has led to an increasing separation of blood flow to the gas exchange organs and blood flow to the rest of the body. Review Pages 868-870
- ▶ In birds and mammals, blood circulates through two circuits: the pulmonary circuit and the systemic circuit.

CIRCULATORY SYSTEMS 885

The Human Heart:Two Pumps in One

- ^ The human heart has four chambers. Valves in the heart prevent the backflow of blood. Review Figure 49.4
- ▶ The cardiac cycle has two phases: systole, in which the ventricles contract; and diastole, in which the ventricles relax. The sequential heart sounds ("lub-dub") are made by the closing of the heart valves. Review Figure 49.5
- ▶ Blood pressure can be measured using a sphygmomanometer and a stethoscope. Review Figure 49.6
- ▶ The autonomic nervous system controls heart rate. Sympathetic activity increases heart rate, and parasympathetic activity decreases it. These actions are due to the effects of norepinephrine and acetylcholine on the rate of depolarization of the membranes of pacemaker cells. Review Figure 49.7
- ▶ The sinoatrial node controls the cardiac cycle by initiating a wave of depolarization in the atria, which is conducted to the ventricles through the atrioventricular node. Review Figure 49.8

^ The EKG records electric potentials resulting from the contraction and relaxation of the cardiac muscles. Review Figure 49.9

The Vascular System: Arteries, Capillaries, and Veins

- ▶ Arteries and arterioles have many elastic fibers that enable them to withstand high pressures. Abundant smooth muscle cells allow these vessels to contract and expand, altering their resistance and thus blood flow. Review Figure 49.10
- ▶ Capillary beds are the site of exchange of materials between blood and tissue fluid.
- ▶ The exchange of fluids between blood and tissues is determined by the balance between blood pressure and osmotic potential in the capillaries. Review Figure 49.12
- ▶ The ability of a specific molecule to cross a capillary wall depends on the architecture of the capillary, the type of substance, and the concentration gradient between the blood and the tissue fluid.
- ▶ A separate system of vessels, the lymphatic system, returns the tissue fluid to the blood.
- ▶ Veins have a high capacity for storing blood. Aided by gravity, by contractions of skeletal muscle, and by the actions of breathing, they carry blood back to the heart. Review Figure 49.13
- ▶ Cardiovascular disease is responsible for about half of all deaths in the United States and Europe. Atherosclerosis and thrombus formation can lead to potentially fatal conditions such as heart attack and stroke. Diet and behavior are the keys to good cardiovascular health. Review Figure 49.14

Blood: A Fluid Tissue

- ▶ Blood can be divided into a plasma portion (water, salts, and proteins) and a cellular portion (red blood cells, white blood cells, and platelets). All of the cellular components are produced from stem cells in the bone marrow. Review Figure 49.15
- ▶ Red blood cells transport respiratory gases. Their production in the bone marrow is stimulated by erythropoietin, which is

produced in response to hypoxia in the tissues. Review Figure 49.16

- Platelets, along with circulating proteins, are involved in clotting responses. Review Figure 49.17
- Plasma is a complex solution that contains gases, ions, nutrient molecules, proteins, and other molecules.

Control and Regulation of Circulation

- Blood flow through capillary beds is controlled by local autoregulation mechanisms, hormones, and the autonomic nervous system. Review Figure 49.18
- Blood pressure is controlled in part by the hormones vasopressin and angiotensin, which stimulate contraction of blood vessels. Review Figure 49.19
- Heart rate is controlled by the autonomic nervous system, which responds to information about blood pressure and blood composition that is integrated by regulatory centers in the brain. Review Figure 49.20
- Diving mammals conserve blood oxygen stores by slowing the heart rate during dives. Review Figure 49.21

For Discussion

1. At the beginning of a race, cardiac output increases immediately before there is any change in blood oxygen or carbon dioxide concentrations. Explain two factors that contribute to this effect. Include the Frank-Starling law in your answer.
2. Explain how the hearts of crocodilians have the advantages of mammalian hearts during exercise but the efficiency of reptilian hearts during rest.
3. A sudden and massive loss of blood results in a decrease in blood pressure. Describe several mechanisms that help return blood pressure to normal.
4. You can describe the cycle of events in a ventricle of the heart by a graph that plots the pressure in the ventricle on the y-axis and the volume of blood in the ventricle on the x-axis. What would such a graph look like? Where would the heart sounds be on this graph? How would the graph differ for the left and the right ventricles?
5. If the major arteries become clogged with plaque and become less elastic because of calcification, the left ventricle must work harder and harder to pump an adequate supply of blood to the body. As a result, the left ventricle can become weakened and begin to fail even though the right ventricle is healthy. A heart attack primarily affecting the left ventricle can have the same effect. This condition is known as congestive heart failure, and commonly leads to fatal pulmonary edema. Explain how left ventricular failure can result in pulmonary edema, and why is it said that this condition creates a vicious circle that makes itself worse rapidly.

50

Animal Nutrition

Recently, The Center for Disease Control has recently determined that one out of every

five people in the United States is obese— at least 30 percent over recommended body mass. This epidemic level of obesity reflects a dramatic increase: Less than 10 years ago, the number was one in eight. The CDC has placed obesity just below smoking as the second largest preventable cause of death. Yet, as a nation, we seem to be more health-conscious than ever before, and at the time of this writing, six diet books are on the New York Times bestseller list. So what is wrong?

Lifestyle changes have played a role. The consumption of "fast food" with a high fat content has risen, snack foods are more prevalent, and people have become more sedentary overall in spite of an increase in planned exercise. Yet different individuals exposed to the same routines and stimuli differ in their propensity to gain weight. Like all other physiological functions, food intake is under genetic and regulatory influences that we are just beginning to understand. In humans, we know that identical twins reared together or apart rarely differ in body mass by more than a few percent. In animals, and now in humans, we know of single-gene mutations that can cause excessive food intake and obesity, and we know of tiny brain areas that when damaged can cause increased or decreased food intake. Can knowledge of nutrition and the physiology of food intake help us fight the epidemic of obesity?

In this chapter we review the nutrients that organisms require for energy, for molecular building blocks, and for specific biochemical functions. We examine briefly the diversity of adaptations for acquiring and ingesting food. Most of the chapter is devoted to how food is digested and absorbed. Then we learn how the body regulates its traffic in metabolic fuels, and return to the quandaries we have just posed about the regulation of food intake and body mass. Last, we raise the issue of environmental toxicology. By taking in nutrients as food, animals also take in com-

A Sizable Problem

Obesity is often caused or compounded by lifestyle. In the United States today, 1 in 5 adults is obese (30 percent or more above recommended weight limits) and liable to have resulting health problems.

pounds that can be toxic. We briefly consider how animals deal with toxic compounds and how human activities that contribute new and highly dangerous toxic compounds to the environment are affecting human health and other organisms in

the environment.

Nutrient Requirements

Animals must eat to stay alive. They eat other organisms— both plants and animals. Since they derive their nutrients from other organisms, they are called heterotrophs. In contrast, autotrophs (most plants, some bacteria, and some protists) trap solar energy through photosynthesis and use that energy to synthesize all of their components. Directly or indirectly, heterotrophs take advantage of—indeed, depend on—the organic synthesis carried out by autotrophs.

Heterotrophs have evolved an enormous diversity of adaptations to exploit, directly or indirectly, the resources made available through the actions of autotrophs (Figure 50.1). In this section we discover how animals use nutrients for energy and to build more complex molecules. We also examine mineral nutrients, such as iron and calcium, and molecules called vitamins that animals need in small quantities.

50.1 The Consumers

Heterotrophs have evolved a range of adaptations for exploiting sources of energy, (a) The staple food of the beaver, a mammalian herbivore, is bark. Trees and shrubs felled in the autumn are stored underwater in their lodges (also constructed of felled tree branches), insuring a constant supply of food during the winter, (b) The long bill and hovering flight pattern of the hummingbird, a fluid feeder, enable it to harvest nectar from individual flowers, (c) Filter-feeding right whales consume massive quantities of tiny phytoplankton by filtering ocean water through baleen plates in their mouths, (d) The carnivorous polar bear is a fearsome predator, preying mainly on marine mammals such as seals.

Energy can be measured in calories

In Chapters 6 and 7, we learned that energy in the chemical bonds of food molecules is transferred to the high-energy phosphate bonds of ATP. ATP provides the energy for cellular work. Each conversion of energy from food molecules to ATP and from ATP to cellular work is inefficient; in fact,

most of the energy that was in the food is lost as heat. Even the useful energy conversions eventually are reduced to heat, as molecules that were synthesized are broken down and the energy of movement is dissipated by friction.

(d) *Ursus maritimus*

In time, all the energy that is transferred to ATP from the chemical bonds of food molecules is released to the environment as heat. Therefore, we can talk about the energy requirements of animals and the energy content of food in terms of a measure of heat energy: the calorie. A calorie is the amount of heat necessary to raise the temperature of 1 g of water 1°C. Since this value is a tiny amount of energy in comparison to the energy requirements of many animals, physiologists commonly use the kilocalorie (kcal) as a unit of measure (1 kcal = 1,000 calories). Nutritionists also use the kilocalorie as a standard unit of energy, but they traditionally refer to it as the Calorie, which is always capitalized to distinguish it from the single calorie. (Scientists are gradually abandoning the calorie as an energy unit as they switch to the International System of Units. In this system, the basic unit of energy is the joule: 1 calorie = 4.184 joules.)

The metabolic rate of an animal (see Chapter 40) is a measure of the overall energy needs that must be met by the animal's ingestion and digestion of food. The components of food that provide energy are, fats, carbohydrates, and proteins. Fats yield 9.5 kcal/g, carbohydrates 4.2 kcal/g, and proteins about 4.1 kcal/g. The basal metabolic rate of a human

50.2 Food Energy and How Fast We Burn It

The energy in kilocalories contained in several common food items is shown at the left. The graph indicates about how long it would take a person with a basal metabolic rate of about 1,800 kcal/day to utilize the equivalent amount of energy while involved in various activities.

(the metabolic rate resulting from all of the essential physiological functions of a resting person) is about 1,300–1,500 kcal/day for an adult female and 1,600–1,800 kcal/day for an adult male. Physical activity adds to this basal energy requirement. For a person doing sedentary work, about 30 percent of total energy consumption is due to skeletal muscle activity, and for a person doing heavy physical labor, 80 percent or more of the total caloric expenditure is due to skeletal muscle activity. Some equivalencies of food, energy, and exercise are shown in Figure 50.2.

Sources of energy can be stored in the body

Although the cells of the body use energy continuously, most animals do not eat continuously. Humans generally eat several meals a day, a lion may eat once in several days, a boa constrictor may eat once a month, and hibernating animals may go 5 to 6 months without eating. Therefore, animals must store fuel molecules that can be released as needed between meals.

Carbohydrates are stored in liver and muscle cells as glycogen ("animal starch," see Chapter 3), but the total glycogen store is usually not more than the equivalent of a day's energy requirements. Fat is the most important form of stored

energy in the bodies of animals. Not only does fat have the highest energy content per gram, but it can be stored with little associated water, making it more compact. If migrating birds had to store energy as glycogen rather than fat to fuel their long flights, they would be too heavy to fly! Protein is not used to store energy, although body protein can be metabolized as an energy source of last resort.

If an animal takes in too little food to meet its needs for metabolic energy, it is undernourished, and must make up the shortfall by metabolizing some of the molecules of its own body. Consumption of self is inevitable. The storage compounds glycogen and fat. Protein loss is minimized for as long as possible, but eventually a starving animal uses its own proteins for fuel. The breakdown of body proteins impairs body functions and eventually leads to death. Blood proteins are among the first to go, resulting in loss of fluid to the intercellular spaces (edema; see Chapter 49). Muscles atrophy (waste away), and eventually even air protein is lost. Figure 50.3 shows the course of starvation.

Our major energy reserve is fat; even a person of average body weight has enough fat to survive 4 or 5 weeks without food.

The carbohydrate reserves of our bodies are meager and are depleted by only a single day without food intake.

When most body fat has been exhausted, the only remaining fuel is protein, which is lost at an accelerating rate, with serious consequences, even death.

50.3 The Course of Starvation

In a person subjected to undernutrition, the energy reserves of the body are eventually depleted. Body fat is our major defense against starvation.

Undernourishment is rampant among people in nonindustrialized and war-torn nations, and a billion people—one-sixth of the world's population—are undernourished. (ironically, one cause of life-threatening undernourishment in Western nations is a self-imposed starvation syndrome called anorexia nervosa that results from a psychological aversion to body fat.)

When an animal consistently takes in more food than it needs to meet its energy demands, it is overnourished. The excess nutrients are stored as increased body mass. First, glycogen reserves build up; then additional dietary carbohydrate is stored as fat. Proteins are converted to body fat. In some species, such as hibernators, seasonal overnutrition is an important adaptation for surviving periods when food is unavailable. In humans, however, overnutrition can be a serious health hazard, increasing the risk of high blood pressure, heart attack, diabetes, and other disorders.

Food provides carbon skeletons for biosynthesis

Every animal requires certain basic organic molecules (carbon skeletons) that it cannot synthesize for itself, but needs to build its own complex organic molecules. An example of a required carbon skeleton is the acetyl group (Figure 50.4). Animals cannot make acetyl groups from carbon, oxygen, and hydrogen molecules; they obtain acetyl groups by metabolizing carbohydrates, fats, or proteins.

The acetyl group can be derived from the metabolism of almost any food. It is unlikely ever to be in short supply for an adequately nourished animal. Other carbon skeletons, however, are derived from more limited sources, and an animal can suffer a deficiency of these materials even if its caloric intake is adequate. This state of deficiency is called malnutrition.

Amino acids, the building blocks of proteins, are a good example of carbon skeletons that can be in short supply.

Humans obtain amino acids by breaking down proteins from food and absorbing the resulting amino acids. Another source of amino acids is the breakdown of existing proteins, which are in constant turnover as the tissues of the body undergo normal remodeling and renewal. From these amino acids and ones from food, the body synthesizes its own protein molecules as specified by its DNA.

Animals can synthesize some of their own amino acids by taking carbon skeletons synthesized from acetyl or other groups and transferring to them amino groups ($-NH_2$) derived from other amino acids. But most animals cannot synthesize all the amino acids they need. Each species has certain essential amino acids that must be obtained from food. Different species have different essential amino acids, and in general, herbivores have fewer essential amino acids than carnivores have!

If an animal does not take in one of its essential amino acids, its protein synthesis is impaired. Think of protein synthesis as using a keyboard to write a story. If one letter on the keyboard doesn't function, the story either comes to a stop or has an error in it whenever that letter is needed. In protein synthesis, the story usually comes to a stop, and a

functional protein is not produced.

There are eight essential amino acids that humans must obtain from their food: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. All eight are available in milk, eggs, or meat, but no plant food contains all eight. A strict vegetarian runs a risk of protein malnutrition. An appropriate dietary mixture of plant foods, however, supplies all eight essential amino acids (Figure 50.5). In general, grains are complemented by legumes or by milk or meat. Legumes are complemented by grains, seeds, and nuts. Long before the chemical basis for this complementarity was understood, societies with little access to meat developed healthy dietary practices. Many

Animals use acetyl groups obtained from their food to build more complex organic molecules.

The acetyl group is present in virtually all of the foods animals ingest.

By combining cereal grains and legumes, a vegetarian can obtain all eight essential amino acids.

Central and South American peoples traditionally eat beans

with rice. The combination of beans and rice provides all the essential amino acids.

with grains. The combination of beans and grains provides all the essential amino acids.

Why are dietary proteins completely digested to their constituent amino acids before being used by the body? Wouldn't it be more energy-efficient to reuse some dietary proteins directly? There are several reasons why ingested proteins are not used "as is."

Macromolecules such as proteins are not readily taken up through plasma membranes, but their constituent monomers (such as amino acids) are readily transported.

Protein structure and function are highly species-specific. A protein that functions optimally in one species might not function well in another species. Foreign proteins entering the body directly from the gut would be recognized as invaders and would be attacked by the immune system.

,

Most animals avoid these problems by digesting food proteins extracellularly and then absorbing the resulting amino acids into the body, where they synthesize new proteins that will function correctly and be recognized as "self" by the immune system.

Using acetyl groups obtained from food, humans can synthesize almost all the lipids required by the body, but we must have a dietary source of essential fatty acids—notably linoleic acid—linoleic acid is an unsaturated fatty acid needed by mammals to synthesize other unsaturated fatty acids such as arachidonic acid, which in turn produces several signaling molecules, including prostaglandins. A deficiency of linoleic acid can lead to problems such as infertility and impaired lactation. Essential fatty acids are also necessary components of membrane phospholipids.

Animals need mineral elements in different amounts

The principal mineral elements required by animals are listed in Table 50.1. Elements required in large amounts are called macrominerals; elements required in only tiny amounts are called micronutrients. Some essential elements are required in such minute amounts that deficiencies are never observed, but these elements are nevertheless essential.

Calcium is an example of a macronutrient. It is the fifth most abundant element in the body; a 70-kg person contains about 1,200 g of calcium. Calcium phosphate is the principal structural material in bones and teeth. Muscle contraction, neuronal function, and many other intracellular functions in animals require calcium. The turnover of calcium in the extracellular fluid is quite high, as bones are constantly being remodeled and calcium is constantly entering and leaving cells. Calcium is lost from the body in urine, sweat, and feces, so it must be replaced regularly from the diet. Humans require about 800 to 1,000 mg of calcium per day in the diet.

Iron is an example of a micronutrient. Iron is found everywhere in the body because it is the oxygen-binding atom in hemoglobin and myoglobin and is a component of enzymes in the electron transport chain. Nevertheless, the total amount of iron in a 70-kg person is only about 4 g, and since iron is recycled so efficiently in the body, we require only about 15 mg per day in our food. In spite of the small amount required, insufficient iron is the most common nutrient deficiency in the world today.

Animals must obtain vitamins from food

Another group of essential nutrients is the vitamins. Like essential amino acids and fatty acids, vitamins are carbon compounds that an animal requires for its normal growth and metabolism, but cannot synthesize for itself. Most vitamins function as coenzymes or parts of coenzymes and are required in very small amounts, compared with the essential amino acids and fatty acids, which have structural roles. The list of vitamins varies from species to species. Most mammals, for example, can make their own ascorbic acid (vitamin C). However, primates (including humans) do not

50.6 A Symptom of Scurvy

Because a vitamin C deficiency weakens connective tissue, the gums bleed, teeth fall out, and blood vessels under the skin break.

have this ability, so for primates ascorbic acid is a vitamin. If we do not get vitamin C in our food, we develop a disease known as scurvy, characterized by bleeding gums, loss of teeth, subcutaneous hemorrhages, and slow wound healing (Figure 50.6). Scurvy was a serious and frequently fatal problem for sailors on long voyages until a Scottish physician, James Lind, discovered that the disease could be prevented if the sailors ate fresh greens or fresh fruit. Eventually the British Admiralty made limes standard provisions for its ships, and ever since British sailors have been called "limeys." The active ingredient in limes was named ascorbic ("without scurvy") acid.

For humans, there are 13 vitamins. They are divided into two groups: water-soluble vitamins and fat-soluble vitamins. Table 50.2 presents these vitamins, their dietary sources, and their functions.

The fat-soluble vitamin D (calciferol), which is essential for the absorption and metabolism of calcium, is a special case because the body can make it. Certain lipids present in the human body can be converted into vitamin D by the action of ultraviolet light on the skin. Thus vitamin D must be obtained in the diet only by individuals with inadequate exposure to the sun, such as people who live in cold climates where clothing usually covers most of the body and where the sun may not shine for long periods of time.

The need for vitamin D may have been an important factor in the evolution of skin color. Human races that are adapted to equatorial and low latitudes have dark skin pigmentation as a protection against the damaging effects of ultraviolet radiation. These peoples generally have extensive skin areas exposed to the sun on a regular basis, so their skin synthesizes adequate amounts of vitamin D. Most human races that became adapted to higher latitudes lost dark skin pigmentation. Presumably, lighter skin facilitates

tates vitamin D production in the relatively small areas of skin exposed to sunlight during the ~shT5ft days of winter. An exception to this correlation between latitude and skin pigmentation is the Iry ujt peoples of the Arcti c. These dark-skinned people obtain plenty of vitamin D from the large amounts of meat and fish oils in t heir diet: for them, ex posur e tO SUNlightj S_P^ nprpscary for nhtaining fhit; v itamin.

When water-soluble vitamins are ingested in excess of bodily needs, they are sirripiy_ diminated in th g_urine. (This is the fate of much of the vitamin C that people take in excessive doses.) The fat-soluble vitamins, however, accumulate in body fat and may build up to toxic levels in the l iver if taken in excess.

Nutrient deficiency diseases

A chronic shortage of any nutrien tpr oduces a characteri stic deficiency disease. If th e deficiency is not remedied, death may follow. An example is kwashiorkor . a disease that results from pr otp'n dpf iriprTry It causes swelling of the extremities, distension of the abdomen (Figure 50.7),breakdown of the immune system, degeneration of the liver, mental retardation, and other problems.

A shortage of any of the vitamins results in specific deficiency symptoms (see Table 50.2). We have already described scurvy, which results from a lack of vitamin C. Another deficiency disease, beriber i : _ wasdirectly involved in the discovery of vitamins. Beriberi means ^xtreme we akness, " It became prevalent in Asia in the nineteenth century, after it became standard practice to mill rice to a high, white polish and discard the hulls that are present in brown rice. A critical observation was that birds—chickens and pigeons—developed beriberi-like symptoms when fed only polished rice. In 1912, Casimir Funk cured pigeons of beriberi by feeding them the discarded hulls.

At the time of Funk's discovery, all diseases were thought to be either caused by microorganisms or inherited. Funk suggested the radical idea that beriberi and some other diseases are dietary in origin and result from deficiencies in specific substances. Funk coined the term "vitamines" because he mistakenly thought that all these substances were amines (compounds with amino groups) vital for life. In 1926, thiamin (vitamin B^—the substance lost in the rice milling process—was theJirst vitamin to be isolated in pure form.

ANIMAL NUTRITION 893

50.7 Kwashiorkor, "The Rejected One"

The swollen abdomen, face, hands, and feet due to edema (fluid retention), as well as the spindly limbs of these children, are hallmarks of serious protein starvation. These symptoms are a result of the body breaking down blood proteins and muscle tissue to obtain needed amino acids.

Deficiency diseases can also result from an inability to absorb or process an essential nutrient even if it is present in the diet. Vitamin B 12 (cobalamin), for example, is present in all foods of animal origin. Since plants neither use nor produce vitamin B 12 , a s trictly vegetari an diet (not supplemented byjrilamuxg\l\s) can lead to a B 19 deficiency d isease ca\\ed(gernicious anerny t, characterized by a failure of r ed blood cells to mature. The most common cause of pernicious anem ia, huwove* , is not a lack of vitamin B 12 in the diet, but an inabi lity to absorb it. Normally, cells in the stomach lining secrete a peptide called intrinsic factor, which binds to vitamin B 12 and makes it possible for it to be absorbed in the ileum of the small intestine. Conditions that damage the stomach lining can therefore cau se an emia.

Inadequate mineral nutrition can also lead to deficiency diseasesvrl^ine^Jbr example, is a constituent of the hor-mone thyronine, w hich is produced in the thyroid gland. If insufficient iodine is obtained in the diet, the thyroid gland grows larger in an attempt to compensate for the inadequate production of thyroxine (see Figure 41.9). The

swelling of the neck that results is called a gcnte r. The introduction of iodiz ed table salt has greatly reduced th e incidence of

goiter in the I Jnitpd States.

Adaptations for Feeding

Heterotrophic organisms can be classified by how they acquire their nutrition. Saprobies (also called saprotrophs or decomposers) are mostly protists and fungi that absorb nutrients from dead organic matter. Detritivores, such as earthworms and crabs, get fed by feeding on dead organic material. Animals that feed on living organisms are predators. They prey on plants, animals, or other animals.

Herbivores and omnivores prey on both. Filter feeders, such as clams and blue whales, prey on small organisms by filtering them from the environment. Fluid feeders include mosquitoes, aphids, and leeches, as well as birds that feed on plant nectar. The anatomical adaptations that enable a species to exploit a particular source of nutrition are usually quite obvious, but physiological and biochemical adaptations can be just as important.

The food of herbivores is often low in energy and hard to digest

Vegetation is frequently coarse and difficult to break down physically, but herbivores must process large amounts of it, since its energy content is low. Most herbivores spend a great part of their time feeding. Many have striking adaptations for feeding, such as the trunk (a flexible, gripping nose) of the elephant or the long neck of the giraffe. Many types of grinding, rasping, cutting, and shredding mouth-parts have evolved in invertebrates for ingesting plant material, and the teeth of herbivorous vertebrates have been shaped by selection to process

coarse plant material. The digestive processes of herbivores can also be quite specialized. The Australian koala, for example, eats nothing but the leaves of eucalyptus trees. Eucalyptus leaves are tough, low in nutrient content, and loaded with pungent, toxic compounds that evolved to protect the trees from predators. Yet the koala's gut can digest and detoxify the leaves and absorb all the nutrients the animal needs from this highly specialized and formidable diet.

Carnivores must detect, capture, and kill prey

The predatory behaviors of many carnivores are legendary. One need only call to mind the hunting skills of hawks, wolves, or any member of the cat family. Carnivores have evolved stealth, speed, large jaws, sharp teeth, and strong gripping appendages. Carnivores also have evolved remarkable means of detecting prey. Bats use echolocation, pit vipers sense infrared radiation from the warm bodies of their prey, and certain fishes detect electric fields created in the water by their prey (see Chapter 45).

Adaptations for killing and ingesting prey are diverse and highly specialized. These adaptations can be especially important when the prey are capable of inflicting damage on the predator. A snake may strike with poisonous fangs,

894 CHAPTER FIFTY

50.8 Adaptations for Feeding

(a) Snakes such as this Texas rat snake (*Elaphe obsoleta*) can ingest large prey (in this case a lizard) by dislocating their jaws, (b) This sea star is eating a clam. While it holds the clam with its arms, enzymes from its everted stomach digest it.

using its venom to immobilize its prey before ingesting it. To swallow large prey, a snake disengages its lower jaw from its joint-with-the-skull (Figure 50.8a). The tentacles of jellyfishes, corals, squid, and octopuses, the long, sticky tongues of frogs and lizards, and the webs of spiders are other fascinating examples of adaptations for capturing and immobilizing prey.

Because some prey items are impossible to ingest, some predators digest their prey externally. Sea stars evert their stomachs (turn them inside out) and digest their molluscan prey while they are still in the invertebrate's shells (Figure 50.8b). Spiders usually prey on insects with indigestible exoskeletons. The spider injects its prey with digestive enzymes and then sucks out the liquefied contents, leaving behind the empty exoskeletons frequently seen in old spider webs.

Vertebrate species have distinctive teeth

Teeth are adapted for the acquisition and initial processing of specific types of foods. Because they are one of the hardest structures of the body, an animal's teeth remain in the environment long after it dies. Paleontologists use teeth to identify animals that lived in the distant past and to deduce what their feeding behavior might have been.

All mammals have a general structure consisting of three layers (Figure 50.9a). An extremely hard material called enamel, composed principally of calcium phosphate, covers the crown of the tooth. The crown and the root contain a layer of bony material called dentine, inside of which is a pulp cavity containing blood vessels, nerves, and the cells that

proHnrrp thp rjpn finp

The shapes and organization of mammalian teeth, however, can be very different, since they are adapted to specific diets (Figure 50.9b). In general, incisors are used for cutting, chopping, or gnawing; canines are used for stab-

bing, ripping, and shredding; and molars and premolars (the cheek teeth) are used for shearing, crushing, and grinding. The highly varied diet of humans is reflected by our multipurpose set of teeth, as is common among omnivores.

Digestion

Most animals digest their food extracellularly. Animals take food into a body cavity that is continuous with the outside environment, into which they secrete digestive enzymes. The enzymes act on the food, reducing it to nutrients that can be absorbed by the cells lining the cavity. Only after they are absorbed by the cells are the nutrients within the body of the animal.

The simplest digestive systems are gastrovascular cavities

that

connect to the outside world through a single opening. An example is the cnidarians, which capture prey using stinging nematocysts and cram it into their gastrovascular cavities with tentacles (see Figures 31.7 and 49.1a). Enzymes in the gastrovascular cavity partly digest the prey. Cells lining the cavity take in small food particles by endocytosis. The vesicles that are created by endocytosis fuse with lysosomes containing digestive enzymes, and intracellular digestion completes the breakdown of the food. Nutrients are released to the cytoplasm as the vesicle breaks down.

Tubular guts have an opening at each end

The guts of most animals are tubular. A mouth takes in food; molecules are digested and absorbed throughout the length of the gut; and solid digestive wastes are excreted through an anus. Different regions in the tubular gut are specialized for particular functions (Figure 50.10). These

functions must be coordinated so that they occur in proper sequence and at appropriate rates to maximize the efficiency of digestion and absorption of nutrients. Keep in mind as we discuss these regions that all locations within the tubular gut are, really, outside the body of the animal. Only by crossing the plasma membranes of cells lining the gut do nutrients enter the body.

"§>

delivered into the next section of gut, the midgut or intestine is well minced and well mixed.

Most materials are digested and absorbed in the midgut. Specialized glands secrete some digestive enzymes into the intestine, and the gut wall itself secretes other digestive enzymes. The hindgut recovers water and ions and stores

undigested wastes, or feces, so that they can be released to the environment at an appropriate time or place. A muscular rectum near the anus assists in the expulsion of feces, the process of defecation.

Within the hindguts of many species are colonies of endosymbiotic bacteria. These bacteria obtain their own nutrition from the food passing through the host's gut while contributing to the digestive processes of the host. Members of the leech genus *Hirudin* for example, produce no enzymes that can digest the proteins in the blood they suck from vertebrates. A colony of gut bacteria produces the enzymes necessary to break down those proteins into amino acids, which are subsequently used by both the leech and

Capillaries

50.1 7 Greater Intestinal Surface Area Means More Nutrient Absorption

The guts of most animals have evolved to maximize their surface area.

the bacteria. Some animals rely on microorganisms in their

microbiome to supply them with vitamins

In many animals, the parts of the gut that absorb nutrients have evolved to have enormous surface areas (Figure 50.11a, b). In vertebrates, the wall of the gut is richly folded, with the individual folds bearing legions of tiny fingerlike projections called villi (Figure 50.11c). The cells that line the surfaces of the villi, in turn, have microscopic projections, called microvilli. This provides an enormous surface area for the absorption of nutrients.

Digestive enzymes break down complex food molecules

Protein, carbohydrate, and fat macromolecules are broken down into their simplest units by hydrolytic enzymes. All of these enzymes cleave the chemical bonds of macromolecules through hydrolysis, a reaction that adds a water molecule (see Figure 3.2). Examples of hydrolysis are the breaking of the bonds between adjacent amino acids of a protein or peptide and between adjacent glucose units of a starch.

Digestive enzymes are classified according to the substances they hydrolyze: carbohydrases hydrolyze carbohydrates; proteases, proteins; lipases, lipids; and nucleases, nucleic acids. The process of digestion occurs "outside" (extracellularly)

Epithelial cells

and endo- ("within") indicate where the enzyme cleaves the molecule. An endoprotease hydrolyzes a protein at an internal site along the polypeptide chain, and an exoprotease snips away amino acids at the ends of the molecule.

How can an organism produce enzymes that hydrolyze biological macromolecules without digesting itself? Most digestive enzymes are produced in an inactive form, known as a zymogen, so that they cannot act on the cells that produce them. When secreted into the gut, zymogens are activated by another enzyme or by conditions in the gut (which, as you will remember, is outside the body). The lining of the gut is not digested because it is protected by a covering of mucus.

Structure and Function of the Vertebrate Gut

The digestive tract of vertebrates is a tubular gut that runs from mouth to anus (Figure 50.12). Different segments of the gut are specialized for different functions associated with digestion and absorption. In addition, there are several accessory structures that produce and export into the gut compounds that contribute to the digestive process.

Similar tissue layers are found in all regions of the vertebrate gut

The cellular architecture of the vertebrate gut follows a common plan throughout. Four major layers of different

Different compartments within the long tubular gut specialize in digesting food, absorbing nutrients, and storing and expelling wastes. Accessory organs contribute digestive juices containing enzymes and other molecules.

Cell types form the wall of the gut (Figure 50.13). These layers differ somewhat from compartment to compartment, but they are always present.

Starting in the cavity, or lumen, of the gut, the first tissue layer is the mucosa. Mucosal cells have secretory and absorptive functions. Some secrete mucus, which lubricates and protects the walls of the gut. Others secrete digestive enzymes, and still others in the stomach secrete hydrochloric acid (HCl). In some regions of the gut, nutrients are absorbed across the plasma membranes of the mucosal cells; the plasma membranes of these absorptive cells have many folds that increase their surface area (see Figure 50.11c).

At the base of the mucosa are some smooth muscle cells, and just outside the mucosa is the second layer of cells, the submucosa. Here we find the blood and lymph vessels that carry absorbed nutrients to the rest of the body. The submucosa also contains a network of nerves; these neurons are

Figure 50.13 Tissue Layers of the Vertebrate Gut

In all compartments of the gut, the organization of the tissue layers is the same, but specialized adaptations of specific tissues characterize different regions.

both sensory (responsible for stomach aches) and regulatory (controlling the various secretory functions of the gut).

External to the submucosa are two layers of smooth muscle cells responsible for the movements of the gut. Innermost is the circular muscle layer with its cells oriented around the gut. Outermost is the longitudinal muscle layer with its cells oriented along the length of the gut. The circular muscles constrict the gut, and the longitudinal muscles shorten the gut. Between the two layers of muscle is another network of nerves that controls the movements of the gut, coordinating the movements of different regions with one another.

Surrounding the gut is a fibrous coat called the serosa. Like other abdominal organs, the gut is also covered and supported by a tissue called the peritoneum.

Peristalsis moves food through the gut

Food entering the mouth of most vertebrates is chewed and mixed with the secretions of salivary glands. A muscular tongue then pushes chewed food toward the back of the buccal cavity. By making contact with the soft tissue at the back of the mouth, the bolus of food initiates a complex series of autonomic reflex actions known as *swallowing*. Stand in front of a mirror and gently touch this tissue at the back of your mouth with a cotton swab. You may gag slightly, but you will also experience an uncontrollable urge to swallow. Swallowing involves many muscles doing a variety of jobs that propel the food through the pharynx (where the mouth cavity and the nasal passages join) and into the esophagus (the food tube). A structure called the epiglottis

I The soft palate is pulled up as the vocal cords close the larynx.

| The larynx is pulled up and forward and is covered by the epiglottis; the bolus of food enters the esophagus.

50.14 Swallowing and Peristalsis

Food pushed to the back of the mouth triggers the swallowing reflex. Once food enters the esophagus, peristalsis propels it through the gut.

prevents the food from entering the trachea (windpipe) or nasal passages (Figure 50.14).

Once the food is in the esophagus, peristalsis takes over and pushes it toward the stomach. Peristalsis is a wave of smooth muscle contraction that moves progressively down the gut from the pharynx toward the anus. The smooth muscle of the gut contracts in response to being stretched. Swallowing a bolus of food stretches the upper end of the esophagus, and this stretching initiates a wave of contraction that slowly pushes the contents of the gut toward the anus.

The movement of food from the stomach to the esophagus is normally prevented by a thick ring of circular smooth muscle at the junction of the esophagus and the stomach. This ring of muscle, the esophageal sphincter, is normally contracted. Waves of peristalsis cause it to relax enough to let food pass from the esophagus into the stomach. Sphincter muscles are found elsewhere in the digestive tract as well. The pyloric sphincter governs the passage of stomach contents into the intestine. Another important sphincter surrounds the anus.

Digestion begins in the mouth and the stomach

Food is chewed in the mouth, and carbohydrate digestion begins there. The enzyme amylase is secreted with saliva and mixed with the food as it enters the mouth. Amylase hydrolyzes the bonds between the glucose monomers that make up starch. The action of amylase is what makes a piece of bread or cracker taste sweet if you hold it in your mouth long enough.

Peristaltic contractions propel the food to the stomach.

Most vertebrates can rapidly consume a large volume of food, but digesting that food is a long, slow process. The stomach stores the food consumed during a meal. The secretions of the stomach kill microorganisms that are taken in with the food and begin the digestion of proteins.

The major enzyme, produced by the stomach is an endopeptidase called pepsin. Pepsin is secreted as a zymogen called pepsinogen by cells in the gastric glands—deep folds in the stomach lining (Figure 50.15). Other cells in the gastric glands produce hydrochloric acid, and still others near the openings of the gastric glands and throughout the stomach mucosa secrete mucus.

Hydrochloric acid (HCl) maintains the low pH in the stomach.

The gastric juice is at a pH between 1 and 3. This low pH activates the conversion of pepsinogen to pepsin, which is achieved by the cleavage of a masking sequence of 44 amino acids from the N-terminal end of the pepsinogen molecule. The conversion is amplified as the newly formed pepsin activates other pepsinogen molecules, a process called autocatalysis. Hydrochloric acid also provides the right pH for the enzymatic action of pepsin. The low pH also helps dissolve the intercellular substances holding the ingested tissues together. Breakdown of the ingested tissues exposes more food surface area to the action of pepsin and eventually other digestive enzymes in the small intestine.

Mucus secreted by the stomach mucosa coats the walls of the stomach and protects them from being eroded and digested by HCl and pepsin. Sometimes, however, the walls of the stomach are exposed to HCl and pepsin; the resulting damage is called an ulcer. It was previously thought that ulcers were mostly due to stress and oversecretion of digestive juices. In recent years, however, it has been discovered that the basis for most ulcers is an infectious bacterium called *Helicobacter pylori*, which has the remarkable

Active pepsin also activates pepsinogen through autocatalysis.

ability to live in the highly acidic environment of the stomach. Lesions started by the bacterial infection are made worse by HCl and pepsin.

Contractions of the muscles in the walls of the stomach churn its contents, thoroughly mixing them with the stomach secretions. The acidic, fluid mixture of gastric juice and partly digested food in the stomach is called chyme. A few substances can be absorbed from the chyme across the stomach wall, including alcohol (hence its rapid effects), aspirin, and caffeine, but even these substances are absorbed in rather small quantities in the stomach.

Peristaltic contractions of the stomach walls push the chyme toward the bottom of the stomach. These waves of peristalsis cause the pyloric sphincter to relax briefly so that little squirts of the chyme can enter the first region of the intestine. The human stomach empties itself gradually over a period of approximately 4 hours. This slow passage of food enables the intestine to work on a little at a time and extends the digestive and absorptive processes throughout much of the time between meals.

The small intestine is the major site of digestion

In the small intestine the digestion of carbohydrates and proteins continues, and the digestion of fats begins and the absorption of nutrients begins. Although the small intestine takes its name from its diameter, it is a very large organ. The small intestine of an adult human is more than 6 m long; its coils fill much of the lower abdominal cavity (see Figure 50.12). Because of its length, and because of the folds, villi, and microvilli of its lining, its inner surface area is enormous: about 550 m², or roughly the size of a tennis court. Across this surface the small intestine absorbs all the nutrient molecules derived from food. The small intestine

odennurP-is and the ileum carry

has three sections. The initial section

the Sigm Of mrtQt Higp

out 90 percent of the absorption of nutrients

Digestion requires many specialized enzymes, as well as several other secretions. Two accessory organs that are not part of the digestive tract—the liver and the pancreas—pro-

vide many of these enzymes and secretions.

The liver synthesizes a substance called bile from cholesterol. Bile secreted from the liver flows through the hepatic duct to the gallbladder and to the duodenum. Bile reaches the gallbladder through a side branch of the hepatic duct (Figure 50.16). It is stored in the gallbladder until it is needed to assist in fat digestion. When fat enters the duodenum, a hormonal signal causes the walls of the gallbladder to contract rhythmically, squeezing bile back out toward the hepatic duct. Below the branch point to the gallbladder, the hepatic duct is called the common bile duct. Bile from the gallbladder flows down the common bile duct to the duodenum.

To understand the role of bile in fat digestion, think of the oil in salad dressing: it is not soluble in water (it is hydrophobic), and it tends to aggregate together in large globules. The enzymes that digest fat, the lipases, are water-soluble and must do their work in an aqueous medium. Bile stabilizes tiny droplets of fat so that they cannot aggregate into large globules. One end of each bile molecule is soluble in fat (it is lipophilic, or hydrophobic); the other end is soluble in water (it is hydrophilic, or lipophobic). Bile molecules bury their lipophilic ends in fat droplets, leaving their

50.16 The Ducts of the Gallbladder and Pancreas

Bile produced in the liver leaves the liver via the hepatic duct. Branching off this duct is the gallbladder, which stores bile. Below the gallbladder, the hepatic duct is called the common bile duct and is joined by the pancreatic duct before entering the duodenum.

lipophobic ends sticking out. As a result, they prevent the fat droplets from sticking together. These very small fat particles are called micelles and their small size maximizes the surface area exposed to lipase action (see Figure 50.17). The pancreas is a large gland that lies just beneath the stomach (see Figures 50.12 and 50.16). It functions as both an endocrine (secreting hormones without ducts to the blood and tissue fluid) and an exocrine (secreting other substances through ducts to the outside of the body) gland. Here we will consider its exocrine products, which are delivered to the gut through the pancreatic duct. The pancreatic duct joins the common bile duct just before it enters the duodenum.

The pancreas produces a host of digestive enzymes, including lipases (Table 50.3). As in the stomach, these enzymes are released as zymogens; otherwise they would digest the pancreas and its ducts before they ever reached the duodenum. Once in the duodenum, one of these inactive enzymes, trypsinogen, is activated by enterokinase, which is produced by cells lining the duodenum. This process is similar to the activation of pepsinogen by low pH (see Figure 50.15). Active trypsin can cleave other trypsinogen molecules to release even more active trypsin (another example of autocatalysis). Similarly, trypsin acts on the other zymogens secreted by the pancreas and releases their active enzymes.

The mixture of zymogens produced by the pancreas can be very dangerous if the pancreatic duct is blocked or if the pancreas is injured by an infection or a blow to the abdomen. A few trypsinogen molecules spontaneously converting to trypsin can initiate a chain reaction of enzyme activation that digests the pancreas in a very short period of time, destroying both its endocrine and exocrine functions. The pancreas produces, in addition to digestive enzymes, a secretion rich in bicarbonate ions (HCO_3^-). Bicarbonate ions neutralize the pH of the chyme that enters the duodenum from the stomach. This neutralization is essential because intestinal enzymes function best at a neutral or slightly alkaline pH.

Nutrients are absorbed in the small intestine

Only the smallest products of digestion can be absorbed through the mucosa of the small intestine and passed on to the blood and lymphatic vessels that lie in the submucosa. The final digestion of pro-

teins and carbohydrates that produces these absorbable products takes place among the micro villi. The (mucosM> fcells jtvith microvilli produc e peptida ses, which cleave larger peptides into tripeptide s, d ipeptide s, and individual amino

arirkjth nt tho mlk ga n.absorb Thp<;p cells also produce the

enzymes maltase, la ctase, a nd sucrase, which cleave the common disaccharides into their constituent, absorbable monosaccharides —gluc ose, gala ctose, and fru ctose .

Many humans stop producing the enzyme lactase around the age of 4 years and thereafter have difficulty digesting lactose, which is the sugar in milk. Lactose is a disaccharide and cannot be absorbed without being cleaved into its constituent units, glucose and galactose. If a substantial amount of lactose remains unabsorbed and passes into the large intestine, its metabolism, by bacteria in the large intestine causes abdominal cramps, gas, and diarrhea.

The mechanisms by which the cells lining the intestine absorb nutrient molecules and inorganic ions are diverse and not completely understood. Many inorganic ions are actively transported into the cells. Carrier proteins exist for sodium and iron. Carriers also exist for certain classes of amino acids and for glucose and galactose, but their activity is much reduced if active sodium transport is blocked. Sodium ions move from the gut contents into the mucosal cells and are then actively transported from the mucosal cells into the submucosa. To diffuse into a mucosal cell, a sodium ion binds to a symport in the mucosal cell membrane. The symport also binds a nutrient molecule such as glucose or an amino acid. The diffusion of the sodium ion, driven by a concentration gradient, therefore drives the absorption of the nutrient molecule. This mechanism is called sodium cotransport.

The absorption of the products of fat digestion does not involve carrier proteins (Figure 50.17). Lipases break down fats into fatty acids and monoglycerides, which are lipid-soluble and are thus able to pass through the plasma membranes of the microvilli and diffuse into the mucosal cells. Once in the cells, the fatty acids and monoglycerides are resynthesized into triglycerides, combined with cholesterol and phospholipids and coated with protein to form water-soluble chylomicrons, which are really little parcels of fat. Rather than entering the blood directly, the chylomicrons pass into the lymphatic vessels in the submucosa. They then flow through the lymphatic system and enter the bloodstream through the thoracic duct. After a meal rich in fats, the chylomicrons can be so abundant in the blood that they give it a milky appearance.

The bile that emulsifies the fats is not absorbed along with the monoglycerides and the fatty acids, but shuttles back and forth between the gut contents and the microvilli. In the ileum, bile is actively reabsorbed and returns to the liver via the bloodstream. As noted earlier, bile is synthesized in the liver from cholesterol. Cholesterol comes from food, but it is also synthesized by liver cells and gut cells.

As we learned in Chapter 4, high cholesterol levels contribute to arterial plaque formation and therefore to cardiovascular disease. The body has no way of breaking down excess cholesterol, so high dietary intake or high levels of synthesis create problems. One major way that cholesterol leaves the body is through the elimination of unabsorbed bile in the feces. The rationale for including certain kinds of fiber in the diet is that the fiber binds bile, decreases its reabsorption in the ileum, and thus helps to lower blood cholesterol levels.

Water and ions are absorbed in the large intestine

Peristalsis gradually pushes the contents of the small intestine into the large intestine, or colon. The rate of peristalsis

902 CHAPTER FIFTY

- « ^

is controlled so that food passes through the small intestine slowly enough for digestion and absorption to be complete, but quickly enough to ensure an adequate supply of nutrients for the body. Most of the available nutrients have been removed from the material that enters the colon, but the material contains a lot of water and inorganic ions.

The colon absorbs water and ions, producing semisolid feces from the slurry of indigestible materials it receives from the small intestine. Absorption of too much water in the colon can cause constipation. The opposite, diarrhea, results if too little water is absorbed or if water is secreted into the colon. (Both constipation and diarrhea can be induced by toxins from certain microorganisms.) Feces are stored in the last segment of the colon and are periodically excreted.

Immense populations of bacteria live within the colon. One of the resident species is *Escherichia coli*, the bacterium that is so popular among researchers in biochemistry, genetics, and molecular biology. This inhabitant of the colon lives on matter indigestible to humans and produces some products useful to its host. Vitamin K and biotin, for example, are synthesized by *E. coli* and absorbed through the wall of the colon. Excessive or prolonged intake of antibiotics can lead to vitamin deficiency because the antibiotics kill the normal intestinal bacteria at the same time they are killing the disease-causing organisms for which they are intended. The intestinal bacteria produce gases such as methane and hydrogen sulfide as by-products of their largely anaerobic metabolism. Humans expel gas after eating beans because the beans contain certain carbohydrates that bacteria—but not humans—can break down.

The large intestine of humans has a small, fingerlike pouch called the appendix, which is best known for the trouble it causes when it becomes infected. The human appendix plays no essential role in digestion, but it does contribute to immune system function. It can be surgically removed without serious consequences. The part of the gut that , »LV-- »

Herbivores have special adaptations to digest cellulose

Cellulose is the principal organic compound in the diets of herbivores. Most herbivores, however, cannot produce cellulolytic enzymes that hydrolyze cellulose. Exceptions include silverfish (well known for eating books and stored papers), earthworms, and shipworms. Other herbivores, from termites to cattle, rely on microorganisms living in their digestive

tracts to digest cellulose for them.

The digestive tracts of ruminants (cud chewers) such as cattle, goats, and sheep are specialized to maximize the benefits of their endosymbiotic microorganisms. In place of the usual mammalian stomach, ruminants have a large, four-chambered organ (Figure 50.18). The first two chambers, the rumen and the reticulum, are packed with anaerobic microorganisms that break down cellulose. The ruminant periodically regurgitates the contents of the rumen (the cud) into the reticulum for chewing. When the more thoroughly ground-up vegetable fibers are swallowed again, they present more surface area to the microorganisms for their digestive actions.

The microorganisms in the rumen and reticulum metabolize cellulose and other nutrients to simple fatty acids, which become nutrients for the host. In addition, the microorganisms themselves provide an important source of protein for the host. The plant materials ingested by a ruminant are a poor source of protein but they contain inorganic nitrogen that the microorganisms use to synthesize their own amino acids. A cow can derive more than 100 g of protein per day from digestion of its endosymbiotic microorganisms.

Carbon dioxide and methane are by-products of the fermentation of cellulose carried out by microorganisms. A single cow can produce and belch 400 liters of methane a day. Methane is the second most abundant of the "greenhouse gases" whose concentration in the atmosphere is increasing,

forms the appendix in humans. The food leaving the rumen

where it functions, as we will see, in cellulose digestion. As our primate ancestors evolved to exploit diets less rich in indigestible cellulose, the cecum no longer served an essential function and gradually became vestigial (reduced to a trace).

| This mixture passes through the omasum, where it is concentrated by water reabsorption.

50.18 The Ruminant Stomach

Four specialized stomach compartments enable ruminants to digest and subsist on protein-poor plant material.

It then enters the true stomach, the abomasum, which secretes hydrochloric acid and proteases.

Reticulum

The microorganisms are killed by the acid, digested by the proteases, and passed on to the small intestine for further digestion and absorption.

The rate of multiplication of microorganisms in the rumen is great enough to offset their loss, so a well-balanced, mutually beneficial relationship is maintained.

ANIMAL NUTRITION 903

and domesticated ruminants are second only to industry as a source of methane gas.

The food leaving the rumen carries with it enormous numbers of the cellulose-fermenting microorganisms. This mixture passes through the omasum, where it is concentrated by water absorption. It then enters the true stomach, the abomasum, which secretes hydrochloric acid and proteases. The microorganisms are killed by the acid, digested by the proteases, and passed on to the small intestine for further digestion and absorption. The rate of multiplication of microorganisms in the rumen is great enough to offset their loss, so a well-balanced, mutually beneficial relationship is maintained.

Some mammalian herbivores other than ruminants have microbial farms and cellulose fermentation. In a branch off the large intestine called the cecum. Rabbits and hares are good examples. Since the cecum empties into the large intestine, the

absorption of the nutrients produced by the microorganisms is inefficient and incomplete. Therefore, some of these animals re-ingest some of their own feces, a behavior known as coprophagy. Coprophagous species usually produce two kinds of feces, one consisting of pure waste (which they discard), and one consisting mostly of cecal material, which they re-ingest directly from the anus. As this cecal material passes through the stomach and small intestine, the nutrients it contains are digested and absorbed.

Control and Regulation of Digestion

The vertebrate gut is an assembly line in reverse—a disassembly line. As with a standard assembly line, control and coordination of sequential processes is critical. Both neural and hormonal controls govern gut functions.

Autonomic reflexes coordinate functions in different regions of the gut

Everyone has experienced salivation stimulated by the sight or smell of food. That response is an autonomic reflex, as is the act of swallowing following tactile stimulation at the back of the mouth. Many autonomic reflexes coordinate activities in different regions of the digestive tract. Loading the stomach with food, for example, stimulates increased activity in the colon, which can lead to a bowel movement.

The digestive tract is unusual in that it has an intrinsic

nerve

called the

enteric nervous system. In addition to autonomic

reflexes involving the CNS, such as salivation and swallowing, neural messages can travel from one region of the digestive tract to another without being processed by the CNS.

Hormones control many digestive functions

Several hormones control the activities of the digestive tract and its accessory organs (Figure 50.19). The first hormone ever discovered came from the duodenum; it was called secretin because it caused the pancreas to secrete digestive juices. We now know that secretin is one of several hormones that control pancreatic secretion; specifically, secretin stimulates the pancreas to secrete a solution rich in bicarbonate ions.

50.19 Hormones Control Digestion

Several hormones are involved in feedback loops that control the sequential processing of food in the digestive tract.

In response to the presence of fats and proteins in the chyme, the mucosa of the small intestine secretes c cH oJecys- tokenin, a hormone that stimulates the gallbladder to release bile and the pancreas to release digestive enzymes. Cholecystokinin and secretin also slow the movements of the stomach, which slows the delivery of chyme into the small intestine.

The stomach secretes a hormone..called \wedge gastrin into the blood. Cells in the lower region of the stomach release gastrin when they are stimulated by the presence of food. Gastrin circulates in the blood until it reaches cells in the upper areas of the stomach wall, where it stimulates the secretions and movements of the stomach. Gastrin release is inhibited when the stomach contents become too acidic—another example of negative feedback.

Control and Regulation of Fuel Metabolism

Most animals do not eat continuously. When they do eat, food is present in the gut and nutrients are being absorbed for some period of time after the meal, called the absorp-

904 CHAPTER FIFTY

tive period. Once the stomach and small intestine are empty \wedge nutrients are no longer \wedge in \wedge g \wedge rh \wedge H During this postabsorptive period, the continuous processes of energy metabolism μ \ biosynthesis must run on internal reserves. Nutrient traffic must be controlled so that reserves accumulate during the absorptive period are used appropriately during the postabsorptive period.

The liver directs the traffic of fuel molecules

The liver directs the traffic of the nutrients that fuel metabolism. When nutrients are abundant in the blood, the liver stores them in the forms of glycogen and fats. The liver also synthesizes blood plasma proteins from circulating amino acids. When the availability of fuel molecules in the blood declines, the liver delivers glucose and fats back to the blood. The \wedge Tver has a n enormous capacity to interconvert fuel molecules. Liver cells can convert monosaccharides into ei-

ther glycogen or fat, and vice versa. The liver can also convert certain amino acids and some other molecules, such as pyruvate and lactate, into glucose—a process called gluco-neogenesis. The liver is also the major controller of fat me-'tabollsm through its production of lipoproteins.

Lipoproteins:The good, the bad, and the ugly

In the intestine jfile solves the problem of processing hydrophobic fats in an aqueous medium. The transportation of fats in the circulatory system presents the same problem, and $\text{d l i poBmtej n sjar e}$ the solution . A lipoprotein is)a parti cle made u p of a cor eof fat and choleste rol and a cove ring of protein th at makes it water-solu ble. The largest lipoprotein particles are the chylomicrons produced by the mucosal cells of the intestine, which transport dietary fat and cholesterol into the circulation (see Figure 50.17). As the chylomicrons circulate through the liver and to adipose (fat) tissues throughout the body, receptors on the capillary walls recog-

4

nize their protein coats, and lipases begin to hydrolyze the fats, which are then absorbed into liver or fat cells. Thus the protein coat of the lipoprotein both makes it water-soluble and serves as an "address" that directs it to a specific tissue. Lipoproteins other than chylomicrons originate in the liver and are classified according to their density. Fat has a low density (it floats in water), so the more fat a lipoprotein contains, the lower its density.

► Very-low-density lipoproteins (VLDL) produced by the liver contain mostly triglyceride fats that are being transported to fat cells in tissues around the body.

► Low-density lipoproteins (LDL) consist of about 50 to 60 percent cholesterol, which they transport to tissues' around the body for use in biosynthesis and for storage.

► High-density lipoproteins (HDL) serve as acceptors of cholesterol (they consist of about 25 percent cholesterol) and are believed to remove cholesterol from tissues and carry it to the liver, where it can be used to synthesize bile.

Because of their differing functions in cholesterol regulation, LDL is sometimes called "bad cholesterol" and HDL "good cholesterol"—designations that are somewhat controversial. However, we do know that a high ratio of LDL to HDL in a person's blood is a risk factor for atherosclerotic heart disease. Cigarette smoking lowers HDL levels, and regular exercise increases them.

Fuel metabolism is controlled by hormones

During the absorptive period, blood glucose levels are high as carbohydrates are digested and absorbed. During this time, the liver takes up glucose from the blood and converts it to glycogen and fat, fat cells take up glucose from the blood and convert it to stored fat, and the cells of the body preferentially use glucose as their metabolic fuel.

During the postabsorptive period these processes are reversed. The liver breaks down glycogen to supply glucose to the blood, the liver and the adipose tissues supply fatty acids to the blood, and most of the cells of the body preferentially use fatty acids as their metabolic fuel.

One tissue that does not switch fuel sources during the postabsorptive period is the nervous system. The cells of the nervous system require a constant supply of glucose. Even though the nervous system can use other fuels to a limited extent, its overall dependence on glucose is the reason it is so important for other cells of the body to shift to fat metabolism during the postabsorptive period. This shift preserves the available glucose and glycogen stores for the nervous system, for as long as possible.

What directs the traffic in fuel molecules? Insulin and glucagon, two hormones produced and released by the pancreas, are responsible for controlling the metabolic directions that fuel molecules take (Figure 50.20). The most

important of these hormones is ^{insulin} which is produced in response to high blood glucose

The pancreas releases insulin into the circulatory system when blood glucose rises above the normal postabsorptive level. Insulin facilitates the entry of glucose into most cells of the body. When insulin is present, most cells burn glucose as their metabolic fuel, fat cells use glucose to make fat, and liver cells convert glucose to glycogen and fat.

As soon as blood glucose falls back to postabsorptive levels, insulin release diminishes rapidly, and the entry of glucose into cells other than those of the nervous system is inhibited. Without a supply of glucose, cells switch to using glycogen and fat as their metabolic fuels. In the absence of insulin, the liver and fat cells stop synthesizing glycogen and fat and begin breaking them down. As a result, the liver supplies glucose to the blood rather than taking it from the blood, and both the liver and the adipose tissues supply fatty acids to the blood.

50.21 Fuel Molecule Traffic during the Absorptive and Postabsorptive Periods

Insulin promotes glucose uptake by liver, muscle, and fat cells during the absorptive period. During the postabsorptive period, the lack of insulin blocks glucose uptake by these same tissues and promotes fat and glycogen breakdown to supply metabolic fuel.

glucose

The pancreas releases glucagon when the blood glucose concentration falls below the normal postabsorptive level. Glucagon has the opposite effect of insulin: it stimulates liver cells to break down glycogen and to carry out gluconeogenesis. Thus, under the influence of glucagon, the liver produces glucose and releases it into the blood.

The traffic of fuel molecules during the absorptive and postabsorptive periods is summarized in Figure 50.21, which indicates the steps controlled by insulin and glucagon. During the absorptive period, all fuel molecules move toward storage, and glucose is the preferred energy source for all cells. During the postabsorptive period, most cells switch to metabolizing their own glycogen reserves, while the blood glucose reserves are saved for the nervous system. The level of circulating glucose is maintained through glycogen breakdown and gluconeogenesis.

906 CHAPTER FIFTY

The Regulation of Food Intake

At the beginning of this chapter we noted that obesity is a major health issue in the United States. People spend billions of dollars every year on schemes to lose weight, but the problem increases. A simple rule—take in fewer calories than your body burns, but maintain a balanced diet—should solve the problem, but it doesn't. Why? As we noted, social and lifestyle factors play a major role, but these factors play out against a genetic and regulatory background.

The amount of food an animal eats is governed by its sensations of hunger and satiety, and these sensations are influenced by a region of the brain called the hypothalamus. If a region in the middle of the hypothalamus of rats, called the ventromedial hypothalamus, is damaged, the animals will increase their food intake and become obese. If a different region of the hypothalamus, called the lateral hypothalamus, is damaged, rats will decrease their food intake and become skinny. In both cases the rats eventually reach a new equilibrium body weight, which they maintain. Thus, regulation is maintained, but the level of regulation has been changed. Other brain regions have also been implicated in control of hunger and satiety.

In Chapter 40 we learned that regulation involves feedback information and a means of comparing that information with a set point. There is some evidence that cells in the hypothalamus and in the liver are sensitive to the levels of blood glucose and insulin with high levels stimulating satiety and low levels stimulating hunger. There is even stronger evidence, however, that signals from fat metabolism influence hunger and satiety.

A single-gene mutation in mice, when present in the homozygous condition, results in mice that eat enormous amounts of food and become obese (Figure 50.22). Using genetics terms, these mice are called *ob/ob* mice due to their double dose of the recessive "obese" gene. The wild-type *ob*

50.22 A Single-Gene Mutation Leads to Obesity in Mice

Leptin serves as a negative feedback signal to the brain to limit food intake. The fat cells of the *ob/ob* mouse (left) do not produce leptin. The wild-type mouse (right) does produce leptin and does not become obese when kept under the same conditions as the *ob/ob* mouse.

gene codes for a protein that has been named leptin (from the Greek leptos, "thin"). When leptin was injected into *ob/ob* mice, they ate less and lost body fat. Leptin is produced by fat cells and circulates in the blood. Receptors for leptin are found in the regions of the hypothalamus that are involved in control of hunger and satiety. It seems that leptin signals the brain about the status of the body fat reserves.

Could leptin be used to reduce human obesity? In a very few cases, obese humans do not produce the hormone leptin, and injections of leptin can curb their appetites and enable them to lose body mass. Most obese humans, however, have higher than normal circulating levels of leptin. It is likely that they have receptors with reduced sensitivity. Leptin appears to be one important feedback signal in the regulation of food intake. Understanding the actions of leptin in normal and obese individuals might provide a partial answer as to why some individuals find it easier than others to avoid excessive food intake and increases in body fat. Additional feedback signals are most certainly involved.

Toxic Compounds in Food

Plant and animal tissues contain nutrients, but as we have seen, they can also contain toxic compounds (Figure 50.23). Some mushrooms, for example, contain poisons and hallucinogens; some mollusks, fishes, and amphibians contain neurotoxins; some plants contain compounds that stimulate or depress the heart; and of course, tobacco contains nicotine, poppies contain opium, and marijuana contains tetrahydrocannabinol. Ingesting many plant and animal tissues, therefore, can be dangerous.

Human activities add millions of tons of synthetic toxic compounds to our environment every year, making the problem worse. Many of these compounds enter the air we breathe and the water we drink, as well as the food we eat. A whole new field, called environmental toxicology, has developed to address the problems of poisons in the environment.

Some toxins are retained and concentrated in organisms

The physical and chemical properties of a toxic compound affect its retention within a biological system. If a compound can dissolve in water, it may be quickly metabolized (and thus detoxified) because it is easily accessible to the wide variety of enzymes that can break down complex molecules in food.

In addition to being broken down or metabolized, many water-soluble compounds can be filtered out of the blood by the kidneys, and therefore do not accumulate in the body. That is why urine tests are used to detect illegal drug use by athletes and other individuals. However, some potentially dangerous water-soluble compounds can be incorporated into the body and disrupt normal functions. An example is lead, which can replace iron in blood and calcium in bone.

Lipid-soluble compounds are usually metabolized more slowly than water-soluble compounds, and they are often

Papaver somniferum

Takifugu rubripes

50.23 Toxins Occur Naturally

Many animals and plants contain dangerous, potentially deadly toxins, (a) Opium poppies are the source of morphine and heroin. (b) The puffer fish is a delicacy in Japanese sushi restaurants; restaurants that serve it have special licenses affirming their chef's ability to prepare the fish so that its neurotoxins do not endanger diners.

stored in the body for a long time because they dissolve in the lipids of membranes and adipose tissues. Lipid-soluble compounds can accumulate in the body and reach very high concentrations. Even compounds that are beneficial or neutral to the body at low concentrations, such as fat-soluble vitamins, can become toxic at high concentrations.

Some toxins can bioaccumulate in the environment

Some lipid-soluble toxins, including many pesticides, can bioaccumulate in the environment; that is, they can become more and more concentrated in predators that eat contaminated prey. The pesticide load is passed up the food chain from prey to predator, growing increasingly concentrated in the tissues of each consumer in turn. In the top predator, the pesticide may be concentrated thousands or millions of times. Many top predators show high levels of pesticides and other synthetic chemicals in their tissues. Long-lived species, such as eagles or bears, are particularly at risk for heavy body burdens of accumulated pesticides because they have many years to accumulate them. Bioaccumulated toxins may be responsible for high rates of cancer and infertility in some wildlife populations.

A well-documented case was the effect of the pesticide DDT on predatory bird populations. Bioaccumulated DDT caused extreme thinning of eggshells and therefore high mortality of embryos (Figure 50.24). As a result, many species of predatory birds, such as ospreys, eagles, and falcons, became endangered. Since the banning of DDT use in the United States, these species have been recovering. Scientists and policy-makers are now setting standards for and researching alternatives to such pesticides to decrease the amounts of synthetic toxins bioaccumulating within natural systems. Since humans are at the top of the food chain, eating at all levels, we must consider the risks of our own exposure to these toxins.

ANIMAL NUTRITION 907

The body cannot metabolize many synthetic toxins

How does the way that the body handles synthetic chemicals differ from the way it handles natural chemicals? In many cases, the detoxification systems that metabolize natural chemicals can also metabolize synthetic chemicals, breaking them apart and eliminating them through the urine. Enzymes called cytochrome P450s are responsible for much of this detoxification.

P450s are less specific in their abilities to bind substrates than are most enzymes. Thus, each P450 can catalyze reactions with a wide range of compounds, and there are many P450s. Phase I P450s make small chemical changes to the substrate, such as adding a —OH group or a —SO₃ group, which prepares the substrate for a second reaction. Phase II P450s use the —OH or —SO₃ group to attach a hydrophilic group onto the substrate, which facilitates the elimination of that substrate from the body. Few natural compounds can escape the P450s, even when the body encounters them for the first time.

Some synthetic chemicals, however, fall outside the range of structures that P450s and other enzymes can metabolize. When such chemicals are lipophilic, they bioaccumulate, and any biological effect they have is greatly magnified. If a synthetic

chemical that cannot be metabolized is structurally similar to a hormone, that synthetic chemical may activate the hormonal signaling pathway within target cells. Whereas the natural hormonal signal can be turned off, the synthetic hormone cannot be, and control of function is lost.

50.24 DDT Affects Bird Eggs

Before its use was banned, the bioaccumulation of DDT in birds resulted in severe thinning of the eggshells of many species, with resulting population declines. This brown pelican egg cracked open long before the embryo inside was ready to hatch.

908 CHAPTER FIFTY

One example of a class of synthetic chemicals that appear to mimic hormones in animals is the polychlorinated biphenyls, PCBs. PCBs were produced extensively for use as an insulating fluid in electrical transformers from the 1930s until recently. PCBs are chemically stable, lipophilic, and are now found throughout the environment. They have been shown to bioaccumulate, reaching dangerously high levels in fish from contaminated waters such as the Great Lakes.

The biological response to exposure to PCBs in the diet varies among species. In rhesus monkeys, PCBs altered reproductive cycles, reduced weight gain in infants, depressed immune system responsiveness, and increased the incidence of death in developing embryos. In communities around the Great Lakes, studies have indicated cognitive impairment in children of mothers with a high body burden of PCBs, probably from eating fish caught in the Great Lakes. Studies of animals and of humans that have been exposed accidentally to high levels of PCBs have shown that effects are slow to reverse, lasting from several months to a year.

The risks of PCBs and DDT are now clear, but it is usually difficult to make a causal connection between a toxin in the environment and specific health effects in a population. Environmental toxicologists must be able to study large populations, use powerful statistics, and do controlled laboratory studies to obtain evidence that will support policy changes to stop and reverse the effects of synthetic environmental toxins.

Chapter Summary

Nutrient Requirements

- ▶ Animals are heterotrophs that derive their energy and structural building blocks from food, and therefore ultimately from autotrophs.
- ▶ Carbohydrates, fats, and proteins in food supply animals with metabolic energy. A measure of the energy content of food is the calorie. Excess caloric intake is stored as glycogen and fat. Review Figure 50.2
- ▶ An animal with insufficient caloric intake is undernourished and must metabolize its stored glycogen, fat, and finally its own protein for energy. Overnutrition in humans can be a serious health hazard. Review Figure 50.3
- ▶ For many animals, food provides essential carbon skeletons that they cannot synthesize themselves. Review Figure 50.4
- ▶ Humans require eight essential amino acids in their diet. All are available in milk, eggs, or meat, but not in all vegetables. Thus, vegetarians must eat a mix of foods. Review Figure 50.5
- ▶ Different animals need mineral elements in different amounts. Macronutrients, such as calcium, phosphorus, sodium chloride, and iron, are needed in large amounts. Micronutrients, such as iron, copper, magnesium, and zinc, are needed in small amounts. Review Table 50.1
- ▶ Vitamins are organic molecules that must be obtained in food. Review Table 50.2
- ▶ Malnutrition results when any essential nutrient is lacking from the diet. Lack of any essential nutrient causes a deficiency disease. Review Table 50.2

Adaptations for Feeding

- ▶ Animals can be characterized by how they acquire nutrition: Saprotrophs and detritivores depend on dead organic matter, filter feeders strain the environment for small food items, herbivores eat plants, and carnivores eat animals.
- ▶ Behavioral and anatomical adaptations reflect feeding types. In vertebrates, teeth have evolved to match the diet. Review Figure 50.9

Digestion

- Digestion involves the breakdown of complex food molecules into monomers that can be absorbed and utilized by cells. In most animals, digestion is extracellular and external to the body, taking place in a tubular gut that has different regions specialized for different digestive functions. Review Figure 50.10
- Absorptive areas of the gut are characterized by a large surface area. Review Figure 50.11
- Hydrolytic enzymes break down proteins, carbohydrates, and fats into their monomeric units. To prevent the organism itself from being digested, these enzymes are released as inactive zymogens, which become activated when secreted into the gut.

Structure and Function of the Vertebrate Gut

- The cells and tissues of the vertebrate gut are organized in the same way throughout its length. The innermost tissue layer, the mucosa, is the secretory and digestive surface. The submucosa contains secretory cells and glands, blood and lymph vessels, and nerves. External to the submucosa are two smooth muscle layers (circular and longitudinal) that move food through the gut. Between the two muscle layers is a nerve network that controls the movements of the gut. Review Figure 50.13
- Swallowing is a reflex that pushes food into the esophagus. Waves of smooth muscle contraction and relaxation called peristalsis move food from the beginning of the esophagus through the entire length of the gut. Sphincters block the gut at certain locations, but they relax as a wave of peristalsis approaches. Review Figure 50.14
- Enzymatic digestion begins in the mouth, where amylase is secreted with the saliva. Protein digestion begins in the stomach with pepsin and HCl secreted by the stomach mucosa. The mucosa also secretes mucus, protects the tissues of the gut. Review Figure 50.15
- In the duodenum, pancreatic enzymes carry out most of the digestion of the food. Bile from the liver and gallbladder assists in the digestion of fats by breaking them into micelles. Bicarbonate ions from the pancreas neutralize the pH of the chyme entering from the stomach to produce an environment conducive to the actions of pancreatic enzymes. Review Figure 50.16, Table 50.3
- Final enzymatic cleavage of peptides and disaccharides occurs on the surface of the cells of the intestinal mucosa. Amino acids, monosaccharides, and many inorganic ions are absorbed by the microvilli of the mucosal cells. In many cases specific carrier proteins in the membranes of these cells transport nutrients into the cells. Sodium cotransport is a common mechanism for actively absorbing nutrient molecules and ions.
- Fats are absorbed mostly as monoglycerides and fatty acids, which are the product of lipase action on triglycerides in food. These products pass through the membranes of mucosal cells and are then resynthesized into triglycerides within the cells. The triglycerides are combined with cholest-

ANIMAL NUTRITION 909

terol and coated with protein to form chylomicrons, which pass out of the mucosal cells and into lymphatic vessels in the submucosa. Review Figure 50.17

- Water and ions are absorbed in the large intestine so that waste matter is consolidated into feces, which are periodically excreted.
- In herbivores such as rabbits and ruminants, some compartments of the gut have large populations of microorganisms that aid in digesting molecules that otherwise would be indigestible to their host. Review Figure 50.18

Control and Regulation of Digestion

- The processes of digestion are coordinated and controlled by neural and hormonal mechanisms. Salivation and swallowing are autonomic reflexes. Actions of the stomach and small intestine are largely controlled by the hormones gastrin, secretin, and cholecystokinin. Review Figure 50.19

Control and Regulation of Fuel Metabolism

- The liver interconverts fuel molecules and plays a central role in directing their traffic. When food is being absorbed from the gut, the liver takes up and stores fats and carbohydrates, converting monosaccharides to glycogen or fat. The liver also takes up amino acids and uses them to produce blood plasma proteins.
- Fat and cholesterol are shipped out of the liver as low-density lipoproteins. High-density lipoproteins act as acceptors of cholesterol and are believed to bring fat and cholesterol back to the liver.
- Fuel metabolism during the absorptive period is controlled largely by the hormone insulin, which promotes glucose uptake and utilization by most cells of the body, as well as fat synthesis in adipose tissue. During the postabsorptive period, the lack of insulin blocks the uptake and utilization of glucose by most cells of the body except neurons. If blood glucose levels fall, the hormone glucagon is secreted, stimulating the liver to break down glycogen to release glucose to the blood. Review Figures 50.20, 50.21

The Regulation of Food Intake

► Food intake is governed by sensations of hunger and satiety that are determined by brain mechanisms. When one hypothalamic region is damaged, rats eat more and become obese; when another region is damaged, they eat less and

become thin. A number of molecules, such as circulating insulin and glucose, provide feedback information to these brain areas.

► Leptin is a hormone produced by fat cells that inhibits food intake.

Toxic Compounds in Food

► Even natural plant and animal foods can contain toxic compounds in addition to nutrients. Human activities such as the use of pesticides and the release of pollutants into the environment have made the problem of toxins in food even worse.

► An organism can accumulate toxic compounds in its body, especially if those compounds are lipid-soluble or take the structural place of a natural molecule.

► Toxins such as PCBs and DDT that accumulate in the bodies of prey are transferred to and further concentrated in the bodies of their predators. This bioaccumulation produces high concentrations of toxins in animals high up the food chain.

For Discussion

1. Several current popular diet books recommend high fat and protein intake and low carbohydrate intake as a means of losing body mass. What could the rationale of a high-fat and high-protein diet be, and what health issues should be considered when someone considers going on such a diet?

2. Carnivores generally have more dietary vitamin requirements than herbivores do. Why?

3. It is said that the most important hormonal control of fuel metabolism in the postabsorptive period is the lack of insulin. Explain.

4. Why is obstruction of the common bile duct so serious? Consider in your answer the multiple functions of the pancreas and the way in which digestive enzymes are processed.

5. Trace the history of a fatty acid molecule from a piece of buttered toast to a plaque on a coronary artery. What possible forms and structures could it have passed through in the body? Describe a direct and an indirect route it could have taken.

51

Salt and Water Balance and Nitrogen Excretion

Blood, sweat, and tears taste salty because they reflect the composition of the tissue fluid that bathes the cells of the body. The volume and the composition of the tissue fluid must remain within certain limits and must be kept relatively free of wastes. Maintaining homeostasis of the tissue fluid can be challenging. Consider the problems of vampires—not the horror film kind, but the bat kind.

Vampire bats are small, tropical mammals that feed on the blood of other mammals, such as cattle. The bat lands on an unsuspecting (usually sleeping) victim, bites into a vein, and drinks blood—a high-protein, liquid food. The bat has only a short time to feed before the victim wakes and shakes it off. To maximize the volume of blood it can ingest, it eliminates water from its food as fast as it can by producing a lot of very dilute urine. The warm trickle down the neck of the victim is not blood!

Once feeding ends, however, this high rate of water loss cannot continue. Now the vampire bat is digesting protein and must excrete large amounts of nitrogenous breakdown products while conserving its body water. Within minutes, the excretory system of the vampire bat switches from producing lots of very dilute urine to producing a tiny amount of highly concentrated urine. Within minutes, the vampire bat is able to switch from an excretory physiology typical of an animal living in fresh water to an excretory physiology typical of an animal living in an arid desert.

In this chapter we discover how the vampire bat and other species accomplish the various feats of salt and water balance and excretion of wastes that adapt them to many different environments. We begin by discussing the challenges presented by different environments; we use some invertebrate examples to illustrate the basic mechanisms used in the excretory systems of all animals.

Turning to vertebrates, we show that the common anatomical unit that accomplishes all of these tasks is the nephron. The nephron

Blood as a Fast Food

The vampire bat, *Desmodus rotundus*, is able to adjust its excretory physiology from water-excreting to water-conserving, depending on whether it is ingesting or digesting its blood meal.

evolved from a structure that enabled animals living in fresh water to excrete water to a structure that enabled animals living in dry terrestrial habitats to conserve water. Finally, we present the mechanisms that control and regulate salt and water balance in mammals, giving the vampire bat and other species their remarkable abilities to exploit unusual diets and extreme environments.

Tissue Fluids and Water Balance

Life evolved in the seas, and seawater is the extracellular environment for the cells of the simplest marine animals. More complex marine animals have an internal environment consisting of extracellular or tissue fluid, which is isolated from seawater but is similar to it in composition and osmotic concentration. Marine vertebrates and terrestrial animals maintain tissue fluids whose concentration and composition differ considerably from that of seawater (see Chapter 49). The concentration of the tissue fluid determines the water balance of the cells, and its composition influences the health and functions of the cells. Recall, for example, the importance of ionic gradients between the tissue fluid and the cytoplasm of nerve and muscle cells (see Chapter 44).

SALT AND WATER BALANCE AND NITROGEN EXCRETION 911

To understand what is meant by water balance, recall that cell plasma membranes are permeable to water and that the movement of water across membranes depends on differences in solute potential. (See the discussion of osmosis in Chapter 5.) If the solute potential (osmolarity) of the tissue fluid is less negative (that is, the fluid contains fewer solutes) than that of the intracellular fluids, water moves into the cells, causing them to swell and possibly burst. If the solute potential of the tissue fluid is more negative (the fluid contains more solutes) than that of the intracellular fluids, the cells lose water and shrink. The solute potential of tissue fluid determines both the volume and the solute potential of the intracellular environment.

Excretory organs control the solute potential of tissue fluid

Excretory organs control the solute potential and the volume of tissue fluid by excreting solutes that are in excess (such as NaCl when we eat lots of salty food) and conserving solutes that are valuable or in short supply (such as glucose and amino acids). In terrestrial organisms, these excretory organs also eliminate the waste products of nitrogen metabolism. The output of the excretory organs is called urine.

The functions of the excretory organs of a species, and therefore the composition of its urine, depend on the environment in which it lives. We will examine excretory systems that maintain salt and water balance and eliminate nitrogen in marine, freshwater, and terrestrial habitats. In spite of the evolutionary diversity of the anatomical and physiological details, all these systems obey a common rule: there is no active transport of water. Water must be moved either by pressure or by a difference in solute potential. Also, in spite of this evolutionary diversity, there are common mechanisms used by excretory systems.

Mechanisms used by excretory systems include filtration, secretion, and resorption

The excretory systems of many species filter the tissue fluid and then process the filtrate through a system of tubules to produce urine. This filtration process is usually carried out on blood plasma driven across capillary walls in the excretory organ by blood pressure. The filtrate then enters a system of tubules. The cells of the tubules change the composition of the filtrate by active secretion and resorption of specific solute molecules. These three mechanisms are used in the excretory systems of freshwater species, which excrete water and conserve salts, as well as in the systems of marine and terrestrial species, which conserve water and excrete salts.

Distinguishing Environments and Animals in Terms of Salt and Water

The salt concentration, or osmolarity, of ocean water is about 1,070 milliosmoles/liter (mosm/l), and fresh water is generally between 1 and 10 mosm/l. Aquatic environments grade continuously from fresh to extremely salty. Consider

a place where a river enters the sea through a bay or a marsh. Aquatic environments within that bay or marsh range in osmolarity from that of the fresh water of the river to that of the open sea. Evaporating tide pools can reach an even greater osmolarity than seawater. Animals live in all these environments. Some species, called osmoconformers, allow the osmolarity

of their tissue fluids to equilibrate with their environment. Others, called osmoregulators, maintain the osmolarity of their tissue fluids at a constant level as the environment changes.

Most marine invertebrates are osmoconformers

Over a wide range of environmental osmolarities, marine invertebrates simply equilibrate the osmolarity of their tissue fluid with that of the environment. There are limits to osmoconformity, however. No animal could survive if its tissue fluid had the osmolarity of fresh water; nor could animals survive with internal osmolarities as high as those that may be reached in an evaporating tide pool. Such solute concentrations cause proteins to denature.

Osmoregulators regulate the concentration of their tissue fluids

All animals have some solutes in their tissue fluids. Therefore, in fresh water, osmosis will cause water to invade the bodies of animals, so osmoregulation is essential. To osmo-regulate in fresh water, animals must excrete water and conserve solutes; hence they produce large amounts of dilute urine. In salt water, the opposite problem exists. For animals that maintain the osmolarity of their tissue fluids below that of the environment, osmosis will cause a loss of water. To osmoregulate in salt water, animals must conserve water and excrete salts; thus they tend to produce small amounts of very concentrated urine.

Even animals that osmoconform over a wide range of environmental osmolarities must osmoregulate in extreme environments. An excellent example is the brine shrimp *Artemia* (Figure 51.1f), which lives in environments of almost any salinity. *Artemia* are found in huge numbers in the most saline environments known, such as Great Salt Lake in Utah or coastal evaporation ponds where salt is concentrated for commercial purposes (see Figure 26.23). The osmolarity of such water reaches 2,500 mosm/l. At these high environmental osmolarities, *Artemia* is capable of maintaining its tissue fluid osmolarity considerably below that of the environment, and therefore acts as a hypotonic osmoregulator. Very few organisms can survive in the crystallizing brine in which *Artemia* thrives. The main mechanism this small crustacean uses for hypotonic osmoregulation is the active transport of NaCl from its tissue fluids out across its gill membranes to the environment.

Artemia cannot survive in fresh water, but they can live in dilute seawater, in which they maintain the osmolarity of their tissue fluids above that of the environment. Under these conditions, *Artemia* behaves as a hypertonic osmoregulator; that is, it maintains the osmolarity of its tissue fluid above the osmolarity of the environment (Figure 51.1b).

912 CHAPTER FIFTY-ONE

57.7 Environments (") ■ BMHMfWJi&iBieS CO

Can Vary Greatly in Salt

Concentration

(a) Brine shrimp are exposed to a range of very different salinities, (fc>) Animals like the brine shrimp that live at the extremes of environmental osmolarities display flexible osmoregulatory abilities. They become hypertonic osmoregulators in very dilute water, or hypotonic osmoregulators in very saline water.

The composition of tissue fluids can be regulated

Osmoconformers can be ionic conformers, allowing the ionic composition, as well as the osmolarity, of their tissue fluids to match that of the environment. Most osmoconformers, however, are ionic regulators to some degree: They employ active transport mechanisms to maintain specific ions in their tissue fluid at concentrations different from those in the environment.

The terrestrial environment presents problems of salt and water balance that are entirely different from those faced by aquatic organisms. Because the terrestrial environment is extremely desiccating (drying), most terrestrial animals must conserve water. (Exceptions are animals such as muskrats and beavers that spend most of their time in water.)

Terrestrial animals obtain their salts from their food. But plants generally have low concentrations of sodium, so most herbivores must conserve sodium ions. Some terrestrial herbivores travel long distances to naturally occurring salt licks. By contrast, birds that feed on marine animals must excrete the large excess of sodium they ingest with their food. Their nasal salt glands excrete a concentrated solution of sodium chloride via a duct that empties into the nasal cavity. Birds, such as penguins and seagulls, that have nasal salt glands can be seen frequently sneezing or shaking their heads to get rid of the very salty droplets that form (Figure 51.2).

Excreting Nitrogen

The end products of the metabolism of carbohydrates and fats are water and carbon dioxide, which are not difficult to eliminate. Proteins and nucleic acids, however, contain nitrogen, so their metabolism produces nitrogenous wastes in addition to water and carbon dioxide. The most common nitrogenous waste is ammonia (NH₃), which is highly toxic. Ammonia must

be excreted continuously to prevent its accumulation, or it must be detoxified by conversion into other molecules for excretion. Those molecules are principally urea and uric acid (Figure 51.3).

Aquatic animals excrete ammonia

Continuous excretion of ammonia is relatively simple for aquatic animals. Ammonia diffuses in and is highly soluble

in water. Animals that breathe water continuously lose ammonia from their blood to the environment by diffusion across their gill membranes. Animals, such as aquatic invertebrates and bony fishes, that excrete ammonia are said to be ammonotelic.

Many terrestrial animals and some fishes excrete urea

Ammonia is a dangerous metabolite for terrestrial animals that have limited access to water. In mammals, ammonia is lethal when it reaches only 5 mg/100 ml of blood. Therefore, terrestrial (and some aquatic) animals convert ammonia into either urea or uric acid. Ureotelic animals, such as mammals, amphibians, and cartilaginous fishes (sharks and rays), excrete urea as their principal nitrogenous waste product.

Urea is quite soluble in water, but excretion of urea solutions at low concentrations could result in a large loss of water that many terrestrial animals can ill afford. As we will see later in this chapter, mammals have evolved excretory systems that can conserve water by producing concentrated urea solutions. The cartilaginous fishes are another story. These marine species keep their body fluids almost isotonic to the marine environment by retaining high concentrations of urea.

Some terrestrial animals excrete uric acid

Animals that conserve water by excreting nitrogenous wastes as uric acid are said to be uricotelic. Insects, reptiles, birds, and some amphibians are uricotelic. Uric acid is very insoluble in water and is excreted as a semisolid (for example, the whitish material in bird droppings). Therefore, a uricotelic animal loses very little water as it disposes of its nitrogenous wastes.

SALT AND WATER BALANCE AND NITROGEN EXCRETION 913

5 7.2 Nasal Salt Glands Excrete Excess Salt

- (a) Marine birds have nasal salt glands adapted to excrete the excess salt from the seawater they consume with their food,
 (b) This giant petrel has returned from a feeding trip at sea and is excreting salt through its nasal salt gland. Note the drop of excreted salt at the tip of the bird's beak.

Most species produce more than one nitrogenous waste

Humans are ureotelic, yet we also excrete uric acid and ammonia. The uric acid in human urine comes largely from the metabolism of nucleic acids and caffeine. In the condition known as gout, uric acid levels in the tissue fluid increase and uric acid precipitates in the joints and elsewhere, caus-

5 7.3 Waste Products of Metabolism

The metabolism of proteins and nucleic acids produces the nitrogenous wastes ammonia, uric acid, and urea. Most aquatic animals, including most fishes, excrete nitrogenous waste as ammonia. Most terrestrial animals excrete either urea or uric acid. Urea is more soluble in water and is the major N excretory product for mammals and amphibians, as well as some fishes. Uric acid is not very soluble in water and is the major N excretory product for birds, reptiles, and insects.

ing swelling and pain. The excretion of ammonia is an important mechanism for regulating the pH of the tissue fluid. In some species, different developmental forms live in quite different habitats and have different forms of nitrogen excretion. The tadpoles of frogs and toads, for example, excrete ammonia across their gill membranes, but when they develop into adult frogs or toads, they gener-ally excrete urea. Some adult frogs and toads that live in arid habitats excrete uric acid. These examples show the considerable evolutionary flexibility in how nitrogenous \ a-^tes are excreted.

The Diverse Excretory Systems of Invertebrates

Most marine invertebrates are osmoconformers and have few adaptations for salt and water balance other than active transport mechanisms for ionic regulation. To excrete nitrogen, they can passively lose ammonia by diffusion to the seawater. Freshwater and terrestrial invertebrates, however, have a wide variety of adaptations for maintaining salt and water balance and excreting nitrogen. All of these adaptations are based on the same set of mechanisms: filtration of body fluids and active secretion and resorption of specific ions.

Protonephridia excrete water and conserve salts

Many flatworms, such as Planaria, live in fresh water. These animals excrete water through an elaborate network of tubules running throughout their bodies. The tubules end in flame cells, so called because each tubule has a tuft of cilia beating inside it, giving the appearance of a flickering flame (Figure 51.4). A flame cell and a tubule together form a protonephridium (plural protonephridia; from the Greek proto, "before," and nephros, "kidney").

Tissue fluid enters the tubules (how it does so is not entirely clear), and the beating of the cilia causes this fluid to flow through the tubules toward the animal's excretory pore. As it flows, the cells of the tubules modify the fluid. As the modified tubule fluid (urine) leaves the planarian, it is less concentrated than the animal's tissue fluid, so ions are conserved and water is excreted by the protonephridium.

Metanephridia process coelomic fluid

Filtration of body fluids and modification of urine by tubules are highly developed processes in annelid worms, such as the earthworm. Recall that annelids are segmented and have a fluid-filled body cavity, called a coelom, in each segment (see Figure 31.23). Annelids have a closed circulatory system through which blood is pumped under pressure (see Figure 49.3). The pressure causes the blood to be filtered across the thin, permeable capillary walls into the coelom. This process is called filtration because the cells and large protein molecules of the blood stay behind in the capillaries while water and small molecules leave them and enter the coelom. In addition, some waste products, such as ammonia, diffuse directly from the tissues into the coelom. But where does this coelomic fluid go?

Excretory • pore

Tubule cells

Body fluids enter the space enclosed by the flame cell...

...and are driven down the tubules toward the excretory pore by the beating of the cilia in the flame cell.

57.4 Protonephridia in Flatworms

The protonephridia of the flatworm *Planaria* consist of tubules ending in flame cells. The tubule cells modify the composition of the fluid passing through them.

Each segment of the earthworm contains a pair of metanephridia (singular metanephridium; from the Greek meta, akin to, and nephros, kidney). Each metanephridium begins in one segment as a ciliated, funnel-like opening in the coelom called a nephrostome, which leads into a tubule in the next segment. The tubule ends in a pore called the nephridiopore, which opens to the outside of the animal (Figure 51.5). Coelomic fluid enters the metanephridia through the nephrostomes. As the fluid passes through the tubules, the cells of the tubules actively resorb certain molecules from it and actively secrete other molecules into it. What leaves the animal through the nephridiopores is a hypotonic (dilute) urine containing nitrogenous wastes, among other solutes.

Malpighian tubules are the excretory organs of insects

Insects can excrete nitrogenous wastes with very little loss of water. Therefore, some species can live in the driest habitats on Earth. The insect excretory system consists of blind tubules called Malpighian tubules. An individual insect has from 2 to more than 100 of these tubules attached to the gut between the midgut and hindgut and projecting into the spaces containing tissue fluid (recall that insects have open circulatory systems) (Figure 51.6).

The cells of the Malpighian tubules actively transport uric acid, potassium ions, and sodium ions from tissue fluid into the tubules. As these solutes are secreted into the tubules, water follows because of the difference in solute potential. The walls of the Malpighian tubules have muscle fibers that contract to help move the contents of the tubules toward the hindgut.

57.5 Metanephridia in Earthworms

The metanephridia of annelids are arranged segmentally. The cross section (left) shows a pair of metanephridia. Longitudinal sections (right) show only one metanephridium of the two in each segment.

The tubule fluid changes in composition while it is in the hindgut. The contents of the hindgut are more acidic than the tubule fluid; as a result, uric acid becomes less soluble and precipitates out of solution as it approaches and enters the rectum. The epithelial cells of the hindgut and rectum actively transport sodium and potassium ions from the gut contents back into the tissue fluid. Because the uric acid molecules have precipitated out of solution, water is free to

follow the resorbed salts back into the tissue fluid through osmosis. Remaining in the rectum are crystals of uric acid mixed with undigested food; this dry matter is what the insect eliminates. The Malpighian tubule system is a highly effective mechanism for excreting nitrogenous wastes and some salts without giving up a significant fraction of the animal's precious water supply.

Vertebrate Excretory Systems Are Built of Nephrons

The major excretory organ of vertebrates is the kidney. The functional unit of the kidney is the nephron. Each human kidney has about a million nephrons. All vertebrate kidneys consist of nephrons, yet the kidneys of different species can serve opposite functions to maintain water and salt balance. The kidneys of freshwater fishes, for example, excrete water, but the kidneys of most mammals conserve water.

To understand how the kidney can fulfill opposite functions in different animals, we need to understand how the different parts of the nephron work and the different ways in which they can work together to influence the composition of the urine. The nephron has three main parts:

- ▶ A ball of capillaries called the glomerulus that filters the plasma
- ▶ Renal tubules that receive and modify the filtrate
- ▶ Peritubular capillaries that serve the tubules

Blood is filtered in the glomerulus

Each nephron has both vascular and tubule components (Figure 51.7). The vascular component is unusual in that it consists of two capillary beds that lie between the arteriole that supplies it and the venule that drains it. The first capillary bed is a dense knot of very permeable vessels called the glomerulus (plural glomeruli) (Figure 51.7). Blood enters the glomerulus through an afferent arteriole and exits through an efferent arteriole. The efferent arteriole gives rise to the second set of capillaries, the peritubular capillaries, which surround the tubule component of the nephron (see Figure 51.7).

The tubule component of the nephron, called a renal tubule, begins with Bowman's capsule, which encloses the glomerulus. The glomerulus appears to be pushed into Bowman's capsule much like a fist pushed into an inflated balloon. Together, the glomerulus and its surrounding Bowman's capsule are called the renal corpuscle. The cells of the capsule that come into direct contact with the glomerular capillaries are called podocytes (see Figure 51.7). These highly specialized cells have numerous armlike extensions, each with hundreds of fine, fingerlike projections. The podocytes wrap around the capillaries so that their fingerlike projections interdigitate and cover the capillaries completely (Figure 51.8b).

The glomerulus filters the blood to produce a tubule fluid that lacks cells and large molecules. The walls of the capillaries, the basal lamina of the capillary endothelium, and the podocytes of Bowman's capsule all participate in filtration. The endothelial walls of the capillaries have pores that allow water and small molecules to leave, but are too small to permit red blood cells to pass through. The mesh-work of the basal lamina is even finer than the pores between the endothelial cells, and it prevents large molecules from leaving the capillaries. Also smaller than the pores in the capillaries are the narrow slits between the fingerlike projections of the podocytes. As a result of these anatomical adaptations, water and small molecules pass from the capillary blood and enter the renal tubule of the nephron (Figure 51.8c), but red blood cells and proteins remain in the capillaries.

The force that drives filtration in the glomerulus is the pressure of the arterial blood. As in every other capillary bed, the pressure of the blood entering the permeable capillaries causes the filtration of water and small molecules. The glomerular filtration rate is high because glomerular capillary blood pressure is unusually high, and because the capillaries of the glomerulus, along with their covering of podocytes, are much more permeable than other capillary beds in the body.

Bowman's capsule receives H₂O and small molecules filtered from glomerular capillaries.

An efferent arteriole carries blood from the glomerulus.

Renal tubule cells alter composition of urine.

Peritubular capillaries carry away reabsorbed substances and bring materials to the tubules that will be secreted into the urine.

T

The renal venule drains the peritubular capillaries.

The processed filtrate (urine) of the individual nephrons enters collecting ducts and is delivered to a common duct leaving the kidney.

51.7 The Vertebrate Nephron

The vertebrate nephron consists of a renal tubule closely associated with a system of blood vessels. The end of the renal tubule system envelops the glomerulus so that the filtrate from the glomerular capillaries enters the tubules. The tubules change the composition of the filtrate by active absorption and secretion of solutes.

The renal tubules convert glomerular filtrate to urine

The composition of the filtrate that enters the nephron is similar to that of the blood plasma. This filtrate contains glucose, amino acids, ions, and nitrogenous wastes in the same concentrations as in the blood plasma, but it lacks the plasma proteins. As this fluid passes down the renal tubule, its composition changes as the cells of the tubule actively resorb certain molecules from the tubule fluid and secrete other molecules into it. When the tubule fluid leaves the kidney as urine, its composition is very different from that of the original filtrate.

The function of the renal tubules is to control the composition of the urine by actively secreting and resorbing specific molecules. The peritubular capillaries serve the needs of the renal tubules by bringing to them the molecules to be secreted into the tubules and carrying away the molecules that are resorbed from the tubules.

57.8 An SEM Tour of the Nephron

These scanning electron micrographs show the anatomical bases for kidney function. (a) The blood vessels in the kidney, showing the knots of capillaries that form the glomeruli. Each glomerulus (Gl) has an afferent and an efferent arteriole (Ar). Peritubular capillaries (Pt) are looser networks surrounding the tubules of the nephron, (b) Those cells that are in direct contact with the capillaries are the podocytes (Po). Each podocyte has hundreds of tiny fingerlike projections that create filtration slits between them. Anything passing from the glomerular capillaries into the tubule of the nephron must pass through these slits, (c) A cross section of a glomerulus shows that it is surrounded by the tubule cells that form Bowman's capsule (BC), which collects the filtrate and funnels it into the tubule (T) of the nephron. The relationship between the glomerulus and Bowman's capsule is like that of a fist punched into a balloon. Therefore, some of the renal tubule cells are in direct contact with the glomerular capillaries.

Both marine and terrestrial vertebrates must conserve water

Since the vertebrate nephron evolved as a structure for excreting water while conserving salts and essential small molecules, how have vertebrates adapted to environments where water must be conserved and salts excreted? The answer to this question differs for each vertebrate group. Even among the marine fishes, the adaptations of bony fishes are different from those of cartilaginous fishes.

marine bony fishes. Marine bony fishes cannot produce urine more concentrated than their tissue fluid, but unlike most marine animals, they osmoregulate their tissue fluid to only one-fourth to one-third the solute potential of sea-water. They prevent excessive loss of water by producing very little urine. Their urine production is low because their kidneys have fewer glomeruli than do the kidneys of freshwater fishes. In some species of marine bony fishes, the kidneys have no glomeruli at all. Even though the glomeruli are reduced or absent, renal tubules with closed ends are retained for active excretion of ions and certain molecules. Marine bony fishes take in seawater with their food, which results in a large salt load. The fish handle these salt loads by simply not absorbing some ions (such as Mg^{2+} or

So $4 \sim$) from their guts and by actively excreting others (such as Na^+ and Cl^-) from the gill membranes and from the renal tubules. Nitrogenous wastes are lost as ammonia from the gill membranes.

cartilaginous fishes. Cartilaginous fishes are osmocon-formers, but not ionic conformers. Unlike marine bony fishes, cartilaginous fishes convert nitrogenous wastes to urea and another compound called tri-methyl amine oxide and retain large amounts of these compounds in their tissue fluids. As a result, their tissue fluids have an osmolarity close to that of seawater. These species have adapted to a concentration of urea in the body fluids that would be fatal to other vertebrates.

Sharks and rays still have the problem of excreting the large amounts of salts they take in with their food. They have several sites of active secretion of $NaCl$, but the major one is a salt-secreting rectal gland.

amphibians. Most amphibians live in or near fresh water and stay in humid habitats when they venture from the water. Like freshwater fishes, most amphibian species produce large amounts of dilute urine and conserve salts. Some amphibians, however, have adapted to habitats that require water conservation.

51.9 Burrowing Frogs

The banjo frog of the Australian desert survives long droughts by burrowing deep in the sand and entering estivation, a state of low metabolic activity. These frogs store water in the form of dilute urine in their enormous bladders.

Amphibians living in very dry terrestrial environments have reduced the water permeability of their skin. Some secrete a waxy substance that they spread over the skin to waterproof it. Several species of frogs that live in arid regions of Australia burrow deep into the ground, where they remain during long dry periods (Figure 51.9). There they enter estivation, a state of very low metabolic activity and therefore low water turnover. When it rains, these frogs come out of estivation, feed, and reproduce. But their most interesting adaptation is that they have enormous urinary bladders. Before entering estivation, they fill their bladders with dilute urine, which can amount to one-third of their body weight. This dilute urine serves as a water reservoir that they use gradually during the long period of estivation. Australian aboriginal peoples dig up estivating frogs as an emergency source of drinking water.

Third, they excrete nitrogenous wastes as uric acid solids, therefore losing little water in the process.

birds. Birds have the same adaptations for water conservation that reptiles have: internal fertilization, shelled eggs, skin that retards water loss, and uric acid as the nitrogenous waste product. In addition, some birds can produce a urine that is more concentrated than their tissue fluids. This last ability is most developed in mammals.

The Mammalian Excretory System

The adaptations of mammals and birds for producing urine hypertonic to their tissue fluids were an important step in vertebrate evolution. These adaptations enabled the excretory system to conserve water while still excreting excess salts and nitrogenous wastes. Mammals and birds have high body temperatures and high metabolic rates, and therefore have the potential for a high rate of water loss. Being able to minimize water loss from their excretory systems made it possible for these highly active species to occupy arid habitats.

We have seen how the nephron originally evolved to excrete water; now we will see how it can serve as the basic structural unit of an organ that is able to conserve water. To understand this evolutionary change of function, it is necessary to understand the structure and function of the nephron in the context of the overall anatomy of the kidney. First, however, let's look at the mammalian excretory system as a whole.

Kidneys produce urine, which the bladder stores

We will use humans here as our example of the mammalian excretory system. Humans have two kidneys just under the dorsal wall of the abdominal cavity in the mid-back region (Figure 51.10). Each kidney filters blood, processes the fil-

The kidneys are positioned in the upper rear of the abdominal cavity.

The internal structure of the kidney includes a cortex and, beneath it, a medulla.

Aorta -

reptiles. Reptiles occupy habitats ranging from aquatic to extremely hot and dry. Three major adaptations have freed the reptiles from maintaining the close association with water that is necessary for most amphibians. First, reptiles do not need fresh water to reproduce, because they employ internal fertilization and lay eggs with shells that retard evaporative water loss. Second, they have scaly, dry skins that retard evaporative water loss.

5.7 The Human Excretory System

The human kidney has a regular internal tissue structure that is the basis for its function of filtering the blood and producing urine.

Nephron

Cortex

Medulla

Renal pyramid

Renal artery

Renal vein

Urine leaves the kidney from the inner surface of the medulla and is collected in the ureter.

Urine enters the urinary bladder, where the urine is stored until it is excreted through the urethra. The urethra is a short tube that opens to the outside at the end of the penis in males or just anterior to the vaginal opening in females.

Two sphincter muscles surrounding the base of the urethra control the timing of urination. One of these sphincters is a smooth muscle and is controlled by the autonomic nervous system. When the bladder is full, a spinal reflex relaxes this sphincter. This reflex is the only control of urination in infants, but the reflex gradually comes under the influence of higher centers in the nervous system as a child grows older. The other sphincter is a skeletal muscle and is controlled by the voluntary, or conscious, nervous system. When the bladder is very full, only serious concentration prevents urination.

Nephrons have a regular arrangement in the kidney.

The kidney is shaped like a kidney bean; when cut down its long axis and split open as a bean splits open, its important anatomical features are revealed (see Figure 51.10). The ureter and the renal artery and renal vein enter the kidney on its concave (punched-in) side. The ureter divides into several branches, the ends of which envelop kidney tissues called renal pyramids. The renal pyramids make up the internal core, or medulla, of the kidney. The medulla is surrounded by tissue with a different appearance, called the cortex. The renal artery and vein give rise to many arterioles and venules in the region between the cortex and the medulla. Each human kidney contains about a million nephrons, and their organization within the kidney is very regular. All of the glomeruli are located in the cortex. The initial segment of a renal tubule is called the proximal convoluted tubule— "proximal" because it is close to its glomerulus and "convoluted" because it is twisted (Figure 51.11). All the proximal convoluted tubules are also located in the cortex.

At a certain point, the renal tubule takes a dive directly down into the medulla. The portion of the tubule in the medulla is called the loop of Henle. It is called a loop because it runs straight down into the medulla, makes a hairpin turn, and comes straight back to the cortex. Where the ascending limb of the loop of Henle reaches the cortex, it becomes the distal convoluted tubule— "distal" because it is farther from its glomerulus than the proximal tubule is. The distal convoluted tubules of many nephrons join a common collecting duct in the cortex. The collecting ducts then run in parallel with the loops of Henle down through the medulla and empty into the ureter at the tips of the renal pyramids.

Blood vessels also have a regular arrangement in the kidney.

The organization of the blood vessels of the kidney closely parallels the organization of the nephrons (see Figure 51.11). Arterioles branch from the renal artery and radiate into the cortex. An afferent arteriole carries blood to each

57.77 The Organization of the Nephron within the Mammalian Kidney

The glomeruli and major portions of the renal tubules are located in the cortex of the kidney, but portions of the renal tubules, called the loops of Henle, run in parallel as straight sections down into the renal medulla and back up to the cortex. Collecting ducts run from the cortex to the inner surface of the medulla, where they open into the ureter.

that joins with venules from other nephrons eventually

the renal vein, which takes blood from the kidney

The volume of glomerular filtration is greater than the volume of urine

excreted and solutes filtered in the glomeruli. ~

appears in the urine. We can reach this by comparing the rate of filtration by the glomeruli with the rate of urine production. The kidney

filters 1 liter of blood per minute, or more than

1.5 L of blood per day. How much of this huge volume is filtered in the glomeruli? The answer is about 12

liters. This is still a large volume. ~ 120 L per day

Since normally only 1 L of urine is excreted per day, about 1%

of the fluid volume that is filtered in the glomerulus is excreted into the blood. Where and how is this enormous fluid volume resorbed?

Most filtrate is resorbed by the proximal convoluted tubule

The proximal convoluted tubule is responsible for most of the resorption of water and solutes from the glomerular filtrate.

The cells of this section of the renal tubule are cuboidal, and their surface facing the tubule has thousands of microvilli, which greatly increase their surface area for resorption. These cells have lots of mitochondria—an indication that they are biochemically active. The tubule actively transports water and other solutes, such as glucose and amino acids: the

tubule fluid. Almost all glucose and amino acid molecules that are filtered from the blood are actively resorbed by these cells and transported back into the tissue fluid. The active transport of solutes into the tissue fluid causes water to follow osmotically. The water and solutes moved into the tissue fluid are taken up by the peritubular capillaries and returned to the venous blood leaving the kidney.

Despite the large volume of water and solutes resorbed

in the proximal convoluted tubule, the overall concentration of solutes in the tubule fluid is not different from that of the blood plasma, although its composition is quite different. How, then, does the kidney produce urine that is more concentrated than the blood plasma?

The loop of Henle creates a concentration gradient in the surrounding tissue

Humans can produce urine that is four times more concentrated than their blood plasma. The vampire bat we encountered at the beginning of this chapter can produce

urine that is 10 times more concentrated than its blood. Some desert-dwelling animals

are able to produce urine that is even more concentrated. The ability of the mammalian kidney is due to the loops of

Henle, which function as a countercurrent multiplier system. The term "countercurrent" refers to the fact that tubule fluid in the descending limb of the loop flows in the opposite direction from that in the ascending limb. "Multiplier" refers to the ability of this system to create a concentration gradient in the renal medulla. The loops of Henle do not themselves produce a concentrated urine; rather, they increase the solute potential of the surrounding tissue fluid.

The segments of the loop of Henle differ anatomically and functionally. Cells of the descending limb and the initial cells of the ascending limb are flat, with no microvilli and few mitochondria. They are not specialized for transport. Partway up the ascending limb, the cells become specialized for active transport. They are cuboidal and have

lots of mitochondria. Accordingly, the loop of Henle is divided into the thin descending limb, the thin ascending limb, and the thick ascending limb. To understand the countercurrent multiplier mechanism, it is easiest to move backward through the renal tubule, starting with the thick ascending limb (Figure 51.11).

The thick ascending limb actively resorbs Na⁺ (with Na⁺-K⁺-ATPase)

from the tubule fluid and moves it into the

surrounding tissue fluid. The thick ascending limb is not permeable

meafc -. : atei 90 the resorption of Na^+ and Cl^- raises the concentration of these solutes in the surrounding tissue fluid.

The thin descending limb, in contrast, is rather permeable to water, but not very permeable to Na^+ and Cl^- . Since surrounding tissue fluid has been made more concentrated by the Na^+ and Cl^- resorbed from the neighboring thick ascending limb, water is withdrawn osmotically from the tubule fluid in the descending limb. Therefore, the fluid in the descending limb becomes more and more concentrated as it flows toward the bottom of the renal medulla.

The thin ascending limb, like the thick ascending limb, is not permeable to water. It is, however, permeable to Na^+ and Cl^- . As the concentrated tubule fluid flows up the thin ascending limb, it is more concentrated than the surrounding tissue fluid, so Na^+ and Cl^- diffuse out of it. When the tubule fluid reaches the thick ascending limb, active transporters move Na^+ and Cl^- from the tubule fluid to the tissue fluid as we saw above.

As a result of the processes described above, the tubule fluid reaching the distal convoluted tubule is less concentrated than the blood plasma, and the solutes that have been left behind in the renal medulla have created a concentration gradient in the surrounding tissue fluid. The tissue fluid in the renal medulla becomes more and more concentrated as we move from the border with the cortex to the tips of the renal pyramids.

Urine is concentrated in the collecting ducts

As Na^+ and Cl^- are transported out of the tubule fluid, urea and other waste products make up a greater proportion of its total solute content as it flows toward the collecting duct. Therefore, the tubule fluid entering the collecting duct

is less concentrated than the blood plasma, but its composition is considerably different from that of the plasma.

Glomerulus 300

Blood plasma (300 mosm/l)

Distal convoluted tubule

Q The loop of Henle acts as a countercurrent multiplier to establish a concentration gradient in the renal medulla.

Q The thick segment of the ascending limb

pumps NaCl out of the urine and into the tissue fluid, but H_2O cannot follow, because this region of the tubule is impermeable to water. Continued pumping of NaCl from the thick ascending limb sets up a concentration gradient in the renal medulla.

Increased concentration of NaCl in the tissue fluid causes osmotic absorption of water from the descending limb, thus concentrating the tubule fluid that enters the ascending limb.

The urine entering the collecting duct is less concentrated than the tissue fluid, so as urine passes down the collecting duct it loses water to the tissue fluid and becomes more and more concentrated.

o Water resorbed from the descending limb and the collecting duct leaves the medulla in the vasa recta.

fj The lower collecting duct is permeable to urea as well as to water. Urea is very concentrated in the urine at this point, so it diffuses into the tissue fluid. The increased osmolarity of the tissue fluid enhances the countercurrent multiplier effectiveness. Urea enters the ascending limb and is recycled.

H⁵ 7.72 Concentrating the Urine

The countercurrent multiplier mechanism enables the kidney to produce urine that is far more concentrated than mammalian blood plasma.

The tubule fluid entering the distal convoluted tubule loses water osmotically as it flows toward the collecting duct.

The concentration gradient established in the renal medulla by the loops of Henle enables the urine to be concentrated in the collecting ducts. The collecting ducts begin in the renal cortex and run through the renal medulla before emptying into the ureter at the tips of the renal pyramids. As the solute concentration of the surrounding tissue fluid increases, more and more water is absorbed from the urine in the collecting duct. By the time it reaches the ureter the urine has been greatly concentrated.

It follows from the process we have just described that the ability of a mammal to concentrate its urine will be determined by the maximum concentration gradient it can establish in its renal medulla. One way to increase the con-

J

centration gradient is to increase the lengths of the loops of Henle. That is precisely the adaptation we find in mammals that live in extremely arid habitats. The desert gerbil, for example, has such extremely long loops of Henle that its renal pyramids (each of its kidneys has only one, in contrast to

Urine

ours) extends far out of the concave surface of the kidney and into the ureter (Figure 51.13). These animals are so effective in conserving water that they can survive on the water released by the metabolism of their dry food; they do not need to drink!

Control and Regulation of Kidney Functions

Control and regulatory mechanisms act on the kidneys to maintain blood osmolarity and blood pressure. We will discuss these various mechanisms separately, but keep in mind that they are always working together.

The kidneys act to maintain the glomerular filtration rate

If the kidneys stop filtering blood, they cannot accomplish any of their functions. The glomerular filtration rate (GFR) depends on an adequate blood supply to the kidneys at an adequate blood pressure. Therefore, the kidneys have mechanisms to maintain their blood supply and blood pressure regardless of what is happening elsewhere in the body. Because these adaptations of the kidney support the maintenance of kidney function, they are called autoregula-

922 CHAPTER FIFTY-ONE

57.73 The Ability to Concentrate

The ability of the mammalian kidney to concentrate urine depends on the lengths of its loops of Henle relative to the overall size of the kidney. Some desert rodents have single renal pyramids so long that they protrude out of the kidney and into the ureter.

tory mechanisms. The kidney's autoregulatory adjustments compensate for decreases in cardiac output or decreases in blood pressure so that the GFR remains high (Figure 51.14).

One autoregulatory mechanism is the dilation (expansion) of the afferent renal arterioles when blood pressure falls. This dilation decreases the resistance in the arterioles and helps maintain blood pressure in the glomerular capillaries. If arteriole dilation does not keep the GFR from falling, then the kidney releases an enzyme, renin, into the blood. Renin acts on a circulating protein to begin converting it into an active hormone called angiotensin.

Angiotensin has several effects that help restore the GFR to normal. First, angiotensin causes the efferent renal arterioles to

constrict, which elevates blood pressure in the

57.74 Maintaining the Glomerular Filtration Rate

Glomerular filtration is driven by arterial pressure, but autoregulatory mechanisms prevent rises and falls in glomerular filtration rate (GFR) over a wide range of pressures.

glomerular capillaries. Second, it causes peripheral blood vessels all over the body to constrict—an action that elevates central blood pressure. Third, it stimulates the adrenal cortex to release the hormone aldosterone. Aldosterone stimulates sodium resorption by the kidney, thereby making the resorption of water more effective. Enhanced water resorption helps maintain blood volume and therefore central blood pressure. Finally, angiotensin acts on structures in the brain to stimulate thirst. Increased water intake in response to thirst increases blood volume and blood pressure.

Blood pressure and osmolarity are regulated by ADH

When you lose blood volume, your blood pressure tends to fall. Besides activating the kidney autoregulatory mechanisms described in the previous section, a drop in blood pressure decreases the activity of the stretch receptors in the walls of the aorta and the carotid arteries (see Chapter 49). These stretch receptors provide information to cells in the hypothalamus that produce antidiuretic hormone (ADH, also called vasopressin) and send it down their axons to the posterior pituitary gland (see Chapter 41). As stretch receptor activity decreases, the production and release of this hormone increases (Figure 51.15).

ADH acts on the collecting ducts of the kidney to increase their permeability to water. When the circulating level of ADH is high, the collecting ducts are very permeable to water, more water is resorbed from the urine, and only small quantities of concentrated urine are produced, thus conserving blood volume and blood pressure. When ADH levels are low, water is not resorbed from the collecting ducts, and lots of dilute urine is produced.

ADH controls the permeability of the collecting ducts by stimulating the production and activity of membrane proteins that form water channels. These proteins, called aquaporins, are found in many tissues that are permeable to water—for example, the capillary endothelium, red blood cells, and the proximal convoluted tubules of the kidney. Differences among tissues in water permeability can be related to the presence or absence of aquaporins. Aquaporins are expressed in the descending limb of the loop of Henle, for example, but not in the ascending limb. One particular aquaporin is found in collecting duct cells and is controlled by ADH on both a long-term and a short-term basis. Over the long term, ADH levels influence the expression of the gene for this aquaporin; over the short term, ADH controls the insertion of the aquaporin into the cell membranes.

ADH also helps regulate blood osmolarity. Sensory cells in the hypothalamus monitor the solute potential of the blood. If blood osmolarity increases, these osmoreceptors stimulate increased release of ADH to enhance water resorption from the kidneys. The osmoreceptors also stimulate thirst. The resulting water retention and water intake dilutes the blood as it expands blood volume.

the heart become stretched. When the atrial muscle fibers are stretched too much, they release a peptide hormone called atrial natriuretic hormone. This hormone enters the circulation, and when it reaches the kidney, it decreases the resorption of sodium. The result is an increased loss of sodium and water, which has the effect of lowering blood volume and blood pressure.

Q Sodium ions (Na^+) and bicarbonate ions (HCO_3^-) are filtered in the glomerulus.

The kidneys help regulate acid-base balance

Besides salt and water balance and nitrogen excretion, the kidneys have another important role in regulating the hydrogen ion concentration (the pH) of the blood. pH is a critical variable because it influences the structure and therefore the function of proteins. One way to minimize changes in a chemical solution is to add a buffer—a substance that can either absorb excess hydrogen ions or supply hydrogen ions (see Chapter 2). The major buffer in the blood is the bicarbonate ion, HCO_3^- , which is formed from the disassociation of carbonic acid, which in turn is formed by the hydration of CO_2 according to the following equilibrium reactions (see Chapter 48):

$\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$ —You can see that if excess H^+ ions are added to this reaction mix, the reaction will move to the left and absorb the excess H^+ . On the other hand, if H^+ ions are removed from the reaction mix, the reaction will move to the right and supply more H^+ ions.

The bicarbonate buffer "system" is important for controlling the pH of the blood because the reactions can be pushed and pulled physiologically. The lungs control the levels of CO_2 in the blood, and the kidneys control the levels of H^+ and HCO_3^- ions in the blood. The renal tubules secrete H^+ and resorb HCO_3^- (Figure 51.16). The kidney has other buffering systems as well, and together they greatly enhance the ability of the kidney to eliminate acid.

57.76 The Kidney Excretes Acids and Conserves Bases

Bicarbonate ions are filtered in the glomerulus, and renal tubule cells secrete hydrogen ions. In the renal tubule, the filtered bicarbonate buffers the secreted hydrogen ions and keeps the urine from becoming too acidic. The CO_2 formed by the reaction of bicarbonate and hydrogen ions is converted back to bicarbonate by the renal tubule cells and transported back into the tissue fluids.

924 CHAPTER FIFTY-ONE

Chapter Summary

Tissue Fluids and Water Balance

► The problems of salt and water balance and nitrogen excretion that animals face depend on their environments, but in all animal excretory systems, there is no active transport of water.

► All adaptations for maintaining salt and water balance and for excreting nitrogen wastes employ the same basic

mechanisms: filtration of body fluids and active secretion and resorption of specific ions.

Distinguishing Environments and Animals in Terms of Salt and Water

► Marine animals can be osmoconformers or osmoregulators. Freshwater animals must be osmoregulators and must continually excrete water and conserve salts. All animals are ionic regulators to some degree. Review Figure 51.1

► On land, water conservation is essential, and diet determines whether salts must be conserved or excreted. Marine birds excrete excess salt through nasal salt glands. Review Figure 51.2

Excreting Nitrogen

► Aquatic animals can eliminate nitrogenous wastes such as ammonia by diffusion across their gill membranes. Terrestrial animals must detoxify ammonia by converting it to urea or uric acid for excretion. Review Figure 51.3

► Depending on the form in which they excrete their nitrogenous waste products, animals are classified as ammonotelic, ureotelic, or uricotelic.

The Diverse Excretory Systems of Invertebrates

► The protonephridia of flatworms consist of flame cells and excretory tubules. Tissue fluid is filtered into the tubules, which process the filtrate to produce a dilute urine. Review Figure 51.4

► In annelid worms, blood pressure causes filtration of the blood across capillary walls. The filtrate enters the coelomic cavity, where it is taken up by open-ended tubules called metanephridia. As the filtrate passes through the tubules to the outside, its composition is changed by active transport mechanisms. Review Figure 51.5

► The Malpighian tubules of insects receive ions and nitrogenous wastes by active transport across the tubule cells. Water follows by osmosis. Ions and water are resorbed from the rectum, so the insect excretes semisolid wastes. Review Figure 51.6

Vertebrate Excretory Systems Are Built of Nephrons

► The nephron, the functional unit of the vertebrate kidney, consists of a glomerulus, in which blood is filtered across the walls of a knot of capillaries, and a renal tubule, which processes the filtrate into urine to be excreted. A system of peritubular capillaries serves the tubule. Review Figures 51.7, 51.8

► The adaptations of marine fishes and terrestrial animals to conserve water are diverse. Bony fishes have few glomeruli and produce little urine. Cartilaginous fishes retain urea so that the osmotic concentration of their body fluids remains above that of seawater. Amphibians remain close to water or have waxy skin coverings. Reptiles have scaly skin, lay shelled eggs, and excrete nitrogenous wastes as uric acid.

► Birds share the adaptations of reptiles; in addition, they can produce urine more concentrated than their tissue fluids. Only birds and mammals can produce such urine.

The Mammalian Excretory System

► The concentrating ability of the mammalian kidney depends on its anatomy. Review Figure 51.10

► The glomeruli and the proximal and distal convoluted tubules are located in the cortex of the kidney. Certain molecules, salts, and water are resorbed in bulk, and other molecules are actively secreted in the convoluted tubules without the urine becoming more concentrated. Straight sections of renal tubules called loops of Henle and collecting ducts are arranged in parallel in the medulla of the kidney. Review Figure 51.11

► The loops of Henle create a concentration gradient in the extracellular fluids of the renal medulla by a countercurrent multiplier mechanism. Urine flowing down the collecting ducts to the ureter is concentrated by the osmotic loss of water caused by the concentration gradient in the surrounding tissue fluid. Review Figure 51.12

Control and Regulation of Kidney Functions

► Kidney function in mammals is controlled by autoregulatory mechanisms that maintain a constant high glomerular filtration rate even if blood pressure varies. Review Figure 51.14

► An important autoregulatory mechanism is the release of renin by the kidney when blood pressure falls. Renin activates angiotensin, which causes the constriction of peripheral blood vessels, causes the release of aldosterone (which enhances water resorption), and stimulates thirst.

► Kidney function in mammals is also controlled by mechanisms responsive to blood pressure and osmolarity. Changes in these variables influence the release of antidiuretic hormone, which controls the permeability of the collecting duct to water and therefore the amount of water that is resorbed from the urine. ADH stimulates the expression of proteins called aquaporins that serve as water channels in the membranes of collecting duct cells. Review Figure 51.15

► Hydrogen ions secreted by renal tubules are buffered in the urine by bicarbonate and other buffering systems. Review Figure 51.16

For Discussion

1. Why is it said that the oceans are a physiological desert? For what animals would this apply?
2. Persons with uncontrolled diabetes mellitus can have very high levels of glucose in their blood. Why do such individuals have a high level of urine production?
3. Inulin is a molecule that is filtered in the glomerulus, but is not secreted or resorbed by the renal tubules. If you injected inulin into an animal and after a brief time measured the concentration of inulin in its blood and urine, how could you determine the animal's glomerular filtration rate? Assume that the rate of urine production is 1 ml per minute.
4. After you did the inulin experiment to measure glomerular filtration rate, how could you use that information to determine whether another substance is secreted or resorbed by the renal tubules? Assume you can measure the concentration of that substance in the blood and in the urine. Urine production is still 1 ml per minute.
5. Explain what would happen with respect to control and regulation of your salt and water balance if you went to a movie and ate a lot of very salty popcorn.

Animal Behavior

*

A troop of Japanese macaques living on an island was being studied by scientists, who fed the monkeys by throwing pieces of sweet potatoes onto the beach from a passing boat. The monkeys tried to brush the sand off the sweet potatoes, but they were still gritty. One day a young female monkey began taking her sweet potatoes to the water and washing them. Soon her siblings and other juveniles in her play group imitated her new behavior. Next their mothers began washing their potatoes. No adult males imitated the behavior of the juveniles or the adult females, but young males learned the behavior from their mothers and their siblings.

The scientists were fascinated by the way the creative, insightful behavior of one juvenile female spread through the population, so they presented the monkeys with a new challenge: They threw wheat onto the beach. Picking grains of wheat out of the sand was tedious and difficult. The same juvenile female came up with a solution: She carried handfuls of sand and grain to the water and threw them in. The sand sank, and the grain floated, enabling her to skim it off the surface and eat it. This behavior spread through the population in the same way potato washing did, first to other juveniles, then to mothers, and then from mothers to both their male and female offspring.

The macaques now routinely wash their food. They play in the water, which they did not do before, and they have added some marine items to their diet. Clearly, this population of monkeys has invented new behaviors that have spread by imitative learning and have become traditions in the population. One could say that they have acquired a culture: a set of behaviors shared by the population and transmitted by learned traditions.

The reason this study of macaques is so interesting is that it erodes what seemed to

Learned Behaviors Shared by a Population Become a Culture

In the space of only a few generations, a population of Japanese macaques (*Macaco fuscata*) learned and transmitted a set of behaviors that included washing food, playing in the water, and eating marine food items—a new "culture" of water-related behaviors.

be a clear distinction between human behavior and the behavior of other animals. The behavior of most animals is largely determined by heredity, with learning playing a relatively minor role. In contrast, most human behaviors are acquired through cultural traditions and learning. The fact that other primates can invent novel behaviors and pass them on culturally shows that there is no absolute dividing line between human and animal behavior.

We begin this chapter with descriptions of some classic studies of behaviors that are largely shaped by inheritance, but to varying degrees are modified by experience. Then we explore how hormones influence the development and expression of behavior.

Next we discuss animal communication, showing how this behavior has been shaped by natural selection. Then we look at studies of biological rhythms and navigation to see how the mechanisms underlying these behaviors have been investigated. Throughout the chapter, we hope you will use what you read to raise your own questions about human behavior, to which we will return at the end of the chapter.

926 CHAPTER FIFTY-TWO

What, How, and Why Questions

Most species of animals can be identified by their behaviors. Behavior is highly visible and shows us what an animal does: how it gets food, how it avoids dangers in the environment, and how it reproduces. Behavior is highly adaptive, and it is therefore not surprising that many behaviors are shaped by natural selection, and are highly species-specific. On the other hand, flexibility of behavior can be extremely valuable to an animal that has to deal with changing conditions and complex situations, as in social interactions. Therefore, to varying degrees, behavior is modifiable by learning.

In studying any behavior, we can ask what, how, and why questions. What questions focus on the details of behavior, including the proximate cause of the behavior—in other words, what stimuli cause the animal to express the behavior. How questions are about the mechanisms of behavior—the underlying neural, hormonal, and anatomical mechanisms that we have been studying in Part Six. How questions can also focus on the means by which an animal acquires a behavior—the relative roles of genetically determined mechanisms and experience. Most behaviors involve complex interactions of inherited anatomical and physiological mechanisms and the ability to alter behavior through learning.

Why questions have to do with the ultimate causes of behavior—the selective pressures that shaped its evolution. In this chapter we will frequently discuss the adaptive nature of behavior, but the evolution of behavior will be the major focus of the next chapter.

Behavior Shaped by Inheritance

Much of the behavior of many animals is highly stereotypic (it is performed in the same way every time) and species-specific (there is little variation in the way different individuals of the same species perform it). We can identify species of spiders, for example, by their web designs (Figure 52.1). Web spinning requires thousands of movements performed in just the right sequence, and for a given species, most of that sequence is performed the same way every time. Different spider species spin webs of different designs, using different sequences of movements.

Web spinning by spiders is also an example of a complex behavior that requires no learning or prior experience. When juvenile spiders hatch, their mother is already dead, and they disperse immediately (remember *Charlotte's Web* by E. B. White?). They have no experience of their mother's web. Yet, when they construct their own webs, they do it perfectly without the benefit of experience or a model to

52.1 Spider Web Designs Are Species-Specific

Each spider performs a stereotypic sequence of movements typical of its species that results in a species-specific web design.

copy. In fact, their web spinning behavior is actually rather resistant to modification by learning. When confronted experimentally with challenges to web construction, young spiders appear incapable of learning how to modify the design of their webs.

Many classic studies of stereotypic and species-specific behaviors were performed by scientists who studied the behavior of animals in nature—a field called ethology. The early ethologists asked to what extent such behaviors are determined by inheritance and to what extent they are modifiable by experience. Two experimental approaches were used to test whether behaviors are hereditary: (1) depriving animals of opportunities to learn and (2) studying the behavior of the offspring of two parents that differ in their behavior.

2. Head flick
3. Tail shake
4. Bill shake
5. Grunt whistle
6. Tail shake

Deprivation and hybridization experiments test whether a behavior is inherited

In a deprivation experiment, an animal is reared so that it is deprived of all experience relevant to the behavior under study. In one such experiment, a tree squirrel was reared in isolation, on a liquid diet, and in a cage without soil or other particulate matter. When the young squirrel was given a nut, it put the nut in its mouth and ran around the cage. Eventually it made stereotypic digging movements in the corner of its cage, placed the nut in the imaginary hole, went through the motions of refilling the hole, and ended by tamping the nonexistent soil with its nose. The squirrel had never handled a food object and had never experienced soil, yet the stereotypic behavior of a squirrel burying a nut was fully expressed.

In a hybridization experiment, closely related species are interbred and the behavior of their offspring observed. Closely related species frequently show distinct differences in certain kinds of behavior. When such species can be interbred, it is possible to see whether their offspring have inherited elements of the behavior of one or both parents.

Konrad Lorenz, a pioneer in the field of ethology, conducted hybridization experiments on ducks to investigate the genetic determinants of their elaborate courtship displays. Dabbling duck species such as mallards, teals, pintails, and gadwalls are closely related to one another and can interbreed, but because of the specificity of their courtship displays, they rarely do so in nature. Each male duck performs a carefully choreographed water ballet that is typical of his species (Figure 52.2), and a female is not likely to accept his advances unless the entire display is successfully and correctly completed.

When Lorenz crossbred duck species, he found that the hybrid offspring expressed some components of the courtship displays of each parent species, but expressed them in new combinations. Of particular interest was his observation that the hybrids sometimes showed display components that were not in the repertoire of either parent species, but were characteristic of the displays of other species. Lorenz's hybridization studies clearly demonstrated that the motor patterns of the courtship displays were inherited. The fact that natural selection was shaping these genetically determined behaviors was evidenced by the fact that females were not interested in males performing hybrid displays.

52.2 Courtship Ballet of the Mallard

The courtship display of the male mallard duck contains about ten elements. The displays of closely related duck species contain some of the same ten elements, but have other elements not displayed by mallards. The elements of the courtship display and their sequence are species-specific and act to prevent hybridization.

A mounted immature male European robin with no red feathers does not stimulate aggression from a territorial adult male...

...but this formless clump of red feathers releases strong aggressive attacks from the territorial adult.

52.3 A Releaser of Aggressive Behavior

Red feathers serve as a releaser of aggressive behavior in male European robins.

Simple stimuli can trigger behaviors

If a behavior is not expressed during a deprivation experiment, it may nonetheless have genetic determinants. The right conditions may not have been available to stimulate the behavior during the experiment. The squirrel described above, for example, had to be given a nut for its digging and burying behaviors to be triggered. Specific stimuli are required to elicit the expression of many inherited behaviors. Two pioneering ethologists, Konrad Lorenz and Niko Tinbergen, who conducted classic studies of the nature of the stimuli that elicit such behaviors, called such stimuli releasers.

Releasers are usually a simple subset of all the sensory information available to an animal. Adult male European robins, for example, have red feathers on their breasts, which serve as releasers of aggressive behavior in other males. During the breeding season, the sight of an adult male robin stimulates another male robin to sing, perform aggressive displays, and attack the intruder if he does not heed these warnings. An immature male robin, whose feathers are all brown, does not elicit this aggressive behavior. A tuft of red feathers on a stick, however, is a sufficient releaser for male aggressive behavior in robins (Figure 52.3).

Tinbergen and A. C. Perdeck carefully examined the releasers involved in the interactions between herring gulls and their chicks during feeding. An adult herring gull has a

A red dot is more important than a realistic profile.

Head color and shape have little effect on the ability of a red dot to stimulate the pecking response.

jL

A red dot will elicit a response, even without a head.

Without a red dot, a long, thin bill elicits the strongest pecking response.

Conclusion: A contrasting dot on a thin bill releases pecking responses. Head shape and color have little or no influence.

52.4 Releasing the Pecking Response

A series of experiments rated the pecking responses of herring gull chicks to artificial models of gull heads to discover which features of the parent were releasers of this behavior.

red dot at the end of its bill (Figure 52.4). When the gull returns to its nest with food, the chicks peck at the red dot, thereby stimulating the adult to regurgitate the food for the chicks to eat.

Tinbergen and Perdeck hypothesized that the red dot was a releaser for the chicks' begging behavior. To test their hypothesis, they made paper cutout models of gull heads and bills, varying the colors and the shapes. Then they rated each model according to how many pecks it received from naive, newly hatched chicks (Figure 52.4). The shape or color of the model head made no difference. In fact, a head was not even necessary; the chicks responded just as well to models of bills alone—as long as they had the red dot. Surprisingly, the most effective releaser for chick pecking behavior was a long, thin

object with a dark tip that bore no resemblance to an adult herring gull. Clearly the chicks had inherited the ability to recognize a simple stimulus and respond to it with their also inherited begging behavior. To the ethologists, this represented an excellent example of a behavior that was genetically determined rather than learned.

Learning also shapes behavior

For their very significant contributions to our understanding of animal behavior, three ethologists, Lorenz, Tinbergen, and Karl von Frisch (whose work on honeybees you will encounter later in this chapter) shared a Nobel Prize in 1973. New generations of behavioral biologists, however, have moved beyond the ethologists' focus on inherited behavior to show that most behavior actually involves an interaction between inheritance and learning. The begging behavior of gull chicks is a case in point. Although newly hatched chicks respond maximally to simplistic artificial releasers, they gradually learn to discriminate between models and real gull heads, and they eventually beg only from their own parents. Thus, the inherited ability to recognize a simple releaser is subsequently refined by learning.

The early ethologists did not ignore learning or deny that it took place; in fact, they pioneered the study of learning. Tinbergen performed an early study of spatial learning, by which an animal learns to recognize features in its environment. In a classic experiment, he placed objects such as pine cones near the entrance of a nest dug by a female digger wasp. After the wasp left her nest, he moved the objects a short distance away. Upon returning, the wasp oriented to the moved objects and could not find her nest entrance (Figure 52.5). She had learned to recognize objects in the en-

Tinbergen's classic experiment showed that a female digger wasp learns the positions of objects in her environment.

interacting with him as if he were their parent (Figure 52.6). When the experiment was repeated by his assistants, each wearing boots with a different design, the goslings imprinted on the boots, and would follow only a person wearing the boots they first saw when they hatched.

The critical period for imprinting is determined by a developmental or hormonal state and can be quite brief. If a mother goat, for example, does not nuzzle and lick her newborn within 5 to 10 minutes after birth, she will not recognize it as her own later. In this case, imprinting depends on olfactory cues, and the critical period is determined by the high levels of the hormone oxytocin circulating in the mother at the time of birth.

Inheritance and learning interact to produce bird song

Many behavior patterns are intricate interactions of inheritance and learning. One example that has been the subject of some elegant experiments is bird song. Adult male songbirds use a species-specific song in territorial displays and courtship. A few species, such as the song sparrow, express their species-specific song even during deprivation experiments, but most species do not. For most species, such as the white-crowned sparrow, learning is an essential step in the acquisition of song.

If the eggs of white-crowned sparrows are hatched in an incubator and the young male birds are reared in isolation, their adult songs will be unusual assemblages of sounds, not the typical species-specific song. This species cannot express its species-specific song without being imprinted on

environment to use as orientation cues. More recently, spatial learning has been studied in animals such as squirrels, chickadees, and jays that cache food items in hundreds and even thousands of locations. Their capacity for learning and remembering where their food is cached is phenomenal.

Imprinting is the learning of a complex releaser

Releasers are generally simple subsets of the available information because there are limits to what can be programmed genetically. A type of learning called imprinting makes it possible to learn, during a limited critical period, a complex set of stimuli that can later serve as a releaser. The classic example is the imprinting of offspring on their parents and parents on their offspring to ensure individual recognition even in a crowded situation such as a colony or a herd.

When Lorenz incubated goose eggs in an incubator, and he was the first thing the goslings saw when they hatched, they imprinted on him, following him everywhere and in-

Conclusion: Even if the bird has the correct song template, he needs auditory feedback to learn to match it.

52.7 Two Critical Periods for Song Learning

To sing his species-specific song as an adult, a male white-crowned sparrow must acquire a song memory by hearing the song as a nestling, and must be able to hear himself as he attempts to match his singing to that memory.

that song as a nestling (Figure 52.7). But even though the male white-crowned sparrow must hear the song of his own species as a nestling to sing it as an adult, he does not sing it as a juvenile. Instead, he uses his auditory imprinting as a nestling to form a song memory in his nervous system. As the young male sparrow approaches sexual maturity the following spring, he tries to sing, and eventually he matches his imprinted song memory through trial and error. If a bird that has heard his species-specific song as a juvenile is deafened before he begins to express his song, he will not develop his species-specific song (see Figure 52.7). The bird must be able to hear himself to match his song memory. If he is deafened after he expresses his correct song, he will continue to sing like a normal bird. Two periods of learning are essential: the first in the nestling stage, the second as the bird approaches sexual maturity.

Genetically determined behavior is adaptive under certain conditions

The ability to learn and to modify behavior as a result of experience is often highly adaptive. Most human behavior is the result of learning. Why, then, are so many behavior patterns in so many species genetically determined? We have already touched on one answer to this question: If role models and opportunities to learn are not available— as in species with nonoverlapping generations, such as spiders—then there is no alternative to inherited behavior.

Inherited behaviors are also adaptive when mistakes are costly or dangerous. Mating with a member of the wrong species is a costly mistake; thus the function of much courtship behavior, such as that of dabbling ducks, is to guarantee species recognition. In an environment in which incorrect as well as correct models exist, learning the wrong pattern of courtship behavior would be possible.

Behavior patterns used to avoid predators or capture of dangerous prey allow no room for mistakes. If the behavior is not performed promptly and accurately the first time, there may not be a second chance (Figure 52.8).

Thus, inherited behavior is highly adaptive for species that have little opportunity to learn, for species that might learn the wrong behavior, and in situations in which mistakes are costly or dangerous.

52.8 Some Things Can't Be Learned by Trial and Error

In total darkness, the sound of a striking rattlesnake triggers an automatic escape jump in a kangaroo rat. The rat does not have to learn this behavior.

Hormones and Behavior

All behavior depends on the nervous system for initiation, coordination, and execution. Frequently, however, it is the endocrine system, through its controlling influences on the development and the physiological state of the animal, that determines when a particular behavior is performed, and even when certain behaviors can be learned. In this section we will present two complex cases in which hormones control the development, learning, and expression of behavior: sexual behavior in rats and maturation of the brain regions required for song learning and expression in birds.

Sex steroids determine the development and expression of sexual behavior in rats

Differences in the behavior of males and females of a species are clear examples of genes influencing the development and expression of behavior. Such sex differences in behavior are the result of actions of the sex steroids on the brain.

Rats, like most other animals, have stereotypic sexual behaviors. A female rat in estrus (receptive to males) responds

to a tactile stimulus of her hindquarters by assuming a mating posture called lordosis. A male rat encountering a female in estrus engages in stereotypic copulatory behavior. The roles of genes and sex steroids in the development and expression of lordosis and male copulatory behavior have been investigated through experiments that manipulated the exposure of the developing and adult rat brain to sex steroids.

Experiments such as those shown in Figure 52.9 led to three conclusions:

► Sex steroids are necessary for adult rats to express sexual behavior. Moreover, the male sex steroid, testosterone, has an effect only in males, and the female sex steroid, estradiol, has an effect only in females.

52.9 Hormonal Control of Sexual Behavior

In newborn rats of both sexes whose reproductive organs (ovaries or testes) have been removed, the presence of testosterone establishes male behavior patterns (no lordosis), and its absence establishes female patterns (lordosis).

932 CHAPTER FIFTY-TWO

► Development of male sexual behavior requires the brain of the new born rat to be exposed to testosterone, but development of female sexual behavior does not require the neonatal brain to be exposed to estradiol.

► Neonatal exposure to testosterone masculinizes the nervous systems of both genetic males and females so that they express male sexual behavior as adults.

Thus, the sex steroids that are present during development determine which pattern of sexual behavior develops, and the sex steroids that are present in adulthood determine whether that pattern is expressed.

Testosterone affects the development of the brain regions responsible for song in birds

As we saw above, learning is essential for the acquisition of bird song. Both male and female birds hear their species-specific song as nestlings, but only the males of most songbird species sing as adults. Male birds use song to claim territory, compete with other males, and declare dominance. They also use song to attract females, which suggests that the females know the song of their species even if they do not sing. Do sex steroids control the learning and expression of song in male and female songbirds?

After leaving the nest where they heard their father's song, young songbirds from temperate and arctic habitats migrate and associate with other species in mixed flocks. During this time they do not sing, and they do not hear their species-specific song again until the following spring. As that spring approaches and the days become longer, the young male's testes begin to grow and mature. As his testosterone level rises, he begins to try to sing. Even if he is isolated at this time from all other males of his species, his song will gradually improve until it is a proper rendition of his species-specific song. At that point the song is crystallized—the bird expresses it in similar form every spring thereafter. The young male's brain has learned the pattern of the song by hearing his father. During the subsequent spring, under the influence of testosterone, he learns to express that song—a behavior that then becomes rigidly fixed in his nervous system.

Why don't the females of most songbird species sing? Can't they learn the patterns of their species-specific song? Do they lack the muscular or nervous system capabilities necessary to sing? Or do they simply lack the hormonal stimulus for developing the behavior? To answer these questions, investigators injected female songbirds with testosterone in the spring. In response to these injections, the females developed their species-specific song and sang just as the males did. Apparently females learn the song pattern of their species when they are nestlings and have the capability to express it, but they normally lack the hormonal stimulation.

What does testosterone do to the brain of the songbird? A remarkable discovery revealed that testosterone causes the parts of the brain necessary for learning and expressing song to grow larger (Figure 52.10). Each spring, certain regions of the males' brains grow. Individual neurons in-

Male canary

Plane of section of brain

Testosterone induces growth in the regions responsible for song.

During the nonbreeding season, the male bird's song regions are similar in size to those of a female's brain.

52.10 Effects of Testosterone on Bird Brains

In spring, rising testosterone levels in the male cause the song regions of the brain to develop. The size of each circle is proportional to the volume of the brain occupied by that region.

crease in size and grow longer extensions, and the numbers of neurons in those regions of the brain increase. Such research on the neurobiology of bird song has revealed that hormones can control behavior by influencing brain structure as well as brain function, both developmentally and seasonally.

The Genetics of Behavior

To say that behavior is inherited does not mean that specific genes code for specific behaviors. Genes code for proteins, and there are many complex steps between the expression of a gene as a protein product and the expression of a behavior. In no case are all the steps between a gene and its influence on a behavior known. Nevertheless, it is clear that behavior has genetic determinants. In this section we will look at three approaches to investigating how genes affect behavior: hybridization, artificial selection and crossing of the selected strains, and molecular analysis of genes and gene products.

Hybridization experiments show whether a behavior is genetically determined

The effects of hybridization on the courtship displays of duck species were the subject of a classic ethological experiment, as we saw above. A more recent set of hybridization experiments was performed on the songs of crickets. Crickets songs, like bird songs, are species-specific, and as in birds, only male crickets "sing." They do so by rubbing one wing against another that has a serrated edge. These sounds can be recorded and analyzed quantitatively.

When two species of crickets were crossed, their offspring (the F₁ generation) expressed songs that had features of the songs of the two parental species. Backcrosses of F₁ individuals with the parental species produced individuals that had songs closer to the parental species used in the back-cross. Clearly the genetic background determined the song pattern. What was amazing, however, was the demonstration that female preferences for male songs were under similar genetic control. Given a choice, females from each parental species preferred the calls of males from their own species, but hybrid females preferred the calls of hybrid males.

These genetic differences between the cricket species and the hybrids were reflected in the properties of their nervous systems. When specific neurons in the crickets' brains were stimulated, songs were expressed that reflected the genotypes of the crickets.

Artificial selection and crossbreeding experiments reveal the genetic complexity of behaviors

Domesticated animals provide abundant evidence that artificial selection of mating pairs on the basis of their behavior can result in strains with distinct behavioral as well as anatomical characteristics. Among dogs, consider retrievers, pointers, and shepherds. Each has a particular behavioral tendency that can be honed to a fine degree by training. However, dogs and other large animals are not the best subjects for genetic studies. Most artificial selection experiments in behavioral genetics have been done on more convenient laboratory animals with short life cycles and large numbers of offspring.

A favorite subject for behavioral genetic studies has been the fruit fly (*Drosophila*). Artificial selection has been successful in shaping a variety of behavior patterns in fruit flies, especially aspects of their courtship and mating behavior. Crossing of these artificially selected strains reveals that most of these behavioral differences are due to multiple genes that probably influence the behavior indirectly by altering general properties of the nervous system. Some single-gene effects, however, can be isolated. One example is the gene *per* (short for "period"), which alters the frequency of the wing vibrations that are part of the male's courtship display. The *per* gene is not a courtship behavior gene, however. It has subsequently been found that this gene codes for a transcription factor that plays an important role in the generation of daily rhythms of rest and activity, as we will see below. How it alters the development of wingbeat frequency is not clear.

Few behavioral genetic studies reveal simple Mendelian segregation of behavioral traits. An exception is nest-cleaning behavior in honeybees. One genetic strain of honeybees practices nest-cleaning, or hygienic, be-

havior, which makes them resistant to a bacterium that infects and kills the larvae of honeybees. When a larva dies, workers uncap its brood cell and remove the carcass from the hive. Another strain of honeybees does not show this hygienic behavior and therefore is more susceptible to the spread of the disease (Figure 52.11).

When these two strains of honeybees were crossed, the results indicated that the hygienic behavior was controlled by two recessive genes. All members of the F₁ generation were nonhygienic, indicating that the behavior is controlled by recessive genes. Backcrossing the F₁ with the hygienic strain produced the typical 3:1 ratio expected for a two-gene trait (see Chapter 10). The behavior of the nonhygienic hybrid individuals was very interesting. One-third of them showed no hygienic behavior at all; one-third uncapped the cells of dead larvae but did not remove them; and one-third did not uncapped cells, but did remove carcasses if the cells were open.

52.11 Genes and Hygienic Behavior in Honeybees

Some honeybee strains remove the carcasses of dead larvae from their nests. This behavior seems to have two components: uncapping the larval cell (u) and removing the carcass (r), each of which is under the control of a recessive gene.

These bees are nonhygienic. They will uncap cells of dead larvae, but won't remove them.

934 CHAPTER FIFTY-TWO

I \ en though these results appear to indicate a gene for uncapping and a gene for remo\ al, these behavior patterns are complex. [hey involve sensor) mechanisms, orientation mo\ ements, and motor patterns, each of which depends on multiple properties o\ many cells. The genetic deficits of nonhygienic bees could influence very small, specific, yet critical properties o\ some cells. If a single critical property, such as a crucial synapse or a particular sensory receptor, \ \ ere lacking, the whole behavior would not be expressed. The responsible gene, then, is not a specific gene that codes for the entire behavior.

Molecular genetics techniques reveal specific genes that influence behavior

Molecular geneticists are investigating specific genes that influence behaviors. Male courtship behavior in fruit flies {Drosophila) is a subject of many such studies. This behavior is stereotypic, species-specific, and requires no learning. Males recognize potential mates, follow them, tap the female's body with their forelegs, extend and vibrate one wing, and lick the female's genitals. If the female is receptive, the male copulates with her (Figure 52.12a). Research in molecular genetics has now shown that most of this male courtship behavior is controlled by a single gene.

In fruit flies with two X chromosomes (females), a gene

called sex-lethal (sxl) is expressed. This gene is at the top of a genetic hierarchy that determines all aspects of sexual differentiation and behavior (Figure 52.12fr). The Sxl protein causes another gene called transformer (tra) to produce the female-specific Tra protein. Fruit flies without the tra gene develop into males anatomically and behaviorally, regardless of how many X chromosomes they have. But it is still another gene in the sex determination hierarchy that is responsible for male behavior.

The Tra protein controls two additional genes called dou-blesex (dsx) and fruitless (fru). The dsx gene mostly controls the

anatomical differentiation of males, and fru causes the formation of a nervous system that expresses male courtship behavior. Mutations of the fru gene do not affect male body form, but they disrupt male courtship behavior. We don't know all of the actions that the male-specific Fru protein has in the development of the fruit fly nervous system, but this is about as close as we can get at present to identifying a gene that controls a complex behavior.

52.12 The fruitless Gene Controls Male Courtship Behavior in Fruit Flies

Communication

Communication is behavior that influences the actions of other individuals. It consists of displays or signals that can be perceived by other individuals and which convey information to them. Natural selection shapes displays or signals into systems of communication if the transmission of information benefits both the sender and the receiver. Thus, the ultimate cause of communication is the selective advantage it gives to individuals that engage in it. The courtship displays of a male, for example, benefit the male if they attract females, and they benefit the female if they allow her to assess whether the male is of the right species and whether he is strong, vigorous, and has other attributes that will make him a good father. A common mutual benefit of communication is the reduction of uncertainty about the status or intentions of the signaler. Even in aggressive interactions, reducing uncertainty helps both sender and receiver to avoid physical harm.

Studies of communication can be complex because they must take into account the sender, the receiver, and the environment. The displays or signals that an animal can generate depend on its physiology and anatomy. Likewise, an animal's ability to perceive displays or signals depends on its sensory physiology and on the environment through which the display or signal must be transmitted.

In Chapter 45, we learned how sensory systems function in chemosensation, tactile sensation, audition, vision, and electrosensation. These are the channels of animal communication. In the discussion that follows, we will explore each of these five channels in turn.

Chemical signals are durable but inflexible

Molecules used for chemical communication between individual animals are called pheromones. Because of the diversity of their molecular structures, pheromones can communicate very specific messages that contain a great deal of information. The mate attraction pheromone of the female silkworm moth is a good example (see Figure 45.4). Male moths as far as several kilometers downwind are informed by these molecules that a female of their species is sexually receptive. By orienting to the wind direction and following the concentration gradient of the molecules, they can find her.

Territory marking is another example in which detailed information is conveyed by chemical communication (Figure 52.13). Pheromonal messages left by mammals such as cats and dogs, for example, can reveal a great deal of information about the animal: species, individual identity, reproductive status, size (indicated by the height of the message), and when the animal was last in the area (indicated by the strength of the scent).

An important feature of pheromones is that once they are released, they remain in the environment for a long time. By contrast, vocal or visual displays disappear as soon as the animal stops signaling or displaying. The durability of pheromonal signals enables them to be used to mark trails, as ants do, or to indicate directionality, as in the

Panthera tigris

52.13 Many Animals Communicate with Pheromones

To mark her territory, this female tiger is spraying pheromonal secretions from a scent gland in her hindquarters onto a tree. Other tigers passing the spot will know that the area is "claimed," and they will know something about the animal who claimed it.

case of the moth sex attractant. However, it also means that the message cannot be changed rapidly. This inflexibility makes pheromonal communication unsuitable for a rapid exchange of information.

The chemical nature and the size of the pheromonal molecule determine its speed of diffusion. The greater the speed of diffusion, the more rapidly the message gets out and the farther it will reach, but the sooner it will disappear. Trail-marking and territory-marking pheromones tend to be relatively large molecules that diffuse slowly; sex attractants tend to be small molecules that diffuse rapidly.

Visual signals are rapid and versatile but are limited by directionality

Visual signals are easy to produce, come in an endless variety, can be changed very rapidly, and clearly indicate the position of the signaler. However, the extreme directionality of visual signals means that they are not the best means of getting the attention of a receiver. The receptors of the receiver must be focused on the signaler, or the message will be missed. Most animals are sensitive to light and can therefore receive visual signals, but sharpness of vision limits the detail that can be transmitted. The complexity of the environment also limits visual communication.

Because visual communication requires light, it is not useful at night or in environments that lack light, such as caves and the ocean depths. Some species have surmounted this constraint on visual communication by evolving their own light-emitting mechanisms. Fireflies use a enzymatic mechanism to create flashes of light. By emitting flashes in species-specific patterns, fireflies can advertise for mates at night.

936 CHAPTER FIFTY-TWO

Fireflies also illustrate how some species can exploit the communication systems of other species. There are predator - of fireflies that mimic the mating flashes of

other species. When an eager suitor approaches the signaling individual, it is eaten. Thus, deception can be part of animal communication systems, just as it is part of human

Auditory signals communicate well over a distance

Compared with visual communication, auditory communication has advantages and disadvantages. Sound can be used at night and in dark environments. It can go around obstacles that would interfere with visual signals, so it can be used in complex environments like forests. It is better than visual signals at getting the attention of a receiver because the receiver does not have to be focused on the signaler for the message to be received. Like visual signals, sound can provide directional information, as long as the receiver has at least two receptors spaced somewhat apart. By maximizing or minimizing the features of the sounds they emit, animals can make their location easier or more difficult to determine.

Sound is useful for communicating over long distances. Even though the intensity of sound decreases with distance from the source, loud sounds can be used to communicate over distances much greater than those possible with visual signals. An extreme example is the communication of whales. Some whales, such as the humpback, have very complex songs. When these sounds are produced at a certain depth (around 1,000 m), they can be heard hundreds of kilometers away. In this way, humpback whales can locate each other over vast areas of ocean.

Auditory signals cannot convey complex information as rapidly as visual signals can, as the expression "A picture is worth a thousand words" implies. When individuals are in visual contact, an enormous amount of information is exchanged instantaneously (for example, species, sex, individual identity, reproductive status, level of motivation, dominance, vigor, alliances with other individuals, and so on). Coding that amount of information, with all of its subtleties, as auditory signals would take considerable time, thus increasing the possibility that the communicators could be located by predators.

The animal world is relatively silent. Most invertebrates do not produce sound; cicadas and crickets are marvelous exceptions. Many amphibians, most fishes, and most reptiles produce no sound.

Tactile signals can communicate complex messages

Communication by touch is extremely common, although not always obvious. Animals in close contact use tactile interactions extensively, especially under conditions that do not favor visual communication. When eusocial insects such as ants, termites, or bees meet, they contact one another with their antennae and front legs. One of the best-studied uses of tactile communication, beginning with the pioneering work of ethologist Karl von Frisch, is the dance of honeybee. When a forager bee finds food, she returns to

(a)

(b)

Food source

Food source

Pattern of waggle dance

Partem of waggle dance

ffl

52.74 The Waggle Dance of the Honeybee (a) By running straight up on the surface of the honeycomb in a dark hive, a honeybee tells her hivemates that there is a food source in the direction of the sun and at least 80 meters from the hive. The intensity of the waggle indicates exactly how far the food source is. If the food source were in the opposite direction from the sun, she would orient her waggle runs straight down, (b) When her waggle runs at an angle from the vertical, the other bees know that the same angle separates the direction of the food source from the direction of the sun.

the hive and communicates her discovery to her hivemates by dancing in the dark on the vertical surface of the honeycomb. The dance is monitored by other bees, who follow and touch the dancer to interpret the message.

If the food is less than 80-100 meters from the hive, the forager performs a round dance, running rapidly in a circle and reversing her direction after each circumference. The odor on her body indicates the flower to be looked for, but the dance contains no information about the direction to go—only that it is within 100 meters of the hive.

If the food source is farther than 80-100 meters, the bee performs a waggle dance, which conveys information about both the distance and the direction of the food source. The bee repeatedly traces out a figure-eight pattern as she runs on the vertical surface. She alternates half-circles to the left and right with vigorous wagging of her abdomen in the short, straight run between turns. The angle of the straight run indicates the direction of the food source relative to the direction of the sun (Figure 52.14). The speed of the dancing

ANIMAL BEHAVIOP 937

indicates the distance to the food source: The farther away it is, the slower the waggle run.

Electric signals can also communicate messages

Some species of fish have evolved the ability to generate electric fields in the water around them by emitting a series of electric pulses (see Chapter 45). These trains of electric pulses can be used for sensing objects in the immediate surroundings, and they can also be used for communication.

An electrode connected to an amplifier and a speaker can be used to "listen" to the signals generated by glass knife fish in a tank. Each individual fish emits a pulse at a different frequency, and the frequency each fish uses relates to its status in the population. Males emit lower frequencies than females. The most dominant male has the lowest frequency, and the most dominant female has the highest frequency. When a new individual is introduced into the tank, the other individuals adjust their frequencies so that they do not overlap, and the signal of the new individual indicates its position in the hierarchy. In their natural environment—the murky waters of tropical rainforests—these fish can tell the identity, sex, and social position of another fish by its electric signals.

Communication has been a very fruitful area for investigating the ultimate causes of behavior and how the resulting adaptations have been shaped by the environment. Next we will return to some studies of proximate causes of behavior to see some examples of how "how" questions can be addressed.

The Timing of Behavior: Biological Rhythms

Among the important proximate causes of behavior are those that determine its organization through time. The study of biological rhythms has led to major discoveries about brain mechanisms down to the molecular level that enable animals to organize their behavior in time. In the discussion that follows, we will examine two types of biological rhythms: circadian rhythms and circannual rhythms.

Circadian rhythms control the daily cycle of behavior

Our planet turns on its axis once every 24 hours, creating a cycle of environmental conditions that has existed throughout the history of life. Daily cycles are characteristic of almost all organisms. What is surprising, however, is that this daily rhythmicity does not depend on the 24-hour cycle of light and dark.

If animals are kept in constant darkness, at a constant temperature with food and water available all the time, they still demonstrate daily cycles of activity sleeping, eating, drinking, and just about anything else that can be measured. This persistence of the daily cycle in the absence of changes between light and dark suggests that animals have an endogenous (internal) clock. Without time cues from the environment, however, these daily cycles are not exactly 24 hours long. They are therefore called circadian

rhythms from the Latin *circa*, "about," and *diēs*, "day".

To discuss biological rhythms, we must introduce some terminology. A rhythm can be thought of as a series of cycles, and the length of one of those is the period of

the rhythm. Any point on the cycle is a phase of that cycle:

Rhythm

Period

Time

Hence, when two rhythms completely match, they are in phase, and if a rhythm is shifted (as in the resetting of the clock), it is phase-advanced or phase-delayed. Since the period of a circadian rhythm is not exactly 24 hours, it must be phase-advanced or phase-delayed even day to day to remain in

phase with the environment.

entrainment. The process of resetting of the circadian

rhythm by environmental cues is called entrainment. An animal kept in constant conditions will not be entrained to the 24-hour cycle of the environment, and its circadian clock will run according to its natural period—it will be free-running. If its period is less than 24 hours, the animal will begin its activity a little earlier each day (see the middle panel of Figure 52.15).

Animals with free-running circadian rhythms can be used in experiments to investigate the stimuli that phase-shift or entrain the circadian clock. Under natural conditions, environmental cues, such as the onset of light or dark, entrain the free-running rhythm to the 24-hour cycle of the real world. In the laboratory, it is possible to entrain circadian rhythms in free-running animals with short pulses of light or dark administered every 24 hours (bottom panel of Figure 52.15).

When you fly across several time zones, your circadian clock is out of phase with the real world at your destination; the result is jet lag. Gradually your endogenous rhythm synchronizes itself with the real world as it is entrained by environmental cues. Since your endogenous

rhythm cannot be shifted by more than 30 to 60 minutes each day, it takes several days to reentrain your clock to real time in your new location. This period of reentrainment is the time during which you experience jet lag, because your endogenous rhythm is waking you up, making you sleepy, initiating activities in your digestive tract, and stimulating many other physiological functions at inappropriate times of the day.

the circadian clock. Where is the clock that controls the circadian rhythm? In mammals, the master circadian clock is located in two tiny groups of cells just above the optic chiasm, the place where the two optic nerves cross. These structures are called the supra chiasmatic nuclei (SCN).

938 CHAPTER FIFTY-TWO

EXPERIMENT

Question: Do daily patterns of rest and activity depend on a 24-hour light-dark cycle?

METHOD Vary the light-dark cycle and record the activity of a mouse on an exercise wheel.

RESULTS

Days 1 l

On a cycle of 12 h light/12 h dark, the mouse is mostly active in the dark and has a rest-activity cycle of 24 hours.

In constant dark, the mouse still expresses a daily cycle of rest and activity, but the period of the cycle is less than 24 hours.

Conclusion: The mouse has an endogenous rest-activity cycle of less than 24 hours, but that cycle can be entrained by the 24 h daily cycle of light and dark.

52.75 Orcadian Rhythms

The marks indicate times when a mouse is running on an activity wheel. Two days of activity are recorded on each horizontal line, such that the data for each day are plotted twice, once on the right half of a line and again on the left half of the next line below; this double plotting makes patterns easier to see. The schedule of light and dark exposure is indicated by the solid bars running across the figure. First the mouse experiences 12 hours of light and 12 hours of dark every day (top panel), then it is placed in constant darkness (middle panel), and finally it is given a 20-minute exposure to light each day (bottom panel). In constant darkness, the circadian rhythm is free-running, but a 20-minute flash of light at 24-hour intervals can entrain it.

the SCN are destroyed, the animal loses circadian rhythmicity. Under constant conditions, the animal is equally likely to be active or asleep at any time of day (Figure 52.16).

Recent experiments have shown that circadian rhythms

of rest and activity can be restored in an animal whose SCN have been destroyed. It receives a transplant of those nuclei

from another animal. In no other known case can a brain transplant restore such a complex behavior. Since the restored rhythm has the period of the animal that donates the tissue, the transplant clearly controls the recipient's behavior.

Circadian rhythms are found in every animal group, as well as in protists, plants, and fungi, but only vertebrates have SCN. Thus, natural selection has produced a variety of circadian clocks. In the mollusk *Bulla*, for example, the cells driving circadian behavior are in the eyes. Birds do have SCN, but the master clock of at least some species resides in the pineal gland, a mass of tissue between the cerebral hemispheres that produces the hormone melatonin. If the pineal gland of a bird is removed, the bird loses its circadian rhythm. In protists and fungi, circadian rhythmicity is a property of individual cells, and the individual cells of many multicellular animals can generate circadian rhythms. What are the molecular mechanisms of these circadian clocks?

EXPERIMENT

Question: Is the suprachiasmatic nucleus (SCN) the site of the circadian clocks in mammals?

METHOD

RESULTS

Days 1

Destroying the SCN eliminates the circadian rhythm.

Conclusion: If the SCN is destroyed, a mammal loses its circadian rhythm

52.76 Where the Clock Is

The circadian clock of mammals is in the suprachiasmatic nuclei (SCN) of the brain. If its suprachiasmatic nuclei are destroyed, a mammal loses its circadian rhythm.

clock genes. Enormous progress has been made in recent years toward discovering the molecular basis of circadian rhythms. The surprise is that there is a high degree of homology in the genes involved across a very wide range of organisms, from bread molds to humans. The story begins with a gene called *period* that was discovered in fruit flies, as mentioned above. Mutations of this gene cause flies to have either short or long circadian periods. Mutations of another circadian gene, called *timeless* (short for "timeless"), cause a loss of circadian rhythms in fruit flies. The presence of mRNA for *period* and *timeless* shows a daily cycle, as does the presence of the *Per* and *Tim* proteins. Thus, the transcription and translation of these two genes shows a circadian rhythm. But what controls the rhythm? The *Per* and *Tim* proteins dimerize in the cytoplasm, and the resulting

heterodimer is translocated into the nucleus, where it acts as a transcription factor inhibiting the transcription of the *per* and *tim* genes (Figure 52.17). These two genes could thus be the wheels of a

It is now known that the mechanism is not so simple, and that there are a number of other genes involved. What is interesting, however, is that homologies have been found between these clock genes in fungi, insects, mice, and humans, indicating how fundamental molecular clock mechanisms are to living organisms on Earth.

Transcription and translation of *per* and *tim* show circadian rhythms.

52.17 Circadian Rhythms May Be Generated by a Molecular Clock

The *per* and *tim* genes discovered in fruit flies are homologous to "clock genes" found in a wide range of organisms. These genes are transcribed and translated on a circadian rhythm that seems to be controlled by positive feedback.

940 CHAPTER FIFTY-TWO

Circannual rhythms control seasonal behaviors

In addition to turning on its axis every 24 hours, our planet revolves around the sun once every 365 days. Because Earth is tilted on its axis, its revolution around the sun results in seasonal changes in day length at all locations except the equator. These changes secondarily create seasonal changes in temperature, rainfall, and other variables. Because the behavior of animals must adapt to these seasonal changes, animals must be able to anticipate the seasons and adjust their behavior accordingly. Most animals, for example, should not produce young in the winter.

For many species, change in day length, or photoperiod, is a reliable indicator of seasonal changes to come. If day length has a direct effect on the physiology and behavior of a species, that species is said to be photoperiodic. If male deer, for example, are held in captivity and subjected to two cycles of change in day length in one year, they will grow and drop their antlers twice during that year.

For some animals, change in day length is not a reliable cue. Hibernators spend long months in dark burrows underground, away from any indicators of day length, but have to be physiologically prepared to breed almost as soon as they emerge in the spring. A bird overwintering in the tropics cannot use changes in photoperiod as a cue to time its migration north to the breeding grounds. Hibernators and equatorial migrants have endogenous annual rhythms, called circannual rhythms. In other words, their nervous systems have a built-in calendar. Just as circadian rhythms are not exactly 24 hours long, circannual rhythms are not exactly 365 days long, but usually shorter. The brain mechanisms of circannual rhythms are completely unknown.

Finding Their Way: Orientation and Navigation

Within a local environment, finding your way is not a problem. Like the wasps Tinbergen studied, you remember landmarks and organize your behavior spatially with respect to those reference points. Such orientation is a very common animal behavior. But what if the destination is a considerable distance away? How does an animal orient to it and find its way?

Many animals navigate long distances through unfamiliar territory. In this section we describe modes of navigation and examine some of their underlying mechanisms.

Piloting animals orient themselves by means of landmarks

In most cases an animal finds its way using simple means: It knows and remembers the structure of its environment. It uses

landmarks to find its nest, a safe hiding place, or a food source. Navigating by means of landmarks is called piloting. Gray whales, for example, migrate seasonally between the Bering Sea and the coastal lagoons of Mexico. They find their way by following the west coast of North America (Figure 52.18). Coastlines, mountain chains, rivers, water currents, and wind patterns can all serve as piloting

feeding range

52.78 Piloting

Gray whales migrate south in winter from the Bering Sea to the coast of Baja California by following the coast of North America.

cues. But some remarkable cases of long-distance orientation and movement cannot be explained by piloting.

Homing animals can return repeatedly to a specific location

The ability of an animal to return to a nest site, burrow, or other specific location is called homing. In most cases, homing is merely piloting in a known environment, but some animals are capable of much more sophisticated homing.

People who breed and race homing pigeons take the pigeons from their home loft and release them at a remote site where they have never been before. The first pigeon that reaches its home wins the race. Data on departure directions, known flying speeds, and distances traveled show that homing pigeons fly fairly directly from the point of release to home. They do not randomly search until they encounter familiar territory.

Scientists have used homing pigeons to investigate the mechanisms of navigation. One series of experiments tested the hypothesis that the pigeons depend on visual cues. Pigeons were fitted with frosted contact lenses so that they could see no details other than degree of light and dark. These pigeons still homed and fluttered down to the ground in the vicinity of their loft. Thus, they were able to navigate without visual images of the landscape.

Marine birds provide many dramatic examples of homing over great distances in an environment where landmarks are rare. Many marine birds fly over hundreds of miles of featureless ocean on their daily feeding trips and then return directly to a nest site on a tiny island. Alba-

Dioinalcn melanophris

52.19 Coming Home

A pair of black-browed albatrosses engage in courtship display over their partially completed mud nest. Many albatrosses return to the site of their own birth to find a mate, and will return to that site year after year.

trosses display remarkable feats of homing. When a young albatross first leaves its nest on an oceanic island, it flies widely over the southern oceans for 8 or 9 years before it reaches reproductive maturity. At that time, it flies back to the island where it was raised to select a mate and build a nest (Figure 52.19). After the first mating season, the pair separate, and each bird resumes its solitary wanderings. The next year they return to the same nest site at the same time, reestablish their pair bond, and breed. Thereafter they return to the nest to breed every other year, spending many months in between at sea.

Migrating animals travel great distances with remarkable accuracy

For as long as humans have inhabited temperate and subpolar latitudes, they must have been aware that whole populations of animals, especially birds, disappear and reappear seasonally—that is, they migrate. Not until the early nineteenth century, however, were patterns of migration established by marking individual birds with identification bands around their legs. Being able to identify individual birds in a population made it possible to demonstrate that the same birds and their offspring returned to the same breeding grounds year after year, and that these same birds were found during the nonbreeding season at locations hundreds or even thousands of kilometers from the breeding grounds.

How do migrants find their way over such great distances? A reasonable hypothesis is that young birds on their

ANIMAL BEHAVIOR 941

first migration follow experienced birds and learn the landmarks by which they will pilot in subsequent years. However, adult birds of many species leave the breeding grounds before the young have finished fattening and are ready to begin their first migration. These naive birds must be able to navigate accurately on their own, and with little room for mistakes.

Navigation is based on internal and environmental cues

Since many homing and migrating species are able to take direct routes to their destinations through areas they have never experienced, they must have mechanisms of navigation other than piloting. Humans use two systems of navigation: distance-and-direction navigation and bicoordinate navigation. Distance-and-direction navigation requires knowing the direction to the destination and how far away that destination is. With a compass to determine direction and a means of measuring distance, humans can navigate. Bicoordinate navigation, also known as true navigation, requires knowing the latitude and longitude (the map coordinates) of both the current position and the destination. From that information, a route can be plotted to the destination.

distance-and-direction navigation. Researchers conducted an experiment with European starlings to determine their method of navigation. These birds migrate between their breeding grounds in the Netherlands and northern Germany and their wintering grounds to the southwest, in southern England and western France (Figure 52.20). The researchers captured birds on their breeding grounds, marked them, transported them to Switzerland—south of their breeding grounds—and released them. The researchers expected that if the starlings were using distance-and-direction navigation, the marked birds would be recovered in France and Spain, to the southwest of where they were released. Naive juvenile starlings did use distance-and-direction navigation, but experienced adult birds were less disrupted by their geographic displacement.

How do animals determine distance and direction? In many instances, determining distance is not a problem as long as the animal recognizes its destination. Homing animals recognize landmarks and can pilot once they reach familiar areas. Evidence suggests that biological rhythms play a role in determining migration distances for some species. Birds kept in captivity display increased and oriented activity at the time of year when they would normally migrate. Such migratory restlessness has a definite duration, which corresponds to the usual duration of migration for the species. Since distance is determined by how long an animal moves in a given direction, the duration of migratory restlessness could set the distance for its migration.

Two obvious means of determining direction are the sun and the stars. During the day, the sun is an excellent compass, as long as the time of day is known. In the Northern Hemisphere, the sun rises in the east, sets in the west, and

942 CHAPTER FIFTY-TWO

EXPERIMENT

Question: Do European starlings migrate from brooding to winter ranges using distance-and-direction navigation or bicoordinate navigation?

METHOD

RESULTS

Capture young birds before their first winter migration.

Mark birds and move them to a distant location and release them.

Record where they are recovered.

52.20 Distance-and-Direction Navigation

European starlings normally make a short winter migration in a southwesterly direction, from the Netherlands to coastal France and southern England (red arrow). Experimental populations of starlings moved to a site in Switzerland did not fly northwest to their traditional wintering grounds, but followed the same southwesterly route (blue arrow), which took them to Spain.

Starlings from Switzerland did not fly northwest to their traditional grounds, but followed the same southwesterly route, which took them to Spain.

Conclusion: Juvenile starlings use distance-and-direction navigation.

points south at noon. As we have seen, animals can tell the time of day by means of their circadian clocks. Clock-shifting experiments have demonstrated that animals use their circadian clocks to determine direction from the position of the sun.

Researchers placed birds in a circular cage that enabled them to see the sun and sky, but no other visual cues (Figure 52.21). Food bins were arranged around the sides of the cage, and the birds were trained to expect food in the bin at one particular direction—south, for example. After training, no matter what time they were fed, and even if the cage was rotated between feedings, the birds always went to the bin at the southern end of the cage for food, even if that bin contained no food.

Next, the birds were placed in a room with a controlled light cycle, and their circadian rhythms were phase-shifted by turning the lights on at midnight and off at noon. After about 2 weeks, the birds' circadian clocks had been phase-advanced by 6 hours. Then the birds were returned to the circular cage under natural light conditions, with sunrise at 6:00 a.m. Because of the shift in their circadian rhythms, their endogenous clocks were indicating noon at the time the sun came up.

If food was always in the south bin, and it was sunup, the birds should have looked for food 90 degrees to the right of the direction of the sun. But since their circadian clocks were telling them it was noon, they looked for food in the direction of the sun—in the east bin. The 6-hour phase shift in their circadian clocks resulted in a 90-degree error in their orientation. These kinds of experiments on many species have shown that animals can orient by means of a time-compensated solar compass.

Many animals are normally active at night; in addition, many day-active bird species migrate at night and thus cannot use the sun to determine direction. The stars offer two sources of information about direction: moving constellations and a fixed point. The positions of constellations change because Earth is rotating. With a star map and a clock, direction can be determined from any constellation. But one point that does not change position during the night is the point directly over the axis on which Earth turns. In the Northern Hemisphere, a star called Polaris, or the North Star, lies in that position and always indicates north.

Stephen Emlen at Cornell University investigated whether birds use these sources of directional information from the stars. He raised young birds in a planetarium, where star patterns are projected on the ceiling of a large, domed room. The star patterns in the planetarium could be slowly rotated to simulate the rotation of Earth. If the star patterns were not rotated, birds caught in the wild could orient well in the planetarium, but birds raised in the planetarium under a nonmoving sky could not. If the star patterns in the planetarium were rotated each night as the young birds matured, they were able to orient in the planetarium, showing that birds can learn to use star patterns for orientation if the sky rotates (Figure 52.22).

These experiments provided no evidence that the birds used their circadian clocks to derive directional information from the star patterns. Experienced birds were not confused by a still sky, or by a sky that rotated faster than normal. These birds were orienting to the fixed point in the sky, the North Star. Young birds raised under a sky that rotated around a different star imprinted on that star and oriented to it as if it were the North Star. These studies showed that

Conclusion: Pigeons have the ability to tell directions by means of a time-compensated solar compass.

Birds whose circadian rhythms were phase-shifted forward by 6 hours oriented as though the dawn sun was at its noon position. These results showed that birds are capable of using their circadian clocks to determine direction from the position of the sun.

birds raised in the Northern Hemisphere learn a star map that they can use for orientation at night by imprinting on the fixed point in the sky.

Animals cannot use sun and star compasses when the sky is overcast, yet they still home and migrate under such conditions. Do other sources provide information they can use for orientation? There appears to be considerable redundancy in animals' abilities to sense direction. Pigeons are able to home as well on overcast days as on clear days, but this ability is severely impaired if small magnets are attached to their heads—evidence that the birds use a magnetic sense. Cells have been found in birds that contain small particles of the magnetic mineral magnetite, but the neurophysiology of the magnetic sense is largely unknown. Another possible cue is the plane of polarization of light, which can give directional information even under heavy cloud cover. Very low frequencies of sound can provide information about coastlines and mountain chains. Weather patterns can also provide considerable directional information.

BiCOORDiNATE navigation. Bicoordinate navigation involves knowing where you are (in longitude and latitude) and where you want to go, and plotting an appropriate course. Longitude can be determined by the position of the sun and the time of day: If the sun comes up earlier than expected, you must be east of where you want to be, and if the sun comes up later than expected, then you are west of

52.22 Star Patterns Can Be Altered in a Planetarium

This scientist has placed birds in a planetarium. By changing the positions or movements of the stars projected on the planetarium ceiling, he can investigate what information the birds use for orientation.

944 CHAPTER FIFTY-TWO

where you want to be. Time and sun position can give information about latitude as well. At a given time of day in the Northern Hemisphere, a sun position higher in the sky than expected indicates you are farther south than you want to be, and if the sun is lower in the sky than expected, you are north of where you want to be. Information about longitude and latitude can also come from sensing Earth's magnetic lines of force and from the positions of the stars.

In spite of the remarkable navigational abilities of animals such as albatrosses, there is currently no evidence that animals use bicoordinate navigation. But, of course, it is not easy to do experiments on animals such as albatrosses!

Human Behavior

As we saw early in this chapter, the behavior of an animal is a mixture of components that are inherited and components that can be molded by learning. However, even some aspects of learned behavior patterns—such as what can be learned and when it can be learned—have genetic determinants. Thus natural selection shapes not only the physiology and morphology of a species, but also its behavior. In some situations natural selection favors inherited behaviors; in others, learned behaviors. In many cases, the optimal adaptation is a mixture of inherited and learned behavioral components. Given these considerations, how would we characterize human behavior?

An important characteristic of human behavior is the extent to which it can be modified by experience. The transmission of learned behavior from generation to generation—culture—is the hallmark of humans. Nevertheless, the structures and many functions of our brains are inherited, including drives, limits to and propensities for learning, and even some motor patterns. Biological drives such as hunger, thirst, sexual desire, and sleepiness are inherent in our nervous systems. Is it reasonable, therefore, to expect that emotions such as anger, aggression, fear, love, hate, and jealousy are solely the consequences of learning?

Our sensory systems enable us to use certain subsets of information from the environment; similarly, the structure of our nervous systems makes it more or less possible to process certain types of information. Consider, for example, how basic and simple it is for an infant to learn spoken language, yet how many years that same child must struggle to master reading and writing. Verbal communication is deeply rooted in our evolutionary past, whereas reading and writing are relatively recent products of human culture.

Some motor patterns seem to be programmed into our nervous systems. Studies of diverse human cultures from around the world reveal basic similarities of facial expressions and body language among human populations that have had little or no contact with one another. Infants born blind still smile, frown, and show other facial expressions at appropriate times, even though they have never observed such expressions in others.

Acknowledging that aspects of our behavior have been shaped through evolution in no way detracts from the

value we place on our ability to learn and the importance of cultural transmission of information to our species. Even so, we are recognizing that culture, in its simplest form, is not uniquely human. In the introduction to this chapter we saw what has been characterized as pre-cultural behavior in Japanese macaques. Individuals invented new behaviors, and those new behaviors were transmitted by imitative learning through the population.

In a recent study, scientists who have spent years studying chimpanzee behavior in seven widely separated areas of Africa compared their findings on chimpanzee behavior. They were able to identify 39 behaviors, ranging from tool use to courtship behavior, that were common in some populations but absent in others. Moreover, the variation in these behaviors was much greater between populations than within a population, and each population had a distinct repertoire of these behaviors. Just as human societies are characterized by different assemblages of culturally transmitted customs or customary behaviors, so are these chimpanzee populations.

It is increasingly more difficult to draw a line between human behavior and animal behavior, especially that of our closest primate relatives. But why should we expect such a line to exist? We do not expect such a lack of continuity in molecular, biochemical, physiological, or anatomical characteristics. Similarly, human and animal behavior is on a continuum, and the challenge is to understand the common mechanisms and the reasons for quantitative differences.

Chapter Summary

What, How, and Why Questions

- Studies of behavior seek to describe behaviors, understand their mechanisms, and understand their evolution.

Behavior Shaped by Inheritance

- Many behaviors of many species are stereotypic and species-specific, and are thus largely determined by inheritance. They do not require learning and are minimally modifiable by learning.
- Deprivation experiments deprive an animal of opportunities to learn a behavior and can therefore reveal that a behavior is hereditary.
- Hybridization experiments can also reveal genetic influences on behavior. Review Figure 52.2
- Some behaviors are triggered by simple stimuli called releasers. Review Figure 52.3, 52.4
- Spatial learning enables an animal to learn and use information about its physical environment. Review Figure 52.5
- Imprinting enables an animal to learn the features of a complex releaser, such as the identity of its parents. Review Figure 52.6
- The acquisition of bird song is an example in which genetic determinants and learning interact, enabling an animal to learn a behavior by focusing on the correct stimuli at the correct times. Review Figure 52.7
- Genetically programmed behavior is highly adaptive for species, such as those with nonoverlapping generations, that have little opportunity to learn, for species that might learn

ANIMAL BEHAVIOR 945

the wrong behavior, and in situations in which mistakes are costly or dangerous.

Hormones and Behavior

- In rats, the sex steroids present during development determine what sexual behavior patterns develop, and the sex steroids present in the adult control the expression of those patterns. Review Figure 52.9
- In birds, testosterone determines a bird's ability to sing by causing the brain regions responsible for song to develop. Review Figure 52.10

The Genetics of Behavior

- There are many complex steps between the expression of a gene as a protein product and the expression of a behavior. Several types of experiments help reveal how genes affect behavior.
- Artificial selection and crossbreeding can produce individuals with particular behavioral traits that are inherited. Review Figure 52.11
- The techniques of molecular genetics can reveal the functions of specific genes that influence behavior. Review Figure 52.12

Communication

- Communication consists of displays or signals, that can be perceived by other individuals and which influence their behavior. Natural selection favors communication systems when both sender and receiver benefit from the exchange of

information.

- ▶ The evolution of communication signals is constrained by the anatomical and physiological characteristics of a species that are available to be shaped by natural selection.
- ▶ Many animals communicate by emitting pheromones into the environment and by sensing the pheromones of other animals. Pheromonal messages can last a long time, but they cannot be changed quickly.
- ▶ Visual communication is easy, versatile, and rapid, but it is limited by its directionality, by the visual acuity of the receiver, and by environmental conditions such as darkness. Many animals communicate via visual signals.
- ▶ Auditory signals can be used at night, can go around objects that would interfere with visual communication, can easily get the receiver's attention, can provide directional information, and can travel long distances. Compared with visual communication, however, auditory communication is slow. Few animals communicate with auditory signals.
- ▶ Tactile signals can communicate complex messages, as the dance of the honeybee demonstrates. Review Figure 52.14
- ▶ The electric signals generated by some fishes can be used for communication.

The Timing of Behavior: Biological Rhythms

- ▶ Animal behaviors are expressed in daily cycles called circadian rhythms. A circadian rhythm is an endogenous rhythm with a period not equal to 24 hours. To remain in phase with the 24-hour daily cycle of the environment, a circadian rhythm must be phase-shifted every day. Phase-shifting cues such as the onset of light and dark entrain circadian rhythms to the natural 24-hour period. Review Figure 52.15
- ▶ In mammals, the clock that controls the circadian rhythm is located in the suprachiasmatic nuclei of the brain. In other animals, different structures function as the circadian clock. Review Figure 52.16
- ▶ Two genes have been identified that are involved in the clock mechanism in a variety of species. Review Figure 52.17
- ▶ Circannual rhythms ensure that animals, such as hibernators and equatorial migrants, that cannot rely on changes in day length as seasonal cues perform the appropriate behaviors at the appropriate times of year.

Finding Their Way: Orientation and Navigation

- ▶ Piloting animals find their way by orienting to landmarks. Review Figure 52.18
- ▶ Homing animals find their way through unfamiliar territory to specific locations. Migrating animals travel long distances with remarkable accuracy.
- ▶ Animals that navigate by distance and direction determine distance in part by recognizing landmarks in the vicinity of their destination and in part by biological rhythms timing how far they travel.
- ▶ Sources of directional information include a time-compensated solar compass and an ability to locate the fixed point in the nocturnal sky. Review Figures 52.20, 52.21
- ▶ The long-distance movements of some species are difficult to explain by distance-and-direction navigation mechanisms. Information for bicoordinate navigation is available from the physical environment, but there is no evidence that any species uses such information.

Human Behavior

- ▶ Like that of all other animals, human behavior consists of genetically determined and learned components. What sets humans apart from other animals is the extent to which we can modify our behavior on the basis of experience.

For Discussion

1. An oystercatcher is a bird that normally lays a clutch of two eggs. If you place an artificial nest with either three artificial but normal-sized eggs or one very large artificial egg near the oystercatcher's nest, the oystercatcher will abandon its own two eggs and attempt to incubate the artificial eggs. How can you explain this behavior?
2. Cowbirds are nest parasites. A female cowbird lays her eggs in the nest of another species, which then incubates the eggs and raises the young. What do you think would characterize the acquisition of song in cowbirds? In a given area, cowbirds tend to parasitize the nests of particular bird species. How do you think female cowbirds learn this behavior? How would you test your hypothesis?
3. The short-tailed shearwater is a bird that winters in Antarctica and summers in the Arctic. What problems would this species have in using either the sun or the stars for navigation? What is the most likely means it uses to find its way to its summer and its winter feeding grounds?
4. Male dogs lift a hind leg when they urinate; female dogs squat. If a male puppy receives an injection of estrogen when it is a newborn, it will never lift its leg to urinate for the rest of its life; it will always squat. How might this result be explained?
5. If you were able to be the first person to visit a human population that had never been in contact with another culture, how

could you use that opportunity to explore whether there were any human behaviors that were genetically determined?

Part Seven

Ecology and

BIOGEOGRAPHY

53

Behavioral Ecology

_*-

For a predator such as a cheetah, it starts to run away but then it usually slows down a bit and performs

a behavior called stotting. It jumps about half a meter off the ground with all four legs held straight and its white rump patch fully everted. Why would an animal that is fleeing from a predator slow down rather than speed up?

Several hypotheses have been proposed to explain why stotting may have evolved. First, the gazelle may be warning other nearby gazelles—particularly its relatives—that it has spotted a predator. Second, stotting individuals in a fleeing herd might distract and confuse a predator. Third, a stotting gazelle may be signaling to the predator that it has been seen and therefore pursuit will not be profitable.

Predictions based on these hypotheses have been tested in the field. The first and second hypotheses can be rejected because even solitary gazelles usually stot when they spot a predator. Only the third hypothesis is supported by existing data: Cheetahs, the most important predators on gazelles, are significantly more likely to abandon a pursuit if a gazelle stots than if it does not.

Individuals of all species, not only gazelles, interact in various ways with individuals of their own and other species and with their physical environments. The task of ecology is to understand the nature and consequences of these interactions. Ecologists may study these interactions by formulating and testing hypotheses, as they did for stotting in gazelles. Ecologists also study patterns of distribution and abundance of organisms to determine how these patterns are established and maintained, and how they change over short and long time periods. From its roots in descriptive natural history, ecology has developed into a complex field of inquiry dealing with levels of organization ranging from relationships of individual organisms with their physical and biological environments to the structure of communities and ecosystems.

As used by ecologists, the term environment includes physical and chemical factors such as water, nutrients, light, temperature, and wind. It also includes biotic factors: all other organisms that influence the lives of individuals. Because species are adapted for life in many different environments, their interactions with their biotic and abiotic environments are also varied. An environmental factor that

A Stotting Gazelle

Although it is being pursued by a cheetah, this Thomson's gazelle (*Gazella thomsoni*) has slowed down to jump high off the ground.

exerts a strong influence on individuals of one species may have no influence on individuals of another species.

Interactions between organisms and their environments are two-way processes. Organisms both influence and are influenced by their environments. Indeed, managing environmental changes caused by our own species is one of the major

problems of the modern world. For this reason, ecologists are often asked to help analyze causes of environmental problems and to assist in finding solutions for them. However, it is important not to confuse the science of ecology with the term "ecology" as it is often used in popular writing, referring to nature as a kind of superorganism.

In this first chapter on ecology, we will discuss behavioral ecology: how animals make decisions* that influence their survival and reproductive success, how ecologists study these decisions, and what they have learned from their studies.

Animals decide where to carry out their activities and how to select the resources they need—food, water, shelter, nest sites. Animals also respond to predators and competitors, and decide how to interact with other members of their own species (called conspecifics). Individual choices are the foundation of much of ecology, because changes in densities and distributions of populations are the cumulative results of the decisions of myriad individuals.

The use of the words "decision" and "decide" here does not imply that the choices animals make are conscious, but rather that these choices influence their survival and reproductive success and thus are molded by natural selection.

948 CHAPTER FIFTY-THREE

Balancing Costs and Benefits of Behaviors

In their attempts to understand the evolution of behavior, ecologists often analyze their observations in terms of costs and benefits. A cost-benefit analysis is based on the principle that an animal has only a limited amount of time and energy to devote to its activities. Animals generally do not perform behaviors whose total costs are greater than the sum of their benefits—the improvements in survival and reproductive success that the animal achieves by performing the behavior.

Of course, animals do not consciously calculate costs and benefits, but over many generations, natural selection molds behavior in accordance with costs and benefits. A cost-benefit approach provides a framework that behavioral ecologists can use to make observations and design experiments that enable them to understand why behavior patterns evolve as they do.

The cost of behaving has three components. The energetic cost of a behavior is the difference between the energy the animal would have expended had it rested and the energy expended in performing the behavior. The risk cost of a behavior is the increased chance of being injured or killed as a result of performing it compared with resting. The opportunity cost of a behavior is the sum of the benefits the animal forfeits by not being able to perform other behaviors during the same time interval. Opportunity costs measure the fitness trade-offs involved in performing different behaviors for different amounts of time. An animal that devotes all of its time to foraging, for example, does not achieve high reproductive success!

During the mating season in September and October, male Yarrow's spiny lizards maintain territories from which they exclude conspecific males. Behavioral ecologists assessed the costs of this behavior by stimulating territorial behavior in the lizards during June and July, a time of year when the lizards normally are only weakly territorial. They did this by inserting small capsules containing testosterone beneath the skin of some males. Control males were also captured and released, but received no testosterone implants.

The testosterone-implanted males patrolled their territories more, performed more threat displays, and expended about one-third more energy (energetic cost) than control

males. As a result, they had less time to feed (opportunity

cost), captured fewer insects, stored less energy, and died at a higher rate (risk cost) (Figure 53.1).

This experiment demonstrated that the costs of active territorial defense in June and July probably explain why the lizards normally reduce territorial behavior at that time of year. Presumably, during the mating season, when females are receptive and territorial behavior can result in increased reproductive success, its benefits are great enough to offset these costs.

Choosing Where to Live and Forage

Selecting a place in which to live is one of the most important decisions an individual makes. Where an individual chooses to live and how it uses that environment strongly

53.1 The Costs of Defending a Territory

By using testosterone implants to increase territorial behavior, experimenters measured the costs to male Yarrow's spiny lizards of defending a territory during the summer months, when females are not receptive.

influence its survival and reproductive success. In this section, we will consider how animals choose environments that provide adequate food and shelter, and how they select their food.

Features of an environment may indicate its suitability

The environment in which an organism normally lives is called its habitat. Once a habitat is chosen, an animal seeks its food, resting places, nest sites, and escape routes from predators within that habitat.

The cues organisms use to select suitable habitats are as varied as the organisms themselves, but all habitat selection cues have a common feature: They are good predictors of general conditions suitable for future survival and reproduction. A simple example of habitat selection cues is that of the red abalone, a gastropod mollusk that begins its life

f

as a fertilized egg in the open ocean. The egg hatches about 14 hours after fertilization, and a motile larva emerges with enough yolk to continue developing for another 7 days. During this time it swims in the open water without eating. At the end of 7 days, the larva stops developing, swims to the seafloor, chooses a place in which to settle, and metamorphoses into an adult. ¹ Abalone larvae settle only on coralline algae, upon which they feed. They recognize coralline algae by the presence of a specific chemical—a water-soluble peptide containing about 10 amino acids—that the algae produce. In the laboratory, abalone larvae will settle on any surface on which this chemical has been placed, but in nature only coralline algae produce it. By using this simple cue, these larvae always settle on a surface that is suitable for their future development.

Red abalone grow to adulthood feeding on a single patch of coralline algae; their habitat is their food. However, most animals must make many choices about where and how to seek and select food after they have settled in a habitat.

How do animals choose what to eat?

Because food is such an important resource, we consider it here in some detail. When an animal is looking for food, how much time should it spend searching in one area before moving to another site? When many different types of prey are available, which ones should a predator take, and which ones should it ignore? Foraging theory attempts to provide answers to these questions.

To construct a hypothesis about how a foraging animal should behave, a scientist first specifies the objective of the behavior and then attempts to determine the behavioral choices that would best achieve that objective. This approach is known as optimality modeling. Its underlying assumption is that natural selection has molded the behavior of animals so that they solve problems by making the best choices available to them. Many hypotheses are possible, because a forager may be attempting to maximize the rate at which it obtains energy, to get enough vitamins or minerals, or to minimize its risk while foraging.

As an example, consider how a predator should choose among the available prey. Let's assume that the predator chooses prey so as to maximize its rate of energy intake. This is a reasonable objective because the more efficiently a predator captures food, the more time and energy it will have for other activities, such as reproduction. Therefore, a more efficient predator should produce more offspring than a less efficient one, and animals should evolve to make prey

choice decisions that maximize their rate of energy intake.

To test this hypothesis, we can characterize each type of prey available to the predator by two features: the amount of time it takes the predator to pursue, capture, and consume one of them, and the amount of energy an individual prey item contains. We then rank the prey according to the amount of energy the predator gets relative to the amount of time it spends pursuing, capturing, and handling the prey. The most valuable prey type is the one that yields the $\frac{\text{energy}}{\text{time}}$ most energy per unit of time invested.

With this information, we can build an optimality model to determine the rate at which a predator would obtain energy given a particular prey selection strategy. We can then compare alternative foraging strategies and determine the one that yields the highest rate of energy intake. Such calculations show that, if the most valuable prey type is abundant enough, a predator gains the most energy per unit of time spent foraging by taking only the most valuable prey type and ignoring all others. However, as the abundance of the most valuable prey type decreases, an energy-maximizing predator adds less valuable prey types to its diet in order of the energy per unit of time that those prey yield.

Ecologists performed laboratory experiments with bluegill sunfish to measure the energy content of different prey types (water fleas of different sizes), the time needed to capture and eat different prey types, the energy spent pursuing and capturing prey, and actual encounter rates with prey under different prey densities.

Using these measurements, the investigators predicted the proportions of large, medium, and small water fleas that bluegills would capture in environments stocked with different densities and proportions of those prey types (Figure 53.2). Based on the optimality model, they predicted

53.2 Bluegills are Energy Maximizers

In an experiment, the prey choices of bluegill sunfish were very similar to those predicted by an optimality model based on the goal of maximizing the rate of energy intake.

950 CHAPTER FIFTY-THREE

that in an environment stocked with low densities of all three types of prey, the fish would take every water flea that they encountered, but that in an environment with abundant large water fleas, the bluegills would ignore smaller water fleas.

To test their predictions, the investigators put the bluegills in environments containing three different prey densities and observed the proportions of the water fleas of different sizes they actually captured. The proportions of large, medium, and small water fleas taken by the fish were very close to those predicted by the model. Such tests of foraging theory using many different kinds of animals have provided ecologists with a set of rules showing how animals find and choose their prey. They have also provided estimates of the energetic costs and benefits of foraging behavior.

Mating Tactics and Roles

Individual animals choose their associates, how to interact with them, and when to leave them. The most important choice of associates and a male makes; is- male's preference

Mating behavior involves only a small set of choices. The most basic mating decision is choosing a partner of the correct species. Once that has been determined, additional decisions can be based on the qualities of a potential mate, on the resources it controls—food, nest sites, escape places—or on a combination of the two. Among those species in which individuals do not control any resources, the traits of the partner are the only criteria for mate selection. Here we will discuss how individuals choose their mating partners and show why males and females approach courtship so differently.

Abundant sperm and scarce eggs drive mating behavior

The reproductive behavior of males and females is often very different. Males usually initiate courtship, and they often fight for opportunities to mate with females. Females seldom fight over males, and they often reject courting males. Why do males and females approach courtship and copulation so differently?

The answer lies in the costs of producing sperm and eggs. Because sperm are small and cheap to produce, one male produces enough to sire a very large number of offspring—usually many more than the number of eggs a female can produce or the number of young she can nourish. Therefore, males of most species can increase their reproductive success by mating with many females.

Eggs, on the other hand, are typically much larger than sperm and are expensive to produce. Consequently, a female is unlikely to increase her reproductive output very much by increasing the number of males she mates with. The reproductive success of a female depends primarily upon the quality of the genes she receives from her mate, the resources he controls, and the amount of assistance he provides in the care of her offspring. Thus, females choose among males based on these criteria. By their

Male widowbirds with shortened tails defended their display sites successfully but attracted fewer females than males with long tails.

choices, females may cause the evolution of exaggerated traits that signal male quality. Why

Sexual selection often leads to exaggerated traits

Traits may evolve among individuals of one sex as a result of sexual selection: the selection of traits that confer advantages to their bearers during courtship or when they compete for mates or resources. Successful competitors for resources may gain exclusive access to mates that are attracted to the resources they control. Traits that improve success in courtship may evolve as a result of mating preferences by individuals of the opposite sex.

"Sexual selection is responsible for the evolution of the remarkable tails of African long-tailed widowbirds, which are longer than their heads and bodies combined. Male widow-birds compete for display sites, at which they perform courtship displays to attract females. To examine the role of the tail in sexual selection, an ecologist shortened the tails of some males by cutting them, and lengthened the tails of others by gluing on additional feathers. Both short-tailed and long-tailed males successfully defended their display sites, indicating that the long tail does not confer an advantage in male-male competition. However, males with artificially elongated tails attracted about four times more females than males with shortened tails (Figure 53.3).

Why do females prefer males with long tails? Probably because the ability to grow and maintain a long tail, which

probably carries energetic costs, indicates that the male is vigorous and healthy. Why, then, don't male widowbirds have even longer tails than they do? A likely answer is that the costs of producing a longer tail would exceed the benefits, but the costs of long tails were not measured in these experiments.

Males attract mates in varied ways

Males employ a variety of tactics to induce females to copulate with them. Males of some species defend territories that contain food, nesting sites, or other resources. Some territories are all-purpose: They provide mating sites, nest-

ing sites, and the food necessary to rear offspring (Figure 53.4rt). Other territories include a breeding and nesting area, but do not supply all of the food necessary to rear young. The territories of many seabirds, such as gannets, penguins, and cormorants, are very, small, consisting of only the area that individuals can defend while sitting on their nests (Figure 53.4/7).

If a male controls no resources, he may use courtship behavior that signals in some way that he is in good health, that he is a good provider of parental care, or that he has a good genotype. For example, males of some species of hangingflies court females by offering them dead insects. By capturing an insect and defending it from other males, he demonstrates his ability as a forager and as a competitor. A female hangingfly will mate with a male only if he provides her with food. The bigger the food item, the longer she copulates with him, and the more of her eggs he fertilizes (Figure 53.5).

Whether a male fertilizes the eggs of a female with whom he has copulated depends on when they copulate and whether she copulates with other males. Males have evolved behavior patterns that increase the probability that it will be their sperm and no other male's that fertilize a female's eggs. The simplest method is to remain with the female for as long as she is fertile and prevent other males from copulating with her, but this method has high opportunity costs because a male can not do anything else while he is guarding a female.

Males of many species have evolved behaviors that are more elaborate but take less time. A male black-winged damselfly grabs a female and, using his penis, scrubs out any sperm other males have deposited in her sperm storage chamber. The male removes 90-100 percent of competing sperm before he inserts his own sperm into the chamber. Males of some other insects deposit a plug that effectively seals the opening to the female's genital chamber and prevents other sperm from entering.

53.5 A Male Wins His Mate

The male hangingfly has just presented a moth to his mate, thus demonstrating his foraging skills. She feeds on the moth while they copulate.

952 CHAPTER FIFTY-THREE

The throat feathers of a male bluethroat reflect ultraviolet light.

Females are the choosier sex

As we have seen, females can improve their reproductive success if they can assess the genetic quality and health of potential mates, the quality of the resources they control, and the quantity of parental care they may provide. But how can females make such assessments without the advantage of males to attempt to signal that they are good in all three of these traits?

By paying particular attention to those signals at which males cannot cheat, females have favored the evolution of "reliable" signals. Possession of a large dead insect indicates that a male hangingfly is a good forager and competent provider. Likewise, a male widowbird with a very long tail is likely to be a high-quality mate.

Like tail length, the brightness of the plumage of birds may indicate their health and genetic quality. Male blue-throats (small Eurasian thrushes) have bright blue throat patches (Figure 53.6). Investigators in Norway tested the hypothesis that females use the throat patch as a sign of male quality by blackening the throats of some males and then measuring those males' success in fertilizing eggs. Although most birds form pair bonds, they sometimes engage in extra-pair copulations, so that some of the eggs in a nest may be fertilized by a male other than the one who attends it. A higher proportion of eggs in the nests of males whose throats had been blackened were fertilized by "other" males than of eggs in the nests of control males.

The investigators also tested the role of the ultraviolet-reflecting "blue" males that had copulated with a female were more reflective of the blue feathers on mate choice by female compared to defend her nest against predators, than males that bluethroats. They reduced the UV reflectance of some males that had not copulated with her. Males also set females with males by applying to their blue patches a mixture of fat and UV-absorbing sunblock. Inexperienced copulated look for food on their territories.

Luscinia svecica

53.6 Ultraviolet Reflectance Affects Mate Choice

Female bluethroats are attracted to males whose throat feathers have high reflectance, which signals a healthy, high-quality mate.

In nests of red-winged blackbirds in Washington state were fathered by a male other than the owner of the territory in which the nest was located. All the other fathers were males holding nearby territories: fertile females went to those territories and solicited copulations from the males.

Females that copulated with more than one male, raised more offspring than females that remained faithful to their partner. Their reproductive success improved because neighbors

from the glands the birds use to oil their own feathers and UV-absorbing sunblock. Control males received the fat coating with no sunblock. Although the two groups of males looked the same to human observers, female bluethroats could distinguish them. Females started laying eggs sooner on the territories of control males, and they preferred control males as partners for extra-pair copulations. These experiments show that females can use subtle clues to assess the quality of males.

Social and genetic partners may differ

Behavioral ecologists have known for many years that animals nearly always copulate with their mates—the individuals

with which they have established pair bonds—but that they sometimes also copulate with other individuals. However, until the recent development of DNA fingerprinting methods, investigators had to assume that mated individuals were the parents of the offspring they raised.

By using the new molecular methods to compare the genomes of offspring with those of their supposed parents and other individuals, ecologists have found that nestling birds are nearly always the offspring of the female attending the nest—that is, females rarely lay eggs in other females' nests. However,

Also, there were fewer infertile eggs in nests with multiple fathers than in nests with single fathers. Females try to prevent their mates from copulating with other females, but they must leave them unguarded at times, both to feed and to seek extra-pair copulations of their own.

Costs and Benefits of Social Behavior

Social behavior evolves when individuals that cooperate with others of the same species have, on average, higher rates of survival and reproductive success than those achieved by solitary individuals. Associations for mating may consist of little more than a coming together of eggs and sperm, but individuals of many species associate for longer times to provide care for their offspring. Associating with conspecifics may also improve survival for reasons unrelated to reproduction, such as by reducing the risk of being captured by a predator.

We describe only a few animal social systems, but these examples demonstrate two important concepts. First, social systems are best understood not by asking how they

benefit the species as a whole, but by asking how the individuals that join together benefit. Second, social systems exist in a single nest often. Individuals constantly communicate with others. For example, 34 percent of nestlings one another and adjust their relationships.

a>

53.7 Individuals Hunting Together Can Subdue Large Prey

By hunting as a group, lionesses can kill larger animals than a single female could subdue alone.

Group living confers benefits and imposes costs

Living in groups may confer many types of benefits on individuals. It may improve hunting success or expand the range of prey that can be captured. For example, by hunting together, social carnivores improve their efficiency in bringing down prey (Figure 53.7). Such cooperative hunting was a key component of the evolution of human social behavior. By hunting in groups, our ancestors were able to kill large mammals they could not have subdued alone. These social humans could also defend their prey and themselves from other carnivores.

Many small birds form flocks. To find out whether flocking provides protection against predators, an investigator released a trained goshawk near wood pigeons in England. The hawk was most successful in capturing a pigeon when it attacked solitary pigeons. Its success decreased as the number of pigeons in the flock increased (Figure 53.8). The larger the flock of pigeons, the sooner some individual in the flock spotted the hawk.

Living in a group typically imposes costs as well as benefits. Individuals in groups may compete for food, interfere with one another's foraging, injure one another's offspring, inhibit one another's reproduction, or transmit diseases to their associates.

The effects of group living on the survival and reproductive success of an individual also depend on its age, sex, size, and physical condition. Individuals may be larger or smaller than the average for their age and sex. Variation in skills, competitive abilities, and attractiveness to potential mates often associated with these size differences.

An almost universal cost associated with group living is higher exposure to diseases and parasites. Long before the causes of disease were known, people knew that association with sick persons increased their chances of getting sick. Quarantine has been used to combat the spread of illness for as long as we have written records. The diseases of wild animals are not well known, but most of those that have been studied are spread by close contact.

EXPERIMENT

Question: Does flocking confer antipredator benefits?

METHOD

f

Wood pigeon

Release hawks near pigeon flocks of different sizes.

RESULTS

Q Observe whether a hawk I captures a pigeon.

I The more pigeons in the flock, the sooner the hawk is spotted and the pigeons initiate evasive action.

1 2-10 11-50 >50

Number of pigeons in flock

I Thus the hawk's attack success is much lower

Conclusion: Flocking provides protection against predation.

53.8 Flocking Provides Defense against Predators

The larger a flock of pigeons, the greater the distance at which they detect an approaching hawk, and the less likely the hawk is to succeed in capturing a pigeon.

Categories of Social Acts

Individuals living together perform many behaviors that are not performed by solitary animals. These acts can be grouped into four categories according to their effects on the interacting individuals:

- ▶ An altruistic act benefits another individual at a cost to the performer. — \ ■*—
- ▶ A selfish act benefits the performer but inflicts a cost on some other individual. —W—
- ▶ A cooperative act benefits both the performer and the recipient. a, v
- ▶ A spiteful act inflicts costs on both the performer and the recipient. _ —

954 CHAPTER FIFTY-THREE

Act benefits the performer (+)

Act costs the performer

(-)

53.9 Types of Social Acts

Social acts can be divided into four categories, based on their effects on the performer and the recipient.

The types of social acts are summarized in Figure 53.9. The terms used are purely descriptive; they do not imply conscious

motivation or awareness on the part of the animal. If a genetic basis for a cooperative or selfish behavior exists, and if performing it increases the fitness of the performer, then the genes governing that behavior will increase in frequency in the lineage. In other words, cooperative or selfish behavior can evolve.

How can behavior that inflicts a cost on the performer evolve? Behavioral ecologists believe spiteful behavior is rare in nature. Altruistic behavior, however, can evolve—both among close relatives and among unrelated individuals.

Altruism can evolve by means of natural selection

Altruistic behaviors evolve most easily when performers and recipients are genetically related. Genetic relatedness is important because an individual can influence its fitness in two different ways. First, it may produce its own offspring, contributing to its individual fitness. Second, it may help its

relatives in ways that increase their fitness.

—'

"Because relatives are descended from a common ancestor, they are likely to be carrying some of the same alleles. Two offspring of the same parents, for example, are likely to share 50 percent of the same alleles; an individual is likely to share 25 percent of its alleles with its sibling's offspring. Therefore, by helping its relatives, an individual can increase the representation of some of its own alleles in the population. This process is called kin selection. Together, individual fitness and kinship determine the inclusive fitness of an individual. Occasional altruistic acts may

eventually evolve into altruistic behavior patterns if the benefits of increasing the reproductive success of relatives

53.70 White-Fronted Bee-Eaters Are Altruists

Relationship to nestlings

White-fronted bee-eaters are African birds that nest colonially (Figure 53.10). Most breeding pairs are assisted by nonbreeding adults that help incubate their eggs and feed nestlings. Nearly all of these helpers assist close relatives. When helpers have a choice of two nests at which to help, about 95 percent of the time they choose the nest with the young most closely related to them.

Several other pieces of evidence suggest that the helping behavior of white-fronted bee-eaters evolved through kin selection. First, both males and females help to care for nestlings, but males help more often than females. Males remain in the social group in which they were born, but females join other social groups when they mature. Therefore, females typically live in

social groups composed primarily of nonreproductive s.

Second, individuals do not appear to gain anything other than inclusive fitness by helping—helpers are not, for example, more successful when they become breeders themselves than birds that do not help. Finally, nests with helpers produce more fledglings than do nests without helpers, showing that helpers do increase the number of fledglings produced by their close relatives. Notice that all these patterns are consistent with the principle that bee-eaters behave in ways that improve their fitness, not in

ways that increase their reproductive success or relatives' reproductive success, ways that benefit the altruist's own reproductive success, ways that benefit the altruist's relatives' reproductive success.

Species whose social groups include sterile individuals

tive success.

Many social groups consist of some individuals that are

close relatives and others that are unrelated or distantly related. Individuals of some species recognize their relatives and adjust their behavior accordingly. White-fronted bee-

is said to be eusocial. This extreme form of social behavior—the "ultimate altruism"—has evolved in termites and

In these

ultimate altruism, many hymenopterans (ants, bees, and wasps), species, worker females defend the group against predators

*

or bring food to the colony, but do not reproduce. Some species have soldiers with large defensive weapons (Figure 53.11). These workers are at risk of being killed while defending the colony.

Both genetic and environmental factors facilitate the evolution of eusociality. The more closely related individuals are to one another, the greater the advantages they can receive by forgoing their own reproduction to help relatives reproduce. The British evolutionary biologist W. D. Hamilton first suggested that eusociality evolved among ants, bees, and wasps because members of the order Hymenoptera have an unusual sex determination system in which males are haploid but females are diploid.

Among the Hymenoptera, a fertilized egg hatches into a female; an unfertilized egg hatches into a male. If a female copulates with only one male, all the sperm she receives are identical because the haploid males have only one set of chromosomes, all of which are transmitted to each sperm cell. Therefore, a female's daughters share all of their father's genes. They also share, on average, half of the genes they receive from their mother. As a result, on average they share 75 percent of their alleles rather than 50 percent, as they would if both parents were diploid. Workers therefore can increase their fitness more by helping their sisters than by reproducing themselves, because they are genetically more similar to their sisters than they would be to their own offspring.

Mating between close relatives, known as inbreeding, can also generate close genetic relationships. Even if two mates are unrelated, but each is the product of generations of intense inbreeding, their offspring can be genetically nearly identical. These individuals would also benefit from helping to rear siblings. Genetic similarity generated by inbreeding could explain the evolution of eusociality among the many hymenopteran species in which queens mate with many males and among termites and naked mole-rats—the most extremely eusocial mammals—in which both sexes are diploid.

BEHAVIORAL ECOLOGY 955

Eusociality may also be favored if establishment of new colonies is difficult and dangerous. Nearly all eusocial animals construct elaborate nests or burrow systems within which their offspring are reared (Figure 53.12). Naked mole-rats live in underground colonies containing 70 to 80 individuals. The tunnel systems are maintained by sterile workers. Breeding is

restricted to a single queen and several kings that live in a nest chamber in the center of the colony. Individuals attempting to found new colonies are at high risk of being captured by predators, and most founding events fail. Thus, high predation rates, which favor cooperation among founding individuals, may facilitate the evolution of eusociality.

Unrelated individuals may behave altruistically toward one another

It is easy to understand how altruistic behavior can evolve among related individuals. It is more difficult to explain the existence of warnings of danger, sharing of food, and grooming among unrelated individuals of the same species, or even between members of different species. How can we explain the evolution of such behavior?

Such behavior among unrelated individuals could evolve through reciprocal altruism; that is, if helpers are in turn recipients of beneficial acts by the individuals they have helped. If there is a genetic basis for the acts, natural selection may increase the frequency of alleles governing this behavior. In order for reciprocal altruism to be a force, several social conditions must be present:

- ▶ Individuals in the group must know one another.
- ▶ They must associate for long periods.
- ▶ Individuals must be aware that their altruistic acts are

53.12 Termite Mounds are Large and Complex

Immense termite mounds such as this one in Kenya are costly to construct and maintain. Elaborate nests or burrows are characteristic of nearly all eusocial animals.

956 CHAPTER FIFTY-THREE

Reciprocal altruism is especially highly developed among rYuman[^], in which these conditions prevail. It illustrates the subtle adjustments in behavior among individuals in social groups.

The Evolution of Animal Societies

The decisions animals make about where to live, with whom to mate, and whether and how to care for their offspring all help determine the type of social system they have. Today's social systems are the result of long periods of evolution, but there are few records of past social systems because behavior leaves few traces in the fossil record. Possible routes of the evolution of social systems must therefore be inferred primarily from current patterns of social organization. Fortunately, many stages of social system complexity exist among species, and the simpler systems provide clues about the stages through which the more complex ones may have passed.

Parents of many species care for their offspring

The origins of all animal societies lie in the association of parents with their offspring. Individuals of many species invest time and energy in caring for offspring. Parental care increases the chances of an offspring's survival, but it usually reduces the ability of the parent to produce additional

offspring.

Parental care may also lower the chances of survival of the parent itself, because the parent could have used the time and energy to engage in other activities that would improve its own chances of survival. In other words, parents balance trade-offs between the success of their current offspring and their own future survival and reproduction.

Males and females often differ strikingly in the kinds and amounts of parental investment they can and do make. Birds, mammals, and fishes illustrate these differences and why they exist. Only female mammals have functional ^wrtfe mma.rv glancJs^nc^pSrannt p rodncp m ilk. Therefore parental care among mammals is usually given by females. On the other hand, among birds, all aspects of reproduction except production of eggs and sperm can be performed readily by both males and females. Not surprisingly, both males and females feed their offspring in about 90 percent of bird species.

Sex roles among fishes differ from those of birds and mammals because most fish species do not feed their young. Parental care consists primarily of guarding eggs and young from predators (Figure 53.13). In many fish species, males are the primary guardians. A male can guard a clutch of eggs while attracting additional females to lay eggs in his nest. A female, on the other hand, can produce another clutch of eggs sooner if she resumes foraging immediately after mating than if she spends time guarding her eggs.

The most widespread form of social system is the family, an association of one or more adults and their dependent offspring. If parental care lasts a long time, or if the breeding season is longer than the time it takes for offspring to

f

*Vn

Abudefduf saxatilis

53.13 A Sergeant Major Guards His Young

This male is defending the eggs a female has deposited. He can court other females while guarding the eggs.

mature, adults may still be caring for younger of fspring when older offspring reach the age at whic h they c ould help their parents.

"Many communal breeding systems, such as the white-fronted bee-eater families described above, most likely evolved via the extended family route. Most mammals evolved social behavior by this route. In simple mammalian social systems, solitary females or male-female pairs care for their young. In species whose young require a long period of parental care, o lder offsp ring are still prp spnt wjien the next generation is bo rru_ and they oft en help rear their younger siblings. In most social mammal species, female offspring re main in the group in which they w ere born, but males tend to _leav e—or are driven out—and must seek other soc i al grou ps. Therefore, among mammals, most helpers are females.

53.14 Savanna Weaverbirds Nest Colonially

Many African weaverbirds nest in colonies in isolated trees. Although these nests are highly conspicuous, it is difficult for most predators to get to them at the tips of the small, thorny branches.

(a) *Coiuwchaetes taurinus*

53. 15 Cooperation among Florida Scrub Jays

These Florida scrub jay helpers, most of which are offspring from the previous breeding season, are helping to feed nestlings and defend the nest against predators, such as the approaching snake. By doing so, they are improving their inclusive fitness.

The environment influences the evolution

of animal societies >-*~Q> *^

The type of s ocial organizati on a species evolves is strongly relate d to the environment in which it lives. Among the N weaverbirds of Africa, species that live i n fqr ests eat insects, J feed alone, and build well-hidden nests. Most of these

species are monogamous, and males and females look alike. In

marked contrast, weaverbirds that live in tree-studded grasslands called savannas eat primarily seeds, feed in large flocks, and nest in colonies, usually in isolated Acacia trees where their nests are large and conspicuous (Figure 53.14). In most colonial species, males have several mates and are more brightly colored than females.

These striking differences probably evolved because nesting sites and food in forests are common and widely dispersed. Solitary pairs can use these resources more efficiently than animals in groups can. In savannas, however, good nesting trees are scarce and highly clumped. Males compete for these limited nest sites; males that hold the best sites—near the tips of branches where they are safe from predators—attract the most females. Males spend their time attempting to attract additional mates rather than helping to rear the offspring they already have, which explains the evolution of brighter plumage among males.

Florida scrub jays live all year on territories, each of which is home to a breeding pair and up to six helpers

BEHAVIORAL ECOLOGY 957

(Figure 53.15). Nearly all the helpers are offspring from the previous breeding season that remain with their parents. This social system probably evolved because all suitable territories are occupied, and young individuals have little chance of establishing new territories on their own. By staying in their parents' territory and helping to raise their siblings, they both improve their inclusive fitness and have a chance of taking over the territory if one of their parents dies. Among the herbivorous hoofed mammals of Africa, social organization and feeding ecology are correlated with the diet of the animals. Smaller animals have higher metabolic demands per unit of body weight than do larger ones. Therefore, smaller hoofed mammals feed preferentially on high-protein foods such as buds, young leaves, and fruits. These foods are dispersed throughout forests, which also provide cover in which to hide from predators. Hiding is a tactic that is effective for solitary animals. In contrast, the largest hoofed mammal species are able to eat lower-quality food, but they must process great quantities of it each day. They feed in grasslands with abundant herbaceous vegetation, follow the rains to areas where grass growth is best, and live in large herds (Figure 53.16a).

Among primates, many diurnal species will eat insects and other animal food when they are available, but most of

53.16 Many Mammals of Open Country Live in Large Groups

(a) East African wildebeest live in large herds that follow the rains to places with fresh grass. (b) Baboons are conspicuous as they forage but are seldom attacked because the formidable males cooperate in defending the group.

958 CHAPTER FIFTY-THREE

them eat fruits, seeds, and leaves. In Africa and Asia, primate group sizes are smallest among arboreal forest-dwelling species, whatever their diets, and largest among the ground-dwelling savanna species, such as baboons (Figure 53.16b). Troops of foraging baboons are conspicuous to predators, but their large males help protect the other troop members. Baboons have a complex social system. In troops with more than one male, strong dominance hierarchies exist among the males, and one or two of them father most of the offspring. Females may also have dominance relationships, and young females often assume the status of their mothers when they mature.

Chapter Summary

- Ecologists study the nature and consequences of interactions among organisms and their environments.
- Behavioral ecology is the study of how animals decide where to carry out different activities, select the resources they need, respond to predators and competitors, and interact with conspecifics.

Balancing Costs and Benefits of Behaviors

- ▶ Cost-benefit analyses of behavior are based on the principle that animals have only limited amounts of time and energy to devote to their activities.
- ▶ A cost of defending a territory may be increased risk of mortality. Review Figure 53.1

Choosing Where to Live and Forage

- ▶ Selecting a habitat in which to live is one of the most important decisions an individual makes.
- ▶ The cues animals use to select habitats are good predictors of conditions suitable for future survival and reproduction.
- ▶ Foraging theory was developed to understand how animals select prey. Review Figure 53.2

Mating Tactics and Roles

- ▶ Individuals choose their associates, how to interact with them, and when to leave them. The most important choice of associates is the choice of a mate.
- ▶ Because males produce enough sperm to fertilize many eggs, males typically increase their reproductive success by mating with many females. The reproductive success of females is typically limited by the cost of producing eggs. As a result, males usually initiate courtship and often fight for opportunities to mate with females. Females seldom fight over males and often reject courting males.
- ▶ Sexual selection often leads to exaggerated traits. Review Figure 53.3
- ▶ While courting, males signal their desirability as mating partners and may perform behaviors that increase the probability that their sperm will fertilize eggs.
- ▶ Males of some species defend territories that contain food, nesting sites, or other resources. Review Figure 53.4
- ▶ By paying particular attention to those signals at which males cannot cheat, females have favored the evolution of "reliable" signals of mate quality.
- ▶ DNA fingerprinting methods have shown that social fathers often are not genetic fathers.

Costs and Benefits of Social Behavior

- ▶ Benefits of social living include better opportunities to capture prey and to avoid predators. Review Figure 53.8
- ▶ Costs of social living include competition for food, interference by conspecifics, and transmission of diseases.

Categories of Social Acts

- ▶ Acts performed by individuals living together can be grouped into four descriptive categories: altruistic, selfish, cooperative, and spiteful. Review Figure 53.9
- ▶ Altruism among closely related individuals can evolve by means of kin selection because individuals that help close relatives can improve their inclusive fitness. Review Figure 53.10
- ▶ Eusocial systems with sterile individuals have evolved among termites, hymenopterans (ants, bees, and wasps), and in a mammal, the naked mole-rat.

The Evolution of Animal Societies

- ▶ The origin of most animal societies is the family, an association of one or more adults and their dependent offspring.
- ▶ The type of social organization a species evolves is strongly related to the environment in which it lives.

For Discussion

1. Most hawks are solitary hunters. Swallows often hunt in groups. What are some plausible explanations for this difference? How could you test your ideas?
2. Because costs and benefits of behaviors can seldom be measured directly, behavioral ecologists often use indirect measures such as correlations between behavior patterns and the presence of predators. What are the strengths and weaknesses of some of these indirect measures?
3. Polyandry is a mating system in which one female has a "harem" of several males. Why is polyandry much rarer among both birds and mammals than polygyny, the situation in which one male forms pair bonds with several females?
4. When frogs mate, a male clasps a gravid female behind

her front legs and stays with her until she lays her eggs, at which time he fertilizes them. In most species of frogs, the male remains clasped to the female for a short time, usually no longer than a few hours. However, in some species, pairs may

remain together for up to several weeks. In view of the fact that a male cannot court or mate with any other female while clasping one, and that a female lays only a single clutch of eggs, why is it advantageous for males to behave this way? What can you guess about the breeding ecology of frogs that remain clasped for long periods? Why should females permit males to clasp them for so long? (Females do not struggle!)

5. Among vertebrates, helpers are individuals capable of reproducing, and most of them later breed on their own. Among eusocial insects, sterile castes have evolved repeatedly. What differences between vertebrates and insects might explain the failure of sterile castes to evolve in the former?

6. The use of DNA fingerprinting technology has shown that in many species, social partners and genetic partners differ. Under what conditions do individuals benefit from copulating with individuals other than their social mates? Do males and females benefit equally from this behavior?

Population Ecology

Large saguaro cacti are conspicuous features of the Sonoran Desert in southern Arizona. But finding a seedling cactus is difficult—at least, until you learn where to search. All the small cacti are found beneath trees or shrubs.

In the harsh environment of the Sonoran Desert, plants are exposed to intense daytime heat and wide temperature fluctuations. Their roots are in extremely dry soil much of the year. Small plants are most vulnerable to these conditions because they have small root systems, and daytime temperatures are extremely high at the soil surface. Therefore, although seeds of saguaro cacti are dispersed widely over the desert by birds, seedling cacti survive only in the shade of trees and shrubs, called nurse plants, where they are protected from the intense daytime heat. Thus, the density and distribution of saguaro cacti are strongly influenced by the number and location of trees and shrubs.

All the individuals of saguaro cacti—or of any other species—within a given area constitute a population. The sizes of populations continually change. To understand how and why these changes happen, population ecologists count individuals in different locations and try to determine the factors that influence birth, death, immigration, and emigration rates.

In addition to studying the dynamics of populations in a particular area, population ecologists also investigate changes over the entire ranges of species. They attempt to answer questions such as: What causes a species to be common or rare? Why is a species common in some parts of its geographic range and rare in others? What determines the limits of the ranges of species?

In this chapter we discuss how and why the sizes of populations vary over space and time, and show how this ecological knowledge is used to predict and manage the growth of populations. To set the stage for studies of populations, we present some background information on how the individuals of a population are distributed.

Population Structure: Patterns in Space and Time

At any given moment, an individual organism occupies only one spot and is of one particular age. The members of

A Cactus Needs Shade

This saguaro cactus (*Cereus giganteus*) grew in the shade of the palo verde tree, which protected it from the intense heat.

A population, however, are distributed over space and differ in age and size. These features are among the components of population structure. As we saw in Chapter 21, geneticists and evolutionary biologists also study population structure, but they are interested primarily in distributions of genotypes and their degree of isolation from one another, because that component of population structure influences how populations evolve.

Ecologists study population structure at different spatial scales, ranging from local subpopulations to entire species. They study the numbers and spatial distributions of individuals because these features influence the stability of populations and affect interactions among species.

Density is an important feature of populations

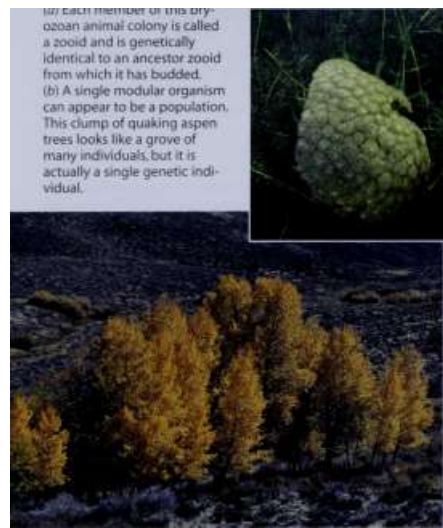

The number of individuals of a species per unit of area (or volume) is its population density. Ecologists are interested in population densities because dense populations often

(a) Each member of this bryozoan animal colony is called a zooid and is genetically identical to an ancestor zooid from which

it has budded.

(b) A single modular organism can appear to be a population. This clump of quaking aspen trees looks like a grove of many individuals, but it is actually a single genetic individual.

(a) *Pectinatella magnified*

(b) *Populus tremuloides*

exert strong influences on their own members as well as on populations of other species. Other scientists—such as those working in agriculture, conservation, or medicine— wish to manage species to raise (in the case of crop plants, aesthetically attractive species, or threatened or endangered species) or lower (in the case of agricultural pests and disease organisms) their densities . To manipulate population densities, we must know what factors make populations increase and decrease in size, and how those factors work.

Because species and their environments differ , population densities are measured in more than one way. Ecologists usually measure the densities of organisms in terrestrial environments by the number of individuals per unit of area, but number per unit of volume is generally a more useful measure for organisms living in water. For species whose members differ markedly in size, as do most plants and some animals (such as mollusks, figeivand reptiles), the total mass of individuals — the biomass—may be a more useful measure of density than the number of individuals.

The fertilized egg of many organisms develops into a zygote of construction called module, which produces addi-

tional modules much like itself. Many plants are modular, and there are many groups of modular protists, fungi, and animals (for example, sponges, corals, and bryozoans; Figure 54.1a). A modular organism may grow to a large size, and it is often difficult to distinguish a modular organism

from a cluster of genetically separate individuals (Figure 54.1b). The effects of modular organisms on their environment often depend primarily on the number and size of the modules. Therefore, ecologists studying modular organisms are often concerned primarily with the number, size, and shape of the modules rather than with the number of genetically distinct individuals.

Under some circumstances, the individuals in a population can be counted directly without missing any of them or counting any of them twice, but this process is usually impossible or too laborious. Ecologists commonly estimate population densities by sampling a population in a representative area and extending their findings to a larger area.

The size of a population can also be estimated by marking and recapturing individuals. For example, if we capture and mark 100 individuals in a population, we can take another sample later and count the individuals in that sample that are already marked. If, say, 10 percent of the individuals in our second sample are already marked, we would conclude that the population contains about 1,000 individuals.

This estimate is based on the mathematical assumption that the number of individuals caught the first time is the same proportion of the total population as the proportion

Spacing patterns reflect interactions among individuals

Ecologists studying population structure also look at the way in which the individuals in a population are spaced. Individuals in a population may be tightly clumped together, evenly spaced, or randomly scattered (Figure 54.2a). Distributions can become clumped when young individuals remain close to their birthplaces, when suitable habitat patches are "islands" separated by unsuitable areas, or by chance. The relatively even spacing of many plants is a result of competition for light, water, and soil nutrients (Figure 54.2b). Among animals, defense of space is the most common cause of even distributions (see Figure 53.4b). Random distributions may result when many factors interact to influence where individuals settle and survive. The saguaro cacti in the Sonoran Desert (discussed at the beginning of this chapter) are distributed randomly because that is how suitable environments are distributed.

54.3 Age Distributions Are Influenced by Timing of Births

A period when birth rates are high may be reflected in a population's age structure for many years, as in (a) humans in the

United States, (6) whitefish in Lake Erie, and (c) black cherry trees in a Wisconsin woods.

Age distributions reflect past events

Populations are composed of individuals ranging from newborns to postreproductive adults. In this chapter we consider an individual to be "born" when it leaves its mother's body as a seed, egg, or baby. The proportions of individuals in each age group in a population make up its age distribution. The density and spacing of individuals are spatial attributes of a population; age distribution is a temporal (time-oriented) attribute.

The timing and rates of births and deaths determine age

distributions. If both birth rates and death rates are high, a

population will be dominated by young individuals. If birth rates and death rates are low, a relatively even distribution of individuals of different ages results. The age distribution of a population thus reveals much about its past history of births and deaths.

The timing of births and deaths may influence age distributions for many years in populations of long-lived species. The human population of the United States is a good example. Between 1947 and 1964, the United States experienced what is called the post-World War II "baby boom." During these years, average family size grew from 2.5 to 3.8 children; an unprecedented 4.3 million babies were born in 1957. Birth rates declined during the 1960s, but Americans born during the baby boom will constitute the dominant age class into the twenty-first century (Figure 54.3a). "Baby boomers" became parents in the 1980s, producing another bulge in the age distribution—a baby boom

The timing of births and deaths may influence age distributions for many years in populations of long-lived species. The human population of the United States is a good example. Between 1947 and 1964, the United States experienced what is called the post-World War II "baby boom." During these years, average family size grew from 2.5 to 3.8 children; an unprecedented 4.3 million babies were born in 1957. Birth rates declined during the 1960s, but Americans born during the baby boom will constitute the dominant age class into the twenty-first century (Figure 54.3a). "Baby boomers" became parents in the 1980s, producing another bulge in the age distribution—a baby boom

962 CHAPTER FIFTY-FOUR

The number of individuals in a population at any given time is equal to the number present at some time in the past, plus the number born between then and now, minus the number that died, plus the number that immigrated, minus the number that emigrated. That is, the number of individuals at a given time, N_t is given by the equation

$$N_t = N_0 + B - D + I - E$$

Survivorship = the proportion of newborns who survive to age x .

Survival rate = the proportion of individuals of age x who survive to age $x + 1$.

Mortality rate = the proportion of individuals of age x who die before the age of $x + 1$.

"echo"—but they had, on average, fewer children than their parents, so the bulge is not as large. Similarly, in Lake Erie, 1944 was such an excellent year for reproduction and survival of whitefish that individuals of that age group dominated whitefish catches in the lake for several years (Figure 54.3b). The population of black cherry trees in a Wisconsin woods is dominated by individuals that began growth between 1923 and 1941 (Figure 54.3c).

Population Dynamics: Changes over Time

At any moment in time, a population has a particular structure determined by the number and distribution of its members in space and their ages. However, as we have just seen, population structure is not static. Changes in the structure of a population influence whether it will increase or decrease; that is, they affect the dynamics of a population. We will now examine how ecologists measure birth and death rates and use that information to understand how population densities change. The study of changes in the size and structure of populations is known as demography.

Births, deaths, and movements drive population dynamics

Knowledge of when individuals are born and when they die provides a surprising amount of information about a population. Births, deaths, and movements of individuals are demographic events—that is, they determine the numbers of individuals in a population. Ecologists measure the rates at which these events take place—the number of such events per unit of time. These rates are influenced by environmental factors, the life history traits of the species, and by population density.

where N_1 is the number of individuals at time 1; N_0 is the number of individuals at time 0; B is the number of individuals born, D the number that died, I the number that immigrated, and E the number that emigrated between time 0 and time 1. If we measure these rates over many time intervals, we can determine how a population's density changes.

Life tables summarize patterns of births and deaths

Life tables summarize data about births and deaths that

can be used to predict future growth rates of populations. We can construct a life table by determining for a group of individuals born at the same time—called a cohort—the number still alive at specific times and the number of offspring they produced during each time interval. An example, based on an intensive study of one population of Darwin's finches carried out on Isla Daphne in the Galapagos archipelago, is shown in Table 54.1.

The data in Table 54.1 are based on a cohort of 210 birds that hatched in 1978 and were followed until 1991, by which time all of them had died. This life table (which presents data only on survival, not on reproduction) shows that the mortality rate was

as high during the first year of life. It then dropped dramatically for several years, followed by a general increase in later years. Mortality rates fluctuated among years because survival of the birds depends on seed production, which is strongly correlated with rainfall. The Galapagos archipelago experiences both drought years, during which plants produce few seeds, birds do not nest, and adult survival is poor, and years of heavy rainfall, during which seed production is high, most birds breed several times, and adult survival is high. The life table reflects these fluctuations.

Ecologists often use graphs to highlight the most important changes in birth and death rates in populations. Graphs of survivorship—the mirror image of mortality—in relation to age show at what ages individuals survive well and at what ages they do not. To interpret survivorship data, ecologists have found it useful to compare real data with several hypothetical curves that illustrate a range of

possible survivorship patterns (Figure 54.4f). At one extreme, nearly all individuals survive for their entire potential life span and die at about the same age (hypothetical curve I). At the other extreme, the survivorship of young individuals is very low, but survivorship is high for most of the remainder of the life span (hypothetical curve III). An intermediate possibility is that survivorship is the same throughout the life span (hypothetical curve II).

Survivorship data from real populations often resemble one of these hypothetical curves. For example, survivorship of humans in the United States remains high for many decades but then declines significantly in older individuals (Figure 54.4g). Many wild birds have survivorship curves similar to hypothetical curve I; the probability of their surviving is about the same over most of the life span once they are a few months old (Figure 54.4c).

A widespread survivorship pattern is found among organisms that produce many offspring, each of which receives few energy resources and no parental care. In these species, low survivorship of young individuals is followed by high survivorship during the middle part of the life span, and then low survivorship toward the end of the life

span. *Spergula vernalis*, an annual plant that grows on sand dunes in Poland, illustrates this pattern (Figure 54.4d).

n

Patterns of Population Growth

If a single bacterium selected at random from the surface of this book, and all its descendants, were able to grow and reproduce in an unlimited environment, explosive population growth would result. In a month the bacterial colony would weigh more than the visible universe and would be expanding outward at the speed of light. Similarly, a single pair of Atlantic cod and their descendants, reproducing at the maximum rate of which they are capable, would fill the Atlantic Ocean in 6 years. But, as Darwin observed, this does not happen in nature.

All populations have the potential for explosive growth because as the number of individuals in the population increases, the number of new individuals added per unit of time accelerates, even if the rate per capita of population increase remains constant. This form of explosive increase is called exponential growth. If we ignore immigration and emigration and assume that births and deaths occur continuously and at constant rates, such a growth pattern forms a continuous curve (Figure 54.5a). This curve can be expressed mathematically in the following way:

(a) Hypothetical curves

I Most individuals may survive their potential lifespan, then die.

| Survivorship may be the same throughout the lifespan...

...or survivorship may be low for the young and remain high for the rest of the life span.

When there are no limits on population growth, r has its highest value, called r_{max} . The r_{max} has a characteristic value for each species. Therefore, the rate of growth of a population under optimal conditions is

$\frac{dN}{dt} = r_{max} N$

N

54.5 Exponential and Logistic Population Growth

(a) A theoretical exponential growth curve. (b) Growth curve of an actual population of willows at Newborough Warren, Wales. The trees experienced a surge of exponential growth when rabbits that fed on the leaves were decimated by disease, (c) a population in an environment with limited resources usually stops growing exponentially long before it reaches the environmental carrying capacity.

The simplest way to picture the limits imposed by the environment is to assume that it can support no more than a certain number of individuals of a particular species. This number, called the carrying capacity of the environment, is determined by the availability of resources—food, nest sites, shelter—as well as by disease, predators, and, in some cases, social interactions. Rather than being exponential, population growth slows down as the population approaches the carrying capacity, so that the growth curve has an S shape (Figure 54.5c).

The S-shaped growth pattern, which is characteristic of many populations growing in environments with limited resources, can be represented mathematically by adding to the equation for exponential growth a term $-\frac{N^2}{K}$, that

But optimal conditions do not continue indefinitely, and growth rates eventually slow down, as we explore in the following section.

Population growth is influenced by the carrying capacity

Natural populations may experience exponential growth for short periods of time under favorable conditions. For example, one population of willows in Wales increased dramatically in the 1970s after the rabbit population, which had severely nibbled the willows, crashed due to an outbreak of the disease myxomatosis (Figure 54.5b). But no real population can maintain exponential growth for very long because environmental limitations cause birth rates to drop

slows the population's growth as it approaches the carrying capacity (K). The simplest such equation is that for logistic growth:

$\frac{dN}{dt} = r_{max} N \left(\frac{K-N}{K} \right)$

$K-N$

K

N

The biological assumption in this equation is that each individual added to the population makes things slightly worse for the others because it competes with them for available resources. Population growth stops when $N = K$ because then $(K-N) = 0$ so $(K-N)/K = 0$, and thus $dN/dt = 0$.

and decreases to rise. In fact, over long time periods, the sizes of most populations fluctuate around a relatively constant number.

The logistic growth equation contains some important simplifications that are not true for most populations. Its most critical assumptions are that (1) each individual exerts equal effects immediately at birth; (2) all individuals produce equal effects on the population; and (3) births and deaths are independent of age. However, in nature, organisms grow during their lives, and their effects on others normally increase with age, so there may be a delay between the birth of an

individual

This population became extinct in 1976, but the site was recolonized in 1988.

This site was colonized in 1986.

The Morgan Hill population is probably the source of individuals for periodic colonization of other sites.

Bay checkerspot butterfly

H¹

^

has been studied for many years by Stanford University biologists. During drought years, most host plants die early in spring before the butterfly larvae have pupated. At least three butterfly subpopulations became extinct during a severe drought in 1975-1977. The largest patch of suitable habitat, Morgan Hill, typically supported thousands of butterflies (Figure 54.6). It probably served as a source of individuals that dispersed to and colonized small habitat patches where the butterflies had become extinct.

Population Regulation $UL^c / ^{-}$

In a limited environment, population growth slows down as density increases because the members increasingly affect one another adversely. As a result, a population above the environmental carrying capacity is likely to decrease in density, and one that is below the carrying capacity is likely

to increase. In this section we discuss how populations may

be influenced by interactions between their density and the

54.6 Subpopulation Dynamics . . . J

editha bayensis is divided into a number of subpopulations con-

finned to habitat patches that contain the plants its larvae feed on. How does population density influence birth and

death rates?

individual and the time at which it begins to affect the other members of its population. A seedling tree, for example, exerts a much smaller effect on its neighbors than a large adult tree does, and it does not begin to reproduce until it reaches a relatively large size.

In addition, the logistic equation models a population in a single habitat patch; it does not take immigration and emigration into account. Next we consider the dynamics of an assembly of local populations, which is more complex than the growth of a single population.

Many species are divided into discrete subpopulations

Many populations are divided into discrete subpopulations among which some exchange of individuals occurs. Such a pattern is often found where suitable habitat occurs in separated patches, or "habitat islands." Each subpopulation has a probability of "birth" (immigration) and "death" (extinction). Within each subpopulation, growth occurs in the ways we

have just discussed, but because subpopulations are typically much smaller than the population as a whole, local disturbances and random fluctuations in numbers of individuals often cause the extinction of a subpopulation. However, if individuals frequently move between subpopulations, immigrants may prevent declining subpopulations from becoming extinct. This process is known as the rescue effect.

The bay checkerspot butterfly provides a good illustration of the dynamics of such divided populations. The larvae of this butterfly feed on only a few species of annual plants that are restricted to outcrops of a particular kind of rock on hills south of San Francisco. The bay checkerspot

If per capita birth or death rates change in response to population density, they are said to be density-dependent. Death and birth rates may be density-dependent for several reasons:

- As a population increases in abundance, it may deplete its food supply, reducing the amount of food that each individual gets. Poor nutrition may increase death rates and decrease birth rates.
- Predators may be attracted to regions where densities of their prey have increased. If predators are able to capture a larger proportion of the prey than they did when prey were scarce, the per capita rate of predation of the prey rises.
- Diseases, which may increase death rates, spread more easily in dense populations than in sparse populations.

A population whose dynamics are influenced primarily by density-dependent factors is said to be regulated.

Factors that change per capita birth and death rates in a population in dependence of its density are said to be density-dependent. A very cold spell in winter, for example, may kill a large proportion of the individuals in a population regardless of its density. However, even environmental factors whose frequency and severity are unrelated to population density may result indirectly in density-dependent mortality. Cold weather may not kill organisms directly, but may increase the amount of food individuals need to eat each day. Individuals pushed by population density into poorer foraging areas may be more likely to die than those in better foraging areas. Or the death rate may be related to the quality of sleeping places. If population density is high, a larger proportion of individuals may be forced to sleep in places that expose them to the cold.

Various combinations of density-dependent and density-independent factors can influence the density of a popula-

966 CHAPTER FIFTY-FOUR

Equilibrium is reached when birth rates and death rates are equal.

If birth rate or death rate, or both, are density-dependent, a population's size tends to fluctuate around an equilibrium value.

54.7 Density-Dependent Factors Regulate Population Size

The densities of all populations fluctuate, but they tend to return to equilibrium value if either birth rate and/or death rate are density-dependent.

tion. The hypothetical graphs in Figure 54.7 show how birth and death rates can change in relation to population density. When birth and death rates are equal (the point at which the two lines cross) the population neither grows nor shrinks. If

birth or death rates, or both, are density-dependent, the population responds to increases or decreases in its

population by increasing or decreasing its birth or death rates. If neither rate is density-dependent, there is no equilibrium and the population is not regulated.

Fluctuations in the density of a species' population are determined by all the factors and processes, density-dependent and density-independent, acting upon it. The combined action of density-independent and density-dependent factors is illustrated by the dynamics of a population of song sparrows on Mandarte Island, off the coast of British Columbia, Canada.

During recent years, in response to variable winter weather and other physical factors, the number of song sparrows on Mandarte has fluctuated between 4 and 72 breeding females and between 9 and 100 breeding males. Density-independent variation caused by weather is modulated by several density-dependent factors. The number of breeding males is limited by territorial behavior: The larger the number of males, the larger the number that fail to gain territories, so more live as "floaters" (Figure 54.8a). Also, the larger the number of breeding females, the fewer offspring each female fledges (Figure 54.8b). And, finally, the more offspring are fledged, the more poorly they survive over the winter (Figure 54.8c).

Disturbances affect population densities

Disturbances—short-term events that influence populations by changing their environment and, hence, its carrying capacity—regularly affect population densities. Common physical disturbances are fires, hurricanes, ice storms,

wind storms, floods, landslides, and lava flows. Biological disturbances include tree falls, disease epidemics, and the burrowing and trampling activities of animals. Disturbances differ in their spatial distribution, frequency, predictability, and severity.

A disturbance typically decreases the environmental carrying capacity for some populations but for others. A landslide, for example, may increase the carrying capacity of the environment for plants that require bare mineral soil for the germination of their seeds and survival of their seedlings. However, it will decrease the carrying capacity for species that require shade and rich organic litter for successful germination.

Populations themselves can influence the frequency of some disturbances. Immediately after a fire, for example, there is not enough combustible organic matter to carry another fire. However, as vegetation grows back, dead wood, branches, and leaves accumulate, gradually increasing the supply of fuel. Thus the frequency of fires may be proportional to the rate at which fuel accumulates through the growth of plant populations, or the rate at which herbivores consume plant materials that would otherwise accumulate. Similarly, as many trees age, their roots and trunks become weakened by fungal infections. Old, large trees are thus susceptible to being toppled by high winds. Therefore, the likelihood of a major blowdown increases as the forest ages.

Organisms cope with environmental changes by dispersing

A common response of animals to environmental changes is dispersal—movement to another habitat. If habitat quality declines greatly, individuals may be able to improve their survival and reproductive success by going elsewhere. If repeated seasonal changes alter a habitat, organisms may evolve life cycles that appear to anticipate the changes. Migration—regular seasonal movement from one place to another—is most widespread among birds, but some insects, such as monarch butterflies, and some mammals also

54.8 Regulation of an Island Population of Song Sparrows

The number of song sparrows on Mandarte Island is mainly determined by the severity of winter weather, but the weather's effect is modulated by several density-dependent factors, including (a) male territorial behavior, (b) the reproductive success of females, and (c) the survival of juveniles.

migrate (Figure 54.9). Most insectivorous birds leave high latitudes for more favorable wintering grounds in autumn, before conditions seriously deteriorate. In arctic regions, caribou migrate each year between winter and summer ranges.

its life, an individual organism ingests nutrients or food, grows, interacts with other individuals of the same and other species, reproduces, and usually moves or is moved so that it does not die exactly where it was born. Life histories describe how an organism divides its efforts among these activities. In previous discussions we have referred to various components of the life histories of organisms. Now we focus our attention specifically on life history patterns and why they have evolved to be as

variable as they are.

The life history traits of organisms have been molded by natural selection acting over many generations. In each lineage, those traits that maximized reproductive success were selected. Over time, natural selection has not produced a single,

Life Histories Influence Population Growth

reproductive pattern of reproduction. Some organisms such

968 CHAPTER FIFTY-FOUR

sands or millions of eggs or seeds in one bout of reproduction. Some organisms begin to reproduce within days or weeks of being born; others live for many years before reproducing. All life histories are based on a certain set of traits, which includes:

- Size and energy supply of the individual at birth
- Its rate and pattern of growth and development
- How many times individuals disperse
- The number and timing of reproductive events
- The number, size, and sex ratio of offspring
- The ages at which individuals die

Life histories include stages for growth, change in form, and dispersal

For at least part of their lives, all organisms grow by gathering and assimilating energy and nutrients. Some organisms, such as birds and mammals, gather energy and nutrients throughout their lives, even after they reach adult size and stop growing.

Energy gathered after growth stops maintains the organism and supports reproduction. In many species, however, energy gathering is confined to a particular life stage. Most moths, for example, feed only when they are larvae. The adults lack mouthparts and digestive tracts, live on the energy they gathered as larvae, and survive only long enough to disperse, mate, and lay eggs (Figure 54.10).

Individuals of many species also change form during their lives. Human babies are unmistakably human, but newborns of many species differ dramatically from adults. Some of the most striking changes are found among insects such as beetles, flies, moths, butterflies, and bees, which undergo metamorphosis from their larval to their adult forms. Many plants have resting stages, such as spores and seeds, that have low metabolic rates and are highly resistant to changes in the physical environment. Growth typically does not take place in these stages.

At some time in their lives, all organisms disperse. Some, such as plants and sessile animals, disperse as eggs, larvae, spores, or seeds. Others, such as insects and birds, disperse primarily as adults. Still others may disperse during several different life stages. Individuals of some species can change their location many times during their lives in response to environmental changes. Others remain in the first place they settle.

human dispersal by

Life histories embody trade-offs

Life history evolution is influenced by inevitable trade-offs. These trade-offs exist because changes that improve fitness by means of one life history trait often reduce fitness by means of another. What are the major tradeoffs in life history traits? One universal trade-off exists between number and size of offspring. Every newborn individual begins to grow with energy and nutrients from its maternal parent, but how much energy and nutrients individuals receive from their mothers varies greatly. The larger the amount of energy

TS>

Polyphemus sp.

54.10 A Life Stage for Sex and Reproduction Only

This female moth has no mouth or digestive tract. She will live only a few days, just long enough to mate and lay her eggs. Provided to each offspring, the larger it can grow before it must gather its own energy, but the fewer offspring a mother can produce for a given amount of energy is a major trade-off. For animals, a trade-off also exists between the number of offspring produced and the amount of care parents provide to their offspring. The more parental care the parents provide, the fewer offspring they can produce for a given investment in reproduction. Birds and mammals produce few offspring at a time and provide extensive care for each one.

Some organisms invest so much in one reproductive effort that they have no energy left for another—or even for their own survival. If two individuals have the same amount of energy to invest in reproduction, and one reproduces only once while the other reproduces several times, the former can produce more offspring in a single episode than the latter because it reserves no energy for itself. Annual plants invest nearly all of the energy they gain during their single growing season in seed production; they do not survive long after reproducing. Some short-lived organisms also reproduce once in their lifetimes and die soon afterward. Pacific salmon (genus *Oncorhynchus*) hatch in fresh water, migrate to the sea, spend a number of years at sea, return to fresh water, spawn, and die (Figure 54.11f). Most agaves (century plants) of the American Southwest likewise store up energy for many years before producing a large flowering stalk, forming many seeds, and dying (Figure 54.11b).

Trade-offs also exist between reproduction and growth. Members of many species do not begin to reproduce until they have reached full size, but others, such as most plants, mollusks, fishes, and reptiles, can reproduce while they are still relatively small and continue to reproduce as they grow. Proportionally, usually reduces growth rate because these two processes compete for the limited amount of energy an individual has at its disposal. Beech trees in Germany, for example, grew more slowly during years when they pro-

duced large crops of nuts than they did during years when their nut crops were small (Figure 54.12).

Nonreproductive form of Agave

(b) Agave sp.

Offspring are like "money in the bank"

If reproduction compromises future growth and survival, why do some organisms start to reproduce when they are small or young? The potential contribution of an individual's offspring to future generations depends, in part, on when they are produced. A useful analogy compares the production of offspring to earning interest on money deposited in a bank. It pays to deposit money in the bank as

interest. Off-

newborn individual does not have the highest reproductive value, even though it has its full reproductive potential ahead of it, because many newborn individuals will die before they have a chance to reproduce. Therefore we must discount the number of offspring an individual could produce if it survived by the chance that it will die before reaching reproductive age, or during reproduction. When we make the appropriate calculations, we find that the reproductive value of an individual steadily increases until it begins to reproduce. Once maturity is reached, reproductive value declines; in most species, it reaches zero when the individual has finished reproducing. However, individuals can still have positive reproductive value after they have stopped reproducing that remain to be born to individuals of a particular age. An individual can continue to assist the survival of their offspring and $\frac{J}{A} < \frac{J}{A} < \frac{J}{A}$ grandoffspring.

managing populations of organisms are based on our understanding of how populations grow and are regulated.

A general principle of population dynamics is that the total number of births and the growth rates of individuals tend to be highest when a population is well below its carrying capacity. Therefore, if we want to maximize the number of individuals of a species that we wish to harvest, we should manage the population so that it is far enough below carrying capacity to have high birth and growth rates. Today most people die of diseases of old age because improved sanitation and public water supplies, as well as medical advances such as immunization, have greatly reduced the incidence of contagious diseases that formerly killed many young people.

their phenotypic effects at that age—even those that are to the individual's survival. As a result,

highly detrimental

harmful alleles are expressed as individuals age, causing increased mortality rates, especially after reproduction has ceased. In this manner, senescence—an increased probability of dying per unit of time with increasing age—has evolved

As a result of improved hygiene and nutrition, most people in modern industrial societies are now spared the contagious diseases that cause death rates to be high among people of all ages in nonindustrial societies. Most people live to the age when the so-called genetic diseases of old age begin to afflict them. Cancer and heart disease, the main killers in industrialized societies, are much more difficult to cure than the contagious diseases that formerly caused most deaths. For this reason, despite the expenditure of enormous resources to extend life, the average age of death in the United States has changed very little during the past 100 years. As one source of mortality is eliminated, another takes its place (Figure 54.13). Life history theory suggests that this situation is likely to continue indefinitely.

Can Humans Manage Populations?

For many centuries, people have tried to reduce populations of species they consider undesirable and increase populations of desirable species. Strategies for controlling and

birds and mammals are established with this objective in mind.

...to the diseases. Life history traits determine how heavily of old age, a population can be exploited

Populations with high reproductive capacities can sustain their growth despite a high rate of harvest. In such populations (many species of fish, for example), each female may lay thousands or millions of eggs. Another characteristic of these fast-reproducing populations is that individual growth is often density-dependent. If prereproductive individuals are harvested at a high rate, the remaining individuals may grow faster. Many fish populations can be harvested heavily for many years because only a modest number of females must survive to reproductive age to produce the eggs needed to maintain the population.

Fish can, of course, be overharvested. Many populations have been greatly reduced because so many individuals were harvested that too few reproductive adults survived to maintain the population. The Georges Bank off the coast of New England—a source of cod, halibut, and other prime food fishes—has been exploited so heavily that many fish stocks have been reduced to levels insufficient to support a commercial fishery.

The whaling industry has also engaged in excessive harvests. The blue whale, Earth's largest animal, was hunted nearly to extinction by the middle of the twentieth century. The industry then turned to smaller species of whales that were still numerous enough to support commercially viable whaling operations (Figure 54.14).

Management of whale populations is difficult for two reasons. First, unlike fish, whales reproduce at very low rates. They have long prereproductive periods, produce only one offspring at a time, and have long intervals between births. Thus many whales are needed to produce even a small number of offspring. Second, because whales are distributed widely throughout Earth's oceans, they are an international resource whose conservation and wise management depends upon cooperative action by all whaling nations. This continues to be difficult to achieve.

Life history information is used to control populations

The same principles apply if we wish to reduce the size of populations of undesirable species and keep them at low

54.14 Overexploitation of Whales

The graphs show the numbers of whales of four species killed each year from 1950 to 1985. As each species reached low population levels, the whaling industry turned to other species. All four species were driven to very low levels by sustained hunting.

Similarly, if we wish to preserve a rare species, the most important step usually is to provide it with sufficient habitat. If habitat is available, the species will usually reproduce at rates sufficient to maintain its population. If the habitat is insufficient, preserving the species usually requires expensive and continuing intervention, such as providing extra food.

Humans have introduced many species to new habitats outside their native ranges. When these introduced species undergo population explosions, humans attempt to reduce their numbers by introducing new predators and parasites from the introduced species' original habitat. For example, the cactus *Opuntia*, introduced into Australia from

Progressively smaller whales were exploited more as populations of larger species decreased.

1950 1955 1960

1965 1970 Year

1975 1980 1985

South America, spread rapidly and became a common pest species over vast expanses of valuable sheep-grazing land. The cactus population was controlled by introducing a moth species (*Cactoblastis cactorum*) whose larvae feed on *Opuntia*. Once egg-laying females find a patch of cactus, their larvae completely destroy the patch (Figure 54.15).

But new patches of cactus arise in other places from seeds dispersed by birds. These new patches flourish until they are found and destroyed by *Cactoblastis*. Over a large region, the numbers of both *Opuntia* and *Cactoblastis* are today fairly constant and low, but in the local areas that make up the whole, there are periodic oscillations resulting

1950 1955 1960 1965 1970 1975 1980 1985

densities. At densities well below carrying capacity, populations have high birth rates and can therefore withstand higher death rates than they could closer to carrying capacity. Killing part of a population whose dynamics are influenced primarily by density-dependent factors only reduces it to the density at which it experiences the most rapid rate of growth. A far more effective approach to reducing the population of a species is to remove its resources, thereby lowering the carrying capacity of its environment. We can rid our dumps and cities of rats more easily by making garbage unavailable (reducing the carrying capacity of the rats' environment) than by poisoning rats.

54.15 Biological Control of an Introduced Pest

Cactoblastis caterpillars consume an Opuntia cactus in Australia.

?'

from the extermination of first the plant and then the herbivore. This is another example of a series of subpopulations connected by occasional dispersing individuals.

Can we manage our own population?

Managing our own population has become a matter of great concern. For thousands of years, Earth's carrying capacity for human populations was set at a low level by food and water supplies and disease. Domestication of plants and animals and cultivation of the land enabled our ancestors to increase the resources at their disposal dramatically. These developments stimulated rapid population growth up to the next carrying capacity limit, which was determined by the agricultural productivity possible with only human- and animal-powered tools. Agricultural technology and artificial fertilizers, made possible by the tapping of fossil fuels, greatly increased agricultural production, further raising Earth's carrying capacity for humans. The development of modern medicine reduced the effectiveness of disease as a limiting factor on human populations, raising the global carrying capacity still further (Figure 54.16). Medicine and better hygiene have allowed people to live in large numbers in areas where diseases formerly kept numbers very low.

What is Earth's present carrying capacity for people? Today's carrying capacity is set by Earth's ability to absorb the by-products—especially CO₂,—of our enormous consumption of fossil fuel energy and by whether we are willing to cause the extinction of millions of other species to accommodate our increasing use of environmental resources. We will explore some of the consequences of high human population densities for the survival of other species in Chapter 58.

Chapter Summary

Population Structure: Patterns in Space and Time

- ▶ A population consists of all the individuals of a species within a given area.
- ▶ The number of individuals of a species per unit of area (or volume) is its population density.
- ▶ Individuals in a population may have uniform, random, or clumped distributions. Review Figure 54.2
- ▶ The age distribution of individuals in a population reveals much about the recent history of births and deaths in the population. The timing of births and deaths may influence age distributions for many years. Review Figure 54.3

Population Dynamics: Changes over Time

- ▶ Births, deaths, immigration, and emigration drive changes in population density and distribution.

- Life tables help us visualize patterns of births and deaths in a population. Review Table 54.1
- Graphs of survivorship in relation to age show when individuals survive well and when they do not. Review Figure 54.4

Patterns of Population Growth

- All populations have the potential to grow exponentially. However, no population can maintain exponential growth for very long because environmental limitations cause birth rates to drop and death rates to rise.
- The number of individuals of a particular species that an environment can support—called the carrying capacity—is determined by the availability of resources and by disease and predators.
- A population in a limited environment at first grows rapidly, but growth rates decrease as the carrying capacity is approached. Review Figure 54.5
- The overall densities of many populations are determined by "births" (colonizations) and "deaths" (extinctions) of local subpopulations. Immigrants may prevent declining subpopulations from becoming extinct, a process known as the rescue effect. Review Figure 54.6

Population Regulation

- Regulation of a population by changes in per capita birth or death rates in response to density is said to be density-dependent.
- If per capita birth and death rates are unrelated to a population's density, the population is not regulated.
- The density of a population is determined by the combined effects of all density-dependent and density-independent factors affecting it. Review Figures 54.7, 54.8

Life Histories Influence Population Growth

- The life history of a species describes how it divides its efforts among growth, dispersal, and reproduction over time.
- Trade-offs inevitably exist between number and size of offspring, between number of offspring and parental care, between survival and reproduction, and between growth and reproduction. Review Figure 54.12
- Reproductive value is the average number of offspring that remain to be born to individuals of a particular age. Reproductive value rises to a peak when individuals first begin to reproduce and declines to zero after reproduction ceases.
- Senescence—an increased probability of dying with increasing age—evolves because natural selection cannot act on alleles that first produce their phenotypic effects after a reproductive value drops to zero. Review Figure 54.13

Can Humans Manage Populations?

- Humans use the principles of population dynamics to control and manage populations of species they consider desirable or undesirable. Nevertheless, many populations have been overexploited. Review Figure 54.14
- Earth's carrying capacity for humans has been increased several times by technological developments. Review Figure 54.16

For Discussion

1. Huntington's disease is a severe disorder of the human nervous system that generally results in death. It is caused by a dominant allele that does not usually express itself phenotypically until its bearer is 35 to 40 years old. How fast is the gene causing Huntington's disease likely to be eliminated from the human population? Would your answer change if the gene expressed itself when its bearer was 20 years old? 10 years old?
2. Many people have improperly formed wisdom teeth and must spend considerable sums of money to have them removed. Assuming, as is probably the case, that the presence or absence of wisdom teeth and their mode of development are partly under genetic control, will we gradually lose our wisdom teeth by evolutionary processes?
3. Some organisms, such as oysters, cod, and elm trees, produce vast quantities of offspring, nearly all of which die before they reach adulthood. What fraction of such deaths are likely to be selective—that is, dependent on the genotypes of the individuals dying? What does your answer imply for the rates of evolution of oysters, cod, and elms?
4. In this chapter we identified a number of trade-offs in life history evolution. Why are these trade-offs inevitable? Why is knowledge about trade-offs important when we attempt to manipulate the life histories of organisms?
5. Ecologists often use the concept of carrying capacity when studying the growth and regulation of populations in nature, even though carrying capacity often changes markedly over time. How can the concept be useful if its value changes so often?
6. Most organisms whose populations we wish to manage for higher densities are long-lived and have low reproductive rates, whereas most organisms whose populations we attempt to reduce are short-lived but have high reproductive rates. What is the significance of this difference for management strategies and the effectiveness of management practices?

7. In the mid-nineteenth century, the human population of Ireland was largely dependent upon a single food crop, the potato. When a disease caused the potato crop to fail, the Irish population declined drastically for three reasons: (1) a large percentage of the population emigrated to the United States and other countries; (2) the average age of a woman at marriage increased from about 20 to about 30 years; and (3) many families starved to death rather than accept food from Britain. None of these social changes was planned at the national level, yet all contributed to adjusting population size to the new carrying capacity. Discuss the ecological strategies involved, using examples from other species. What would you have done had you been in charge of the national population policy for Ireland?

8. From a purely ecological standpoint, can the problem of world hunger ever be overcome by improved agriculture alone? What components must a hunger-control policy include?

Community Ecology

*4

Some people like their food spicy hot; others don't. The spices that impart strong flavors to foods are actually antioxidant, antimicrobial[^] and antiviral chemicals. These chemicals evolved because they protected the plants that produced them from predators and diseases. When we add spices during cooking, we borrow the plants' survival "recipes" and use them to protect our own food. The protection that spices provide was especially important before refrigeration and freezing were widely available, but even today, spices help prevent contamination of foods in most parts of the world.

Organisms interact with one another in a variety of ways. Some of these interactions involve eating and being eaten, but organisms may also interact competitively, or they may benefit one another. All organisms are potentially or actually food for some other organism, and most of them have evolved defenses that make them more difficult to find and capture, or less palatable or nutritious if they are captured. Consumers of those organisms have, in turn, evolved ways of getting around the defenses of their prey.

The organisms that live together in a particular area constitute a natural community. Each species interacts in unique ways with other species in its community and with its physical environment. Some of these interactions are strong and important; others are weak and affect the functioning of the community very little. The study of such interactions, and how they determine which and how many species live in a place, is the focus of community ecology.

For several decades, ecologists debated whether which species live together in communities is determined primarily by the interactions of individuals with the physical environment or by their interactions with other organisms. Some ecologists even suggested that a community is a superorganism in which each species plays a particular role, just as each organ plays a role within the body of an individual organism. That view has been abandoned because organisms, unlike organs, do not evolve under

Some Like It Hot

The peppers on the right of this photo are the seeds of a tropical vine, *Piper nigrum*. The hot chiles (upper left) are the fruits of an unrelated pepper plant, *Capsicum annuum*. The chemicals in peppers and other "hot" spices are often antimicrobial agents.

the influence of natural selection to serve their community. Nevertheless, determining the roles of species interactions with the biotic and abiotic environment is a major challenge for community ecologists today.

In this chapter we do consider interactions between organisms and their physical environment, but we concentrate on the major biological interactions and show how they influence the structure and functioning of ecological communities.

Types of Ecological Interactions

Organisms interact with one another in five major ways:

► Two organisms may mutually harm one another. This type of interaction is common when two organisms use the same resources and those resources are insufficient to supply their combined needs[^]. Such organisms are called competitors and their interactions constitute

competition ;

► One organism, by its activities, may benefit itself while harming another, as when individuals of one species eat individuals of another. The eater is called a predator or parasite, and the eaten is its prey or host. These interactions are known as predator-prey or parasite-host interactions.,

COMMUNITY ECOLOGY 975

\
C

- If both participants benefit from an interaction, we call them mutualists, and their interaction is a mutualism.
- If one participant benefits but the other is unaffected, the interaction is a commensalism.
- If one participant is harmed but the other is unaffected, the interaction is an amensalism.

These categories of species interactions are summarized in Table 55.1. But they are not clear-cut, both because the strengths of interactions vary and because many cases do not fit the categories neatly. Nevertheless, most interactions fit these categories well enough for us to use them as a guide for exploring interactions among species in this chapter.

Resources and Consumers

Many interactions between organisms within communities center on resources and their consumers. A resource is anything directly used by an organism that can potentially lead to the growth of the population and whose availability is

reduced when it is used. We usually think first of resources that can be consumed by being eaten, but space—including hiding places, nest sites, and establishment sites for sessile organisms—becomes unavailable if it is occupied, so it, too, is a resource. Factors such as temperature, humidity, salinity, and pH, even though they may strongly affect population size, are not resources because they can be neither consumed nor monopolized.

Some resources, such as nest sites, are not altered by being used and immediately become available for occupancy again when the user leaves. Other resources must regenerate before they are again available to consumers.

Biotic interactions influence the conditions under which species can persist

Each species can persist only under a certain set of environmental conditions, which define its ecological niche. If there were no competitors, predators, or disease organisms, in its environment, a species would be able to persist in a broader array of physical conditions (its fundamental niche) than it can in the presence of other species that negatively affect it (its realized niche). On the other hand, the presence of beneficial species may increase the range of physical conditions in which a species can persist.

An experiment performed on two species of barnacles, *Balanus balanoides* and *Chthamalus stellatus*, demonstrated the importance of both abiotic and biotic factors in determining the fundamental and realized niches of these two species. These barnacles live between high tide and low tide levels on rocky North Atlantic shores. Adult *Chthamalus* generally live higher in the intertidal zone than do adult *Balanus*, but young *Chthamalus* settle in large numbers in the *Balanus* zone.

In the absence of *Balanus*, young *Chthamalus* survive and grow well in the *Balanus* zone, but if *Balanus* are present,

they grow more poorly and die more rapidly than when they are alone.

Young *Balanus* settle in the *Chthamalus* zone, but they grow poorly because they lose water rapidly when exposed to air. *Chthamalus* compete successfully with them there, but *Balanus* would persist slightly higher in the intertidal zone in the absence of *Chthamalus*. By experimentally removing one or the other species, researchers have shown that the vertical ranges of adults of both species are greater in the absence of the other species. The result of their interaction is intertidal zonation, with *Chthamalus* growing above *Balanus* (Figure 55.1).

Limiting resources determine the outcomes of interactions

Resources whose supply is less than the demand made upon them by organisms are called limiting resources. Resources that are not limiting may have little influence on a species' population dynamics. For example, most terrestrial animals have strict but similar requirements for a certain minimum level of oxygen. However, studying the use of oxygen reveals very little about the structure of terrestrial communities because the concentration of oxygen, which is about 21 percent of the atmosphere, is nearly always above that minimum level.

The limiting resources that influence distributions and abundances of terrestrial species are those that are de-pletable and regenerate slowly, such as food. In freshwater aquatic environments, however, where the maximum concentration of dissolved oxygen is only 0.5 percent, organisms regularly deplete oxygen. Aquatic ecologists, unlike terrestrial ecologists, pay careful attention to oxygen levels.

Which resources are limiting differs among environments, but some kinds of resources, such as food supplies,

55.1 Potential and Actual Distributions of Two Barnacle Species

Integrating the relative importance of each resource makes the zone each species occupies smaller than the zone it could potentially occupy in the absence of the other species. The width of the red and gold bars is proportional to the density of the populations.

are often limiting. Because of the importance of resources in the lives of all species, we first examine competition that takes place among organisms needing scarce resources, and then consider predation.

Competition: Seeking and Using Scarce Resources

If two or more individuals use the same resources, and those resources are insufficient to meet their demands, the individuals are competitors, whether they are members of the same or a different species. Intraspecific competition — competition among individuals of the same species — may result in reduced growth and reproductive rates for some individuals, may exclude some individuals from better habitats, and may cause the deaths of others. Interspecific competition — competition among individuals of different species — affects individuals in the same way, but in addition, it can exclude one species; many are kept out of habitats where it can compete successfully, a phenomenon called competitive exclusion. In extreme cases, a competitor may cause the extinction of another species. In this section we will show how ecologists study competition and discuss how it influences species distributions and the composition of ecological communities.

Plants are good subjects for experiments to test the nature and results of competitive interactions because they compete for light, water, and nutrients, all of which can easily be manipulated. For example, the relative importance of root and shoot competition can be assessed by growing plants in shared or separate pots so that either the shoots or roots, or both, compete for resources: nutrients and water in the case of roots, light in the case of shoots. The results of an experiment

measuring root and shoot competition between a clover (*Trifolium repens*) and a grass (*Lolium perenne*) are shown in Figure 55.2. The grass outcompeted the clover in both root and shoot competition because a rich supply of nutrients, which the grass was able to use more efficiently than the clover, was provided.

Competition can restrict species' ranges

The role of competition in restricting the ranges of species is illustrated by the interaction of the two barnacle species described in Figure 55.1. In some cases, competition can completely exclude a species from part or all of its range.

Parasitic wasps were introduced into southern California to control outbreaks of scale insects that were seriously damaging citrus orchards. The Mediterranean wasp *Aphytis chrysomphali* was established in southern California by 1900, but it did not effectively control scale insects. Therefore, a close relative from China, *A. lingnanensis*, which has a higher reproductive rate, was introduced in 1948. *A. lingnanensis* increased rapidly, and within a decade it had displaced *A. chrysomphali* from most of its California range (Figure 55.3).

Question: What are the relative effects of root and shoot competition on plant growth?

METHOD

No interspecific competition (control)

Perennial ryegrass White clover

Interspecific competition (experimental)

Root competition Shoot competition

Root and shoot competition

No inter-specific competition

Root competition

Shoot competition

Root and shoot competition

Conclusion: In this experiment, both root and shoot competition were important but shoot competition was more important.

55.2 Plants Compete with their Roots and Shoots

By growing plants in separate pots or together, experimenters can distinguish the influences of root and shoot competition on plant growth. An experiment using white clover (*Trifolium repens*) and perennial ryegrass (*Lolium perenne*) showed that both roots and shoots of these plants are involved in competition.

Competition can reduce species' abundances

Often competition reduces the abundances of competing species rather than eliminating them from an area. Many species of seed-eating ants and rodents live together in the Sonoran Desert of Arizona. To determine whether competition between ants and rodents influences their abundances, ecologists removed ants from some sites, rodents from other sites, and both ants and rodents from a third set of sites. When they removed ants, the density of rodents increased slightly, but seed densities did not change. When they removed rodents, the density of ant colonies nearly doubled, but again, seed densities did not change. When they removed both ants and rodents, seed densities increased to five times their previous value. These results showed that ants and rodents were competing for and influencing their food supply, but that rodents had a much stronger effect on ants than vice versa, $v^{\wedge},^{\wedge}$ Jts. $\wedge s=\wedge=> C$ To determine whether different species of rodents also compete with one another, the ecologists erected rodent-proof fences around 50 x 50-m desert plots. The fences around the experimental plots had holes that small rodents could pass through, but were too small to allow the passage of large kangaroo rats. The holes in the fences surrounding control plots were large enough for all rodents to pass through. Within 2 years of the exclusion of kangaroo

rats from the experimental plots, densities of small seed-eating rodents increased more than twofold, and the plots without kangaroo rats supported more rodent species than the control plots. These results showed that kangaroo rats reduce populations of some rodent species and eliminate others from places where they live. Kangaroo rats compete with other seed-eating rodents both by reducing their food supply—exploitative competition—and by aggressively defending space—interference competition: I

In most natural communities, many species with similar ecological requirements live together, as seed-eating ants and rodents do in the Sonoran Desert. How can so many similar species share natural environments? Part of the answer is that natural environments are variable in space and time. That is why competing species often eliminate one another from some parts of the environment, but not from others. Also, natural environments typically provide many types of food, so that competing species do not overlap completely in their use of resources. In addition, other factors, such as predators, disease, and bad weather, may keep populations well below the environmental carrying capacity so that they rarely compete.

Predator-Prey and Parasite-Host Interactions

Competitive interactions in nature are often subtle, indirect, and difficult to detect. In contrast, predation is often direct, conspicuous, and easy to study. Consequently, our knowledge of predator-prey relationships is extensive. In this section we discuss how the dynamics of predator-prey and parasite-host interactions differ, and why interacting predator and prey populations typically fluctuate over time. Then we consider the evolutionary results of predator-prey interactions.

are typically larger than and live outside the

predators

bodies of their prey. Generally they kill prey individuals when they eat them. Parasites are smaller than their hosts and may live inside or outside their bodies. Parasites often live in or on their hosts without killing them and may live for many generations within a single host. As a result, parasite-host interactions differ in interesting ways from predator-prey interactions.

Parasite-host interactions

Some parasites are only slightly smaller than their hosts, but others, such as viruses and protozoa, which are called microparasites, are much smaller than their hosts. Microparasites are able to reproduce within their hosts because their generation times are much shorter than those of their hosts. A host may harbor thousands or millions of them.

To understand the dynamics of microparasite-host interactions, it is useful to divide a host population into three distinct classes: susceptible; infected; or recovered and immune. Changes in the numbers of individuals in each class depend on births, deaths, infections, and development and

EXPERIMENT

Question: Do tent caterpillar populations crash due to food shortages or infection by a virus?

METHOD

RESULTS

Introduce virus-infected caterpillars into experimental caterpillar populations that have ample food.

The experimental populations crash at the same time as the natural population from which infected caterpillars were introduced.

N*

Conclusion: The virus, not food shortage, causes the caterpillar population to crash.

55.4 Microparasites Can Cause Population Crashes

Transferring infected tent caterpillars from a natural population that was about to crash to uninfected populations caused those populations to decline even though food was abundant.

loss of immunity. For a microparasite population to survive in a host population, on average at least one new host individual must become infected before each infected host dies.

A microparasite can readily invade a host population dominated by susceptible individuals, but as the infection spreads, fewer and fewer susceptible individuals remain. Eventually a point is reached at which infected individuals do not, on average, transmit the infection to at least one other individual. Then the infection dies out in the host population. As a result, microparasite infections typically rise, then fall, and do not rise again until a sufficiently dense population of susceptible host individuals has reappeared.

Interactions between a microparasite—a virus—and populations of its host—the western tent caterpillar (*Mala-cosoma californicum*)—have been investigated experimentally (Figure 55.4). Larval western tent caterpillars eat the leaves of a variety of species of deciduous trees and shrubs in North America. Their populations fluctuate dramatically, with peak densities occurring about every 10 years. Food supply cannot, by itself, drive these cycles, because populations often collapse before they defoliate the trees. Rather, a virus appears to be responsible. This virus typically kills an infected caterpillar within a few weeks. When it dies, the caterpillar ruptures and releases millions of viruses onto the leaves and bark of trees, infecting many other caterpillars. After an outbreak of the virus, tent caterpillar populations remain low for many years until the remaining viruses are killed by exposure to sunlight.

To test whether viruses drove the population cycles,

;

COMMUNITY ECOLOGY

r r

ecologists introduced caterpillars from infected populations into experimental sites where caterpillar populations had abundant food and were starting to increase. Caterpillars in the experimental populations became infected and were killed by the introduced virus; consequently, these experimental populations declined at the same time as the populations from

which the introduced caterpillars were drawn. In contrast, densities of caterpillars in control populations with abundant food continued to increase.

Predator-prey interactions

When a predator captures and eats a prey individual, it reduces the size of the prey population by one, but the effects of predators on prey population dynamics cannot be determined simply by counting the number of prey eaten. We also need to know how prey densities influence the ease with which prey are captured and how rapidly they reproduce. To understand the complex interactions between predators and their prey, it is useful to consider the process of predation from the perspective of an individual predator. Consider, for simplicity, a predator species that eats only one kind of prey. An individual predator can find enough to eat if the rate at which it encounters prey is above a certain threshold value. Below that threshold, it will lose weight and eventually starve. Nevertheless, the predator may continue to eat prey while slowly losing weight, driving

ing the prey population down further. Eventually the number of predators increased, which may allow the prey population to increase in numbers. This increase may, in turn, permit the prey population to increase further.

because of this pattern, fluctuation often lags behind the prey population. Predator-prey interactions often cause fluctuations in the densities of both populations, just as microparasites often cause fluctuations in populations of their hosts.

Population density changes among small mammals and their predators living at high latitudes are the best-known examples of predator-prey oscillations. Populations of Canadian lynx and their principal prey, hares, oscillate on a 9- to 11-year cycle. For many years, these numbers were thought to be driven only by interactions between hares and lynxes. Recently, however

ecologists asked whether any part of the lynx-hare oscillation could be explained by fluctuations in food supply in addition to predation.

To answer this question, the ecologists set up 1-km² blocks of undisturbed coniferous forest in Yukon Territory, Canada. In two of the blocks, the hares were given supplemental food year-round. An electric fence with a mesh large enough to allow hares, but not lynxes, to pass through was erected around two of the blocks. In one of these blocks, extra food was provided. In two other blocks, fertilizer was added to the quality of plant food for the hares. The two blocks served as unmanipulated controls.

These experiments produced striking results. Excluding lynxes doubled, and adding food tripled, hare densities. The increase and decline phases of a cycle. Predator exclusion combined with food addition

55.6 Prey Population Cycles May Have Multiple Causes

Experiments showed that both food supply and predation (but not food quality) affect the population densities of snowshoe hares.

chorus frogs (*Pseudacris triseriata*) are found in only some of the habitats that seem suitable for them. Three major predators—the larvae of a salamander, nymphs of a large dragonfly, and dytiscid beetles—eat chorus frog tadpoles. An ecologist noticed that the tadpoles were common in ponds containing beetles, but were rare in ponds with salamander larvae and dragonfly nymphs. In laboratory experiments, he established that the salamander larvae could eat only small tadpoles, but that dragonfly nymphs could eat tadpoles of all sizes. Therefore, he hypothesized that dragonfly nymphs were responsible for eliminating chorus frogs from many ponds.

To test this hypothesis, he selected two large ponds that contained dragonfly nymphs but no tadpoles, and two other ponds that contained tadpoles but no nymphs. So that all the tadpoles would be handled equally, he removed the tadpoles from the two ponds that lacked dragonfly nymphs and then reintroduced them at the same densities. He introduced dragonfly nymphs into one of those ponds at typical densities. He also removed nearly all dragonfly nymphs from one of the ponds that had them and then introduced tadpoles into both of those ponds.

The dramatic results of the experiment supported his hypothesis (Figure 55.7). Tadpoles were eliminated from ponds with dragonfly nymphs, but survived well in ponds from which dragonfly nymphs were absent, or nearly so. This experiment shows that a particular predator may eliminate its prey in certain environments; however, it does not tell us why dragonfly nymphs were naturally absent from some of the ponds.

Predator-prey interactions change over evolutionary time

Because predators do not capture prey individuals randomly, they are agents of natural selection as well as agents of mortality. As a consequence, prey species have evolved a rich variety of adaptations that make them more difficult to capture, subdue, and eat. Among the evolutionary adaptations of prey are toxic hairs and bristles, tough spines, noxious chemicals and the means for ejecting them (Figure 55.8), camouflage, and mimicry of inedible objects or of larger or more dangerous organisms. Predators, in turn, may evolve to be more effective at overcoming prey defenses, leading to an evolutionary "arms race."

mimicry is an evolved defense. Among the best-studied adaptations of prey to predation is mimicry, an evolved resemblance to, some inedible or unpalatable item. In Batesian mimicry, a palatable species mimics an unpalatable or noxious one. Examples are the mimicry of ants by spiders and of bees and wasps by many different insects (Figure 55.9). Batesian mimicry works because a predator that captures an individual of an unpalatable or noxious species learns to avoid any prey of similar appearance.

However, if a predator captures a palatable mimic, it is rewarded with food, and it learns to associate palatability with the appearance of that prey. As a result, individuals of unpalatable species are attacked more often than they would be if they had no Batesian mimics. Because unpalatable individuals that differ from their mimics more than the average are less likely to be attacked by predators that have eaten a mimic, directional selection causes unpalatable species to evolve away from their mimics. Batesian mimicry systems are stable only if a mimic evolves toward the appearance of an unpalatable species faster than the unpalatable species evolves away from it, which usually requires that the mimic be less common than the unpalatable species.

Another type of mimicry is Mullerian mimicry, the convergence over evolutionary time in the appearance of two

55.8 Defenses of Animal Prey

(a) A bombardier beetle ejects a noxious spray at the temperature of boiling water in the direction of a predator. The spray is ejected in high-speed pulses more than 20 times in succession, (b) The Indo-Pacific lionfish is among the most toxic of all reef fishes. Glands at the base of its spines can inject poison into an attacker. Its bright markings are thought to warn potential predators of this capability.

982 CHAPTER FIFTY-FIVE

55.9 A Batesian Mimic Falsely Advertises Danger

By mimicking a wasp, this ctenucid moth is protected from predators.

or more unpalatable species. All species in a Müllerian mimicry system, including the predators, benefit when inexperienced predators eat individuals of any of the species because the predators learn rapidly that all species of similar appearance are unpalatable. Some of the most spectacular tropical butterflies are members of Müllerian mimicry systems (Figure 55.10), as are many kinds of bees and wasps.

EVOLVED CHEMICAL DEFENSES ARE WIDESPREAD among plants. In addition to physical defenses against herbivores, such as tough leaves, hairs, or spines, most plant tissues also contain defensive chemicals called secondary compounds. There are two types of defensive secondary compounds: acute toxins and digestibility-reducing compounds.

[Acute toxins disrupt herbivore metabolism. Some of these toxins, such as nicotine, interfere with the transmission of nerve impulses to muscles. Others are hallucinogens, which cause individuals that ingest them to have a seriously distorted view of their environment. Some toxins imitate insect hormones and prevent insects from completing metamorphosis. Still others are unusual amino acids that become incorporated into herbivore proteins and interfere with their functioning. Other acute toxins defend

plants against viruses and bacteria. As we saw at the beginning of this chapter, most of the spices used in human cuisines have antibiotic properties. We can safely include them in our food because they are toxic only to microorganisms.

Digestibility-reducing compounds are secondary compounds that make plant tissues difficult to digest. The most common of these substances are tannins, which are present in the leaves of some herbaceous and most woody species. When an herbivore chews on a leaf, tannins are released from the intracellular compartments in which they are stored. They bind to proteins in the leaf and to the herbivore's digestive enzymes, reducing the ability of the herbivore to extract proteins from the leaves. Tannins may be present in such large quantities that watery drainage from forests dominated by tanniferous plants are tea-colored.

Neutral and Beneficial Interspecific Interactions

During predator-prey and competitive interactions, one or both participants in the interaction are harmed \ Amensal-

1 Highly unpalatable or noxious

J Moderately unpalatable or noxious

I Highly palatable (Batesian mimics)

□ Palatability not yet tested with birds

* Müllerian mimics of

butterflies in the same group

55.10 Müllerian and Batesian Mimics

By converging in appearance, the unpalatable Müllerian mimics among these different species of Costa Rican butterflies and moths reinforce each other in deterring predators. The palatable Batesian mimics benefit because predators have learned to associate these color patterns with distasteful or noxious effects.

55.17 Danger Comes From Above

Shrubs and herbaceous plants are often damaged by branches falling from tall trees.

IsrQ cause s harm to one of the partners without affecting Jhejither,. In the other two types of interspecific interactions—commensalism and mutualism—neither partner is harmed, and one or both may benefit. We examine these interactions in the sections that follow.

In a men s alism and commensalism, one participant is unaffected

\Amen salisms^i n which an individual harms another organism but is unaffected by the species it harms, are widespread and important in nature. Ma mmals, for example, create bare spaces aroun d water holes. They benefiL by dnnking~vvat er, but not by tramp ling t he plants they kill. Leaves and branches falling from trees damage smaller plants beneath them (Figure 55.11). The trees drop these old structures regardless of whether or not they damage other plants.

\ ^Commens alism\)enefits one partner but has no effect on the other. An example is the relationship between cattle egrets and grazing mamm als. Cattle egrets are found throughout the tropics and subtropics. They typically forage on the ground around cattle or other large mammals, concentrating thpirj^tigntin n npar thp hpads and feet of the m ammals, where they catch insects fl nshpH by thpir hooves an d m ouths (Figure 55.12). Cattle egrets that forage close to grazing mammals capturemo re food for le ss effort than egre ts that d o not. The benefit t o the egrets is clear ; the mammals neith er gair fnor lose!

Mutualisms benefit both participants

VMutualism^ are interactions that benefit both participants. Mutualistic interactions ex ist between plants a nd microorganisms, protists a nd fungi, plants and insects, _a nd among jglants. Animals also have mutualistic interactions with pro-

tists and with one another. As you learned in Chapter 27, the ev olution of eu karyotic organisms is believed to be the .^result of mutualistic interactions between previously free-living prok~aryotes and the cells they originally infected.

intergroup mutualisms. Some of the most complex and ecologically important mutualisms are between members of different kingdoms or domains.

Most plants have beneficial associations with soil-inhabit ing fun gi called mycorrhizae that enhance the~plaht's abil-ity to extract mine rals from the soil (see Figure 30.16). And in the critical mutualistic relationship of some plants with nitrogen-fixing bacteria of the genus Rliizobium (discussed at length in Chapter 36), the bacteria receive protection and nutrients from their host plant while providing the host with usable nitrogen.

Lichens are compound organisms consisting of highly mod ified fungi t hat harbo r cyanobacter ia)r_ green algae among their hyphae (see Figure 30.18). The fungi absorb water and nutrients from the environment and provide these as well as a supporting structure for the mlcroorgan-isms, w hich in turn provide the fungi with the pr oducts of photosynthesis.

"Animals have important mutualistic interactions with protists. For example, corals, some anemones, and some tunicates gain most of their energy from photosynthetic protists that live within their tissues. In exchange, they provide the protists with nutrients from the small animals they capture (see Figure 4.16c).

Termites have nitrogen-fixing protists in their guts that help them digest the cellulose in the wood they eat. Young termites must acquire their protists by eating the feces of other termites. If prevented from doing so, they soon die. The protists are provided with a suitable environment in which to live and an abundant supply of cellulose.

55.12 Commensalism Benefits One Partner

Cattle egrets catch more insects with less effort when they forage around large grazing mammals, such as cape buffalos. The buffalos are neither harmed nor helped by the egrets.

984 CHAPTER FIFTY-FIVE

55.73 A Plant-Animal Mutualism

Some Acacia species have large, swollen, hollow thorns in which ants build their nests.

thorns in which ants of the genus *Pseudomyrmex* construct their nests and raise their young (Figure 55.13). These ants live only on acacias. They feed on nectar that the trees produce at the bases of their leaf petioles and on special nutritive bodies on the leaves. The ants attack and drive off leaf-eating insects, eat the eggs and larvae of herbivorous insects, and sting browsing mammals. They also block the tips of other plants that grow over their host tree. The ants get room and board; the

plants get protection against herbivores and competing plants.

Experiments in which acacias are deprived of their ants demonstrate the amount of protection the ants provide (Figure 55.14).

Many angiosperms depend on animals to transport both their pollen and the seeds. The plants benefit from pollination by having their pollen carried to other conspecific plants and by receiving pollen to fertilize their ovules. Animals benefit by obtaining food in the form of nectar and pollen (Figure 55.15a). Plants also benefit from having their seeds dispersed to sites where they are more likely to germinate and survive than directly under the parent plant (Figure 55.15b). Animal dispersers benefit by eating the nutritious fruits surrounding the seeds. The plants pay a price for the benefits they receive: The energy and materials a plant uses to produce nectar, fruits, and other rewards for animals cannot help with or seed production.

■ c^

y&>

-r^

ANIMAL-ANIMAL MUTUALISMS. Many

species of ants have mutualistic relationships with aphids. Ants "milk" the small, plant-sucking insects by stroking the m

with their forelegs and antennae. The aphids respond by secreting droplets of partly digested plant sap that has passed through their guts. In return, the ants protect the aphids from predatory wasps, beetles, and other natural enemies. The aphids lose nothing, because plant sap is high in sugar but low in amino acids. Thus, the aphids inevitably inject more sugar than they can use.

plant-animal mutualisms. Terrestrial plants have many mutualistic interactions with animals. A complex mutualism between trees and ants that live in Central America illustrates the benefits of such interactions. Trees of the species *Acacia cornigera* have large, hollow

55.15 Plants Incur Costs to Attract Mutualists

(a) Some animal pollinators such as this long-tongued bat are attracted by rewards of nectar or pollen, (b) The nutritious pulp of fruits are attractive to many birds, such as this Bohemian waxwing.

COMMUNITY ECOLOGY 985

influenced by interactions with a wide variety of predators, parasites, prey, or mutualists. For example, most flowers are pollinated by a number of animal species and most

pollinators visit many species of flowers.

The traits of fruits that surround many seeds are also the result of diffuse coevolution. Few fruits are adapted for dispersal by only a few species of animals. Most bird-dispersed fruits are red, or some combination of red and another color, and have no obvious odor to humans. Fruits dispersed by nocturnal animals, many of which lack color vision, are typically "purple," are not highly visible to birds, and usually have a pleasant odor. Bat-dispersed fruits are typically green and have a fruity odor. They are inconspicuous during the day, but are easy for bats to detect at night. Many bird-dispersed fruits have unpleasant tastes to mammals.

Species-specific coevolution is much rarer than diffuse coevolution, but yucca plants and the moths of the genus *Tegeticula* that pollinate them have this kind of relationship. Female yucca moths lay their eggs only in the ovules of yucca flowers, and yucca flowers are pollinated only by *Tegeticula*. A female *Tegeticula* lays no more than five eggs in any one flower. After she has laid her eggs, she scrapes pollen from the flower's anthers, rolls it into a small ball, flies to another yucca plant, and places the pollen ball on the stigma of a flower before laying another batch of eggs. When the eggs hatch, the larvae burrow into the ovary and feed upon the developing seeds. Each yucca species has a specific moth species associated with it (Figure 55.17).

One feature of the coevolved relationship between *Tegeticula* and *Yucca* is surprising: Why do female moths lay so few eggs per flower? Wouldn't a female moth that laid more than five eggs per flower produce more surviving off-

Interactions between plants and their pollinators and seed dispersers are clearly mutualistic, but they are not purely mutualistic. Many seed dispersers are also insect predators that destroy some of the seeds they remove from plants. Some organisms that collect these rewards are not mutualists at all. Many animals visit flowers without transferring any pollen. Some of them cut holes to get to the nectar-producing regions at the base of the flowers. On the other hand, some plants exploit their pollinators. The flowers of certain orchids, for example, mimic female insects, enticing male insects to copulate with them (Figure 55.16). The male insects neither sire any offspring nor obtain any reward, but they transfer pollen between flowers, benefiting the orchid.

Coevolution of Interacting Species

The relationships between plants and their pollinators and seed dispersers show how the evolution of species traits can be influenced by interactions with other species. Species that have mutually influenced one another's evolution are said to have

many species' traits are

55.16 Some Orchids Mimic Female Insects

The flowers of this orchid so closely resembles a female wasp that male wasps are tricked into attempting to copulate with

them, as this male is doing. The orchid gets pollinated, but the wasp gets no reward.

986 CHAPTER FIFTY-FIVE

55.17 Yucca- Yucca Moth Coevolution

The Joshua tree (a) is pollinated only by the yucca moth (b), shown here on a flower. The moth's larvae feed on developing yucca seeds fertilized by the pollen she transports.

(b) *Tegeticula yuccasella*

spring than moths that lay only the usual number? The evolutionary reason for their restraint is that *Yucca* plants abort flowers in which more than five eggs are laid. As a result, no moth offspring are produced in such flowers. Thus, the mutualism is stabilized at a level that represents an "evolutionary compromise" between the fitness of the moths and the yuccas.

Some Species Have Major Influences on Community Composition

Organisms influence the communities in which they live through all of the types of interactions that we have just described. Through these interactions, they may influence the species richness of their communities—that is, the number of species that live there. They also influence their communities by altering microclimate, soil structure and chemistry, and water movement. These alterations affect the suitability of the physical environment for other organisms. Organisms also change the amounts and distributions of resources in the community. Species whose influences on ecological communities are greater than would be expected on the basis of their abundance are called keystone species. Keystone species may influence the species richness of communities, the flow of energy and materials in ecosystems, or both.

Some species have major influences on their communities simply through their abundance. For example, in terrestrial communities, plants form most of the structural environment, are the major modifiers of the physical environment, and are the pathway through which energy and nutrients enter communities. Anyone who has walked into the shade of a tree on a hot, sunny day knows that climate near the ground is strongly influenced by plants.

Animals may change vegetation structure and species richness

Animals that are able to change vegetation structure alter the environment for many other species, for example, beavers, to create meadows by cutting down trees and create ponds by building dams. Large grazing and browsing mammals may also dramatically change the structure and composition of vegetation.

To determine the influence of bison (*Bison bison*) on prairie vegetation, 30 individuals were introduced to the Konza Prairie Research Natural Area in northeastern Kansas, the largest tract of unplowed tallgrass prairie in North America. The herd, now about 200 animals in size, has unrestricted access to 10 watersheds that are regularly burned in spring. Bison prefer to graze on and eat few of the forbs (flowering plants) that grow among the grasses. Bison also prefer to graze on recently burned areas.

Areas from which bison are excluded and which are burned annually are dominated by tall grasses and have few plant species. In contrast, regularly burned areas that are grazed by bison have more forbs—and many more species of forbs—because the bison, by preferentially grazing on the grasses, create space for them (Figure 55.18). Also, urea in bison urine is hydrolyzed to ammonium and its nitrogen is available to plants within a few days; decomposing plant litter releases nitrogen

much more slowly. Therefore, plants in areas grazed by bison have higher leaf nitrogen levels and grow faster.

Predators may change marine community structure

Predation by the sea star *Pisaster ochraceus*, an abundant animal in rocky intertidal communities on the Pacific coast of North America, increases local species richness. In the

Biosphere

55.78 Bison Increase Plant Species Richness and Productivity

By grazing preferentially on grasses, bison increase the density of forbs and overall plant productivity.

absence of sea stars, their preferred prey, the mussel *Mytilus californianus*, crowds out other competitors in a broad belt of the intertidal zone. By consuming mussels, *Pisaster* creates bare spaces that are taken over by a variety of other species (Figure 55.19).

The influence of *Pisaster* on community composition was demonstrated by experimentally removing them from selected areas in the intertidal zone repeatedly over a 5-year period. These removals resulted in two major changes. First, the lower edge of the mussel bed extended farther down into the intertidal zone, showing that sea stars are able to eliminate mussels completely where they are covered with water most of the time. Second, and more dramatically, 28 species of animals and algae disappeared from the removal zones, until only *Mytilus*, the dominant competitor, occupied the entire substrate. By altering competitive relationships, predation by *Pisaster* largely determines which species live in these rocky intertidal communities.

Temporal Changes in Communities

Because organisms alter soil structure and chemistry and microclimates, the species composition of ecological communities changes constantly over time. The plants that first colonize a site after a disturbance, for example, differ from those that dominate the site later. Such a sequence of change in the species composition of a community is called ecological succession. Patterns and causes of ecological succession are varied, but the early colonists often alter the environment for arriving species grow.

Ecologists divide succession into two major types. Primary succession begins with the establishment of organisms on newly available sites that previously had no organisms. Secondary succession begins when organisms reestablish themselves on disturbed sites where some organisms survived the disturbance.

55.19 Sea Stars are Keystone Predators

This sea star (*Pisaster ochraceus*) is resting on a bed of mussels (*Mytilus* sp.), its preferred prey.

A good example of primary succession is the sequence of changes following the retreat of a glacier in Glacier Bay, Alaska, over the last 200 years. The retreating glacier left a series of moraines —gravel deposits formed where the glacial front was stationary for a number of years. No scientist was present to measure changes over the 200-year period, but ecologists have inferred the temporal pattern of succession by examining plant communities on moraines of different ages. The youngest moraines, close to the current glacial front, are populated with bacteria, fungi, and photo-synthetic microorganisms. Slightly older moraines have lichens, mosses, and a few species of shallow-rooted herbs. Successively older moraines have shrubby willows, alders, and conifers.

By comparing moraines of different ages, ecologists deduced the pattern of plant succession and of changes in the soil at Glacier Bay. Succession was caused in part by changes in the soil brought about by the organisms themselves. An herbaceous plant, *Dryas*, and alder trees have nitrogen-fixing bacteria in nodules on their roots. Because nitrogen is virtually absent from glacial moraines, nitrogen fixation by *Dryas* and alders improved the soil for the

988 CHAPTER FIFTY-FIVE

change dramatically, a forest community dominated by spruces is likely to persist for many centuries at Glacier Bay (Figure 55.20).

The changes that take place when all or part of the dead body of some plant or animal is decomposed are examples of/secondary succession] The succession of fungal species that decompose pine needles in litter beneath Scots pines (*Pinus sylvestris*) is shown in Figure 55.21. New litter is continually

ously deposited under pines, so that the surface layer of litter is young and deeper layers are progressively older. Decomposition begins when the first group of fungi starts consuming the needles as soon as they fall. Each group of fungi decomposes certain compounds, converting them to other compounds that are decomposed by the next successional group. This process continues over about 7 years, by which time the last group of organisms—basictiorrtycetes— has decomposed the litter completely.

Alder trees fix nitrogen in soil, improving conditions for the growth of spruces.

Indirect Effects of Interactions among Species

In the experiments we have described above, one member of a community was removed or added, and investigators measured the resulting changes. Single-species removals or additions can demonstrate the direct effects of species on one another, but to quantify indirect effects, observations and manipulations of several species are needed.

e*

Ecologists have assembled a variety of data to help them understand relationships between oak forests and the animals that eat their leaves and acorns. Most damage to leaves in the oak forests of eastern North America is caused by gypsy moths; most acorns are eaten by mice, chipmunks, deer, squirrels, and birds (Figure 55.21). Ineabundance of mice and chipmunks is controlled largely by _acorn abundance, which varies greatly from year to year. Deer consume large quantities of acorns during years of high acorn production, but during poor acorn years they shift to other foods.

Gypsy moths eat oak leaves. During years when their populations are very large, they may defoliate large expanses of forest. Outbreaks of gypsy moths occur once every 6-10 years. Gypsy moth populations collapse after they defoliate a forest because most larvae die of starvation. In the year following defoliation, oak trees are full of leaves, but gypsy moth populations remain low for many years. Why don't they quickly rebound?

To determine whether predation by mice prevented gypsy moth populations from recovering after a crash, ecologists measured predation rates by attaching freeze-dried gypsy moth pupae to small squares of burlap. They placed the burlap panels on oak tree trunks at sites where gypsy moths typically pupate. During a year of moderately dense mouse populations, all of the pupae were eaten within 8 days. During a year of low mouse density, half of the pupae remained after 18 days, which is longer than it would take them to complete metamorphosis and emerge. These results suggest that in years when acorns are abundant, mice keep gypsy moth populations at low densities by eating

most of their pupae. In so doing, they allow the oak trees to recover from defoliation and accumulate enough energy reserves to produce another large crop of acorns. Predators typically reduce mouse populations within 1.5 years after a year of high acorn production, after which gypsy moth populations rebound and again defoliate the trees. If few mice were present, the gypsy moths might rebound so quickly that the oaks could never produce large crops of acorns. If the investigators had studied only the interactions between mice and acorns or between gypsy moths and oak trees, they would not have discovered the important influences of other species on these interactions.

Chapter Summary

Types of Ecological Interactions

► Species interact with one another in five major ways: competition, predator-prey or parasite-host interactions, mutualism, commensalism, and amensalism. Review Table 55.1

Resources and Consumers

► A resource is anything directly used by an organism that can potentially lead to the growth of the population and whose availability is reduced when it is used.

► Biotic interactions, as well as the physical environment, influence the conditions under which species can persist. Review Figure 55.1

Competition: Seeking and Using Scarce Resources

► If organisms use the same resources and those resources are in short supply, the individuals are competitors. Competition may be either intraspecific or interspecific.

990 CHAPTER FIFTY-FIVE

► Plants are good subjects for competition studies because the resources for which they compete are easily manipulated. Review Figure 55.2

► Competition may restrict species ranges. Review Figure 55.3

► Species that use similar resources commonly coexist in nature because nature is spatially and temporally complex, many resources typically are available, and other factors often keep populations below carrying capacity so that they do not compete strongly.

Predator-Prey and Parasite-Host Interactions

► The relative sizes of predators and prey influence their interactions. Microparasites are typically much smaller than their prey and may live in or on their hosts without killing them.

► To understand the dynamics of host-microparasite interactions, it is useful to divide a host population into three distinct classes—susceptible, infected, and recovered and immune.

► Experimental manipulation of parasites and predators in nature reveals that they are often important in determining both numbers and distributions of their prey. Review Figures 55.4, 55.5, 55.6, 55.7

► Predators act as evolutionary agents by selecting for adaptations to protect against them. Prey have evolved many such adaptations, such as toxic hairs and bristles, tough spines, noxious chemicals, and mimicry of inedible objects or dangerous organisms. Review Figure 55.10

Neutral and Beneficial Interspecific Interactions

► Commensal interactions, in which one partner benefits while the other is unaffected, are common in nature.

► Mutualistic interactions, in which both participants benefit, are also common in nature. Mutualistic interactions occur between members of different groups of organisms (between plants and prokaryotes, between fungi and protists, and between animals and protists). Animals have mutualistic interactions with other animals and with plants, such as pollination and seed dispersal. Review Figure 55.14

Coevolution of Interacting Species

► Some mutualistic relationships, such as those between yuccas and yucca moths, are tightly coevolved, but diffuse coevolution between many species is much more common.

Some Species Have Major Influences on Community Composition

► Keystone species have influences on ecological communities that are greater than would be expected from their abundances, but abundant species also have major influences on community structure.

^ Vascular plants, mammals that change vegetation structure, predators on dominant competitors, and microorganisms often have major influences on ecological communities. Review Figure 55.18

Temporal Changes in Communities

► Ecological succession involves changes in the species composition of a community over time. Early colonists often alter the conditions under which later-arriving species grow.

* ■ Primary succession begins at sites that have never been modified by organisms. Review Figure 55.20

► Succession may take place when all or part of the dead body of some organism is decomposed. Review Figure 55.21

Indirect Effects of Interactions among Species

► Indirect effects of species interactions influence many species populations. For example, mice prevent gypsy moth populations from recovering quickly after they defoliate oak trees, thereby allowing the trees to recover. Review Figure 55.22

For Discussion

1. Environmental factors such as temperature, humidity, and salinity, even though they are important in the lives of many organisms, are not considered to be resources. Why not?
2. Kangaroo rats prevent smaller species of rodents from occupying some Sonoran desert habitats. They also reduce populations of seed-harvesting ants, but they do not cause elimination of ants from any habitats. Why can they competitively exclude other rodents, but not ants?
3. On the eastern side of the Sierra Nevada in California, four species of chipmunks occupy adjacent habitats from which they exclude one another by direct aggressive interference. In the San Jacinto Mountains of southern California, three other chipmunk species similarly occupy adjacent habitats, but no interspecific aggression is observed. Each species simply remains in its own habitat. Which of these two assemblages do you think is the older one? Why?
4. What features of predator-prey interactions tend to generate instabilities that lead to fluctuations in the densities of both species? Given that instabilities are expected, what keeps populations of either predator or prey from fluctuating to extinction?
5. Parasites usually have generation times much shorter than those of their hosts. Consequently, they should be able to evolve faster. What prevents them from evolving so fast that they completely overcome the resistance of their hosts and exterminate them?
6. Mimicry of inedible, toxic, or dangerous objects is widespread in nature, but most species are not mimics. Why don't more species evolve to mimic such objects?
7. Wind does not direct pollen toward conspecific stigmas. Given this inefficiency, why are there so many wind-pollinated plants? Similarly, if seeds that land close to the parent plant survive less well than those that are carried farther away, why do so many plants produce seeds lacking dispersal devices?
8. Some direct interactions between two species benefit only one of those species. Give examples of such "one-way" benefits in each of the following cases:
 - a. between two species of plants (give one example of energetic and another example of physical support)
 - b. between a plant and an eater of its leaves
 - c. between a predator and its prey
9. Wood is an abundant food source that has been available for millions of years. Why have so few animals evolved to be able to eat wood?
10. A keystone species exerts a larger influence on the ecological community in which it lives than one would expect given its abundance. What traits are likely to result in a species having such major ecological effects?

56

Ecosystems

IN 1976 THE OUTLET OF SOUTHERN INDIAN Lake in northern Manitoba, Canada, was dammed, raising the lake level 3 meters. Engineers then diverted the Churchill River so that rather than flowing into the lake, it flowed southward across a drainage divide and through a series of hydroelectric generating stations.

Before the dam was built, ecologists studied the lake in detail to assess the likely consequences of raising its level and greatly reducing the flow of river water into it. They predicted that fewer nutrients would enter the lake, but that the reduction would be compensated for by nutrients derived from increased soil erosion along the newly submerged shoreline. Based on their predictions, they believed that the Southern Indian Lake whitefish fishery, the most important commercial fishery in northern Manitoba, would not be harmed.

The ecologists' predictions of the future nutrient status of the lake and amounts of photosynthesis by algae were correct. However, to everyone's surprise, the whitefish fishery was ruined. The greatly increased soil erosion on the new shoreline released large quantities of mercury into the lake. Mercury concentrations in fish in Southern Indian Lake now exceed Canadian safety standards and will probably remain above standard for many years. From 1977 to 1982, Manitoba Hydro, the builder of the dam, subsidized the commercial fishermen, and in 1982, it provided a onetime cash settlement of \$2.5 million Canadian dollars for future losses to the fishermen.

Un expected sur prises commonly follow not only the damming of rivers and lakesTBut mo st attempts to alter ecological systems . Sur-prises arise because the behavior of ecosystems is the result of interactions among many different processes, most of which are only incompletely understood. Ecologists now recognize that mercury pollution often results from the raising of lake levels, but they did not know that in the 1970s. As humans continue to alter Earth's ecological systems, new

surprises confront us each year.

Dams: Some Surprising Aftereffects

Damming rivers and lakes in the expectation of creating benefits for the human population often results in unexpected and unpredictable detrimental effects on the ecosystem.

I

The organisms living in a particular area, such as Southern Indian Lake, together with the physical environment with which they interact constitute an ecosystem. Ecosystems can be recognized and studied at many different spatial scales, ranging from local units—such as a lake—to the entire globe. At the global scale, Earth is a single ecosystem.

The dynamics of ecosystems are the result of the activities of myriad individual organisms, which are influenced by processes in the physical environment. Some of these processes are, in turn, altered by organisms, and some are not. Individuals of the many different species that interact do so by capturing energy and materials, transforming and retaining them, and transferring them to other organisms.

In this chapter we discuss climates on Earth and how they influence ecosystem processes. We then describe patterns of energy flow and the cycles of materials in ecosystems. We will see how knowledge about ecosystems can be used to understand how and why they respond as they do to human-caused disturbances, and how we can learn from our mistakes.

Climates on Earth

The energy of the sun drives the global circulation patterns of air and ocean waters. The warming and cooling of moving masses of air and water explain most of Earth's climatic patterns. Climates, in turn, exert a powerful influence on the distributions, abundances, and evolution of species.

992 CHAPTER FIFTY-SIX

Climates vary greatly from place to place on Earth, primarily because different places receive different amounts of solar energy. The amount of incident solar energy is nearly constant at the equator, but varies dramatically at high latitudes. In this section we will examine how differences in solar energy input determine atmospheric and oceanic circulation.

Solar energy inputs drive global climates

Every place on Earth receives the same total number of hours of sunlight each year—an average of 12 hours per day—but not the same amount of heat. The rate at which heat arrives on Earth per unit of ground area depends primarily on the angle of sunlight. If the sun is low in the sky, a given amount of solar energy is spread over a larger area (and is thus less intense) than if the sun is directly overhead. In addition, when the sun is low in the sky, sunlight must pass through more of Earth's atmosphere, with the result that more of its energy is absorbed and reflected before it reaches the ground. At high latitudes (closer to the poles), there is more variation in both day length and the angle of arriving solar energy over the course of a year than at latitudes closer to the equator. On average, mean annual air temperature decreases about 0.4°C for every degree of latitude (about 110 km) at sea level.

Air temperature also decreases with elevation. The effect of elevation on temperature is due to the properties of gases. As a parcel of air rises, it expands, its pressure drops, and energy is expended in pushing molecules apart. With that loss of energy, the temperature of the air drops. When the parcel of air descends, it is compressed, its pressure rises, the same amount of energy is recovered, and its temperature increases.

When wind patterns bring air into contact with a mountain range, the air rises to pass over the mountains, cooling as it does so. Because cool air cannot hold as much moisture as warm air, clouds frequently form, and moisture is released as rain or snow. On the leeward side of the range, the air, now containing little moisture, descends, warms, and picks up moisture. This pattern often results in a dry area, called a rain shadow, on the leeward side of a mountain range (Figure 56.1).

Global atmospheric circulation influences climates

Earth's climates are strongly influenced by global air circulation patterns. Air rises not only when it crosses mountains, but also when it is heated by the sun. Warm air rises in the tropics, which receive the greatest solar energy input. This air is replaced by air that flows toward the equator from the north and south. That air, in turn, is replaced by air from aloft that descends after having traveled away from the equator at great heights. At roughly 30° north and south latitudes, air that

cooled and lost its moisture when it rose at the equator descends and warms. Many of Earth's deserts, such as the Sahara and the Australian deserts, are located at these latitudes.

At about 60° north and south latitudes, air rises again. Cold, dense air descends at the poles, where there is little

Q Prevailing winds pick up moisture over water bodies.

Q On the windward side of the mountain, air rises and cools, releasing moisture in the form of rain or snow.

On the leeward side of the mountain, air descends, warms, and picks up moisture, which results in little rain.

rp ^ 56.1 A Rain Shadow

Average annual rainfall tends to be lower on the leeward side of a mountain range than on the windward side.

input of solar energy. The black arrows around the edges of Figure 56.2 show these vertical patterns, which are one component of Earth's winds.

The spinning of Earth on its axis influences surface winds because Earth's spinning velocity is rapid at the equator, but relatively slow close to the poles. An air mass at a specific latitude has the same velocity as Earth has at that latitude. As an air mass moves toward the equator, it confronts a faster and faster spin, and its rotational movement is slower than that of Earth beneath it. Similarly, as an air mass moves poleward, it confronts a slower and slower spin, and it speeds up relative to Earth beneath it. Therefore, air masses moving latitudinally are deflected to the right in the Northern Hemisphere and to the left in the Southern Hemisphere. Winds blowing toward the equator from the north and south veer to become the northeast and southeast trade winds, respectively. Winds blowing away from the equator also veer and become the westerlies that prevail at mid-latitudes. The average directions of these surface winds are shown by the blue arrows in Figure 56.2.

Because Earth's axis is tilted, the amount of solar energy that reaches a given region varies seasonally as Earth orbits the sun. At any given location, the amount of solar energy input is at its maximum at the time of year when the sun is closest to being overhead at noon. The location of greatest solar energy input in the tropics, and the site where the trade winds converge and air rises, is called the intertropical convergence zone (see Figure 56.2). It shifts to the north during the northern summer (southern winter) and to the south during the southern summer (northern winter). Seasonal changes in climate (rainy and dry seasons) in the tropics are associated with the movement of the intertropical convergence zone because whenever an area is within the zone, air rises and heavy rains fall. When the zone is to the north or south of a tropical region, the prevailing winds are trade winds, which seldom yield rain unless forced to rise over mountains.

ECOSYSTEMS 993

56.2 Circulation of Earth's Atmosphere

If we could stand outside Earth and observe its air movements, we would see vertical air movements similar to those indicated by the black arrows and surface winds similar to those shown by the blue arrows. The vertical and horizontal circulation patterns shift to the north during the northern summer and to the south during the northern winter. Thus the intertropical convergence zone is on the equator only twice during each year.

Southeast trades

Global oceanic circulation is driven by winds

The global pattern of wind circulation drives the circulation of ocean water. Ocean water generally moves in the direction of the prevailing winds (Figure 56.3). Winds blowing toward the equator from the northeast and southeast cause water to converge at the equator and move westward until it encounters a continental land mass. At that point the water splits, some of it moving north and some of it moving south along continental shores. The poleward movement of ocean water that has been warmed in the tropics is a major mechanism of heat transfer to high latitudes. As it moves toward the poles, the water veers right in the Northern Hemisphere and left in the Southern Hemisphere. Thus water moves eastward until it encounters another continent and is

deflected laterally along its shores. In both hemispheres, water flows toward the equator along the west sides of continents, continuing to veer right or left until it meets at the equator and flows westward again. The oceans play an important role in world climates, both because their waters move long distances and because water has a high specific heat. The specific heat of a substance is the amount of energy required to raise the temperature of 1 gram of the substance 1°C. For water, this value is 1 cal/g at 15°C. Similarly, 1 gram of water that cools 1°C gives off 1 cal/g. Air and land surfaces have a much lower specific heat. Consequently, in comparison with continents, oceans warm up more slowly in summer because it takes more heat to raise their temperature. Oceans cool off more slowly in winter because more heat must be released to cool them.

56.3 Global Oceanic Circulation

To see that ocean currents are driven primarily by winds, compare the surface currents shown here with the prevailing surface winds shown in Figure 56.2. Deep ocean currents differ strikingly from the surface ones shown here.

56A Primary Production in Different Ecosystems

The primary production of Earth's ecosystems is measured in several ways, (a) The geographic extent of the different ecosystems. (b) Net annual primary production and (c) the percentage of Earth's total primary production contributed by each ecosystem.

Both wind circulation patterns and the properties of ocean water affect terrestrial climates. At high latitudes, the temperatures of the interiors of large continents fluctuate greatly with the seasons, becoming very cold in winter and ^To TuTsununer, a pattern called a continental climate. The coasts of continents, particularly those on west sides at middle latitudes, where the prevailing winds blow from ocean to land, have maritime climates, with smaller differences between winter and summer temperatures.

The amount and annual pattern of energy input in a region determines the rates at which ecosystem processes operate and the kinds of organisms that live there. Next we will discuss how climates influence the amount of energy that flows through ecosystems.

Energy Flow through Ecosystems

As you learned in Chapter 6, all energy transformations obey the laws of thermodynamics. The first law of thermodynamics states that energy is neither created nor destroyed; that is, the total amount of energy in the universe is constant. The second law of thermodynamics states that when energy is converted from one form to another, some of it becomes unavailable to do work. This law governs patterns of energy flow through ecosystems.

(b) Average net primary production (grams per m² per year)

(c) Percentage of Earth's net primary production

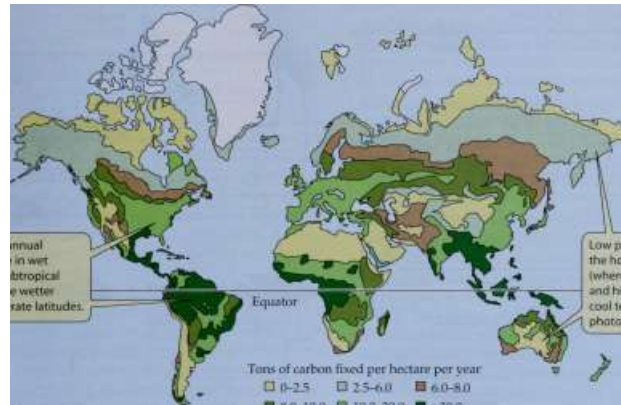

Organisms depend on inputs of energy (in the form of sunlight or high-energy molecules), water, and minerals for metabolism and growth. Except for a few limited ecosystems (some caves, deep-sea hydrothermal systems) in which solar energy is not the main energy source, all energy utilized by organisms comes (or once came) from the sun. Even the fossil fuels—coal, oil, and natural gas—upon which the economy of modern human civilization is based are reserves of captured solar energy locked up in the remains of organisms that lived millions of years ago.

Only about 5 percent of the solar energy that arrives on Earth is captured by photosynthesis. The remaining energy is either radiated back into the atmosphere as heat or consumed by the evaporation of water from plants and other surfaces. The energy that is captured by photosynthesis powers the ecosystem processes. How that energy subsequently passes through a series of organisms is the topic of the next section.

Photosynthesis drives energy flow in ecosystems

Energy flow in most ecosystems originates with photosynthesis. The rate at which plants assimilate energy is called gross primary productivity. Water availability and temperature are major determinants of gross primary productivity. The total amount of energy that plants assimilate by photosynthesis, typically measured over a year, is called gross primary production. The production that remains after subtracting the energy that plants use for their own maintenance (respiration), building tissues, reproduction, and defense is called net primary production (Figure 56.4).

Areas of high annual production are in wet tropical and subtropical regions and the wetter parts of temperate latitudes

Tons of carbon fixed per hectare per year □ 0-2.5 □ 2.5-6.0 □ 6.0-8.0 ■ 8.0-10.0 □ 10.0-30.0 ■ >30.0

Low production characterizes the hot subtropical deserts where moisture is limiting) and high latitudes (where cool temperatures lower photosynthetic rates).

56.5 Net Primary Production of Terrestrial Ecosystems

Variations in temperature and water availability over Earth's land surface affect the annual production of its ecosystems.

The distribution of primary production worldwide reflects the distribution of temperature and moisture on Earth. Close to the equator at sea level, temperatures are high throughout the year and typically the water supply is adequate much of the time. In these climates, highly productive forests thrive. In lower-latitude and mid-latitude deserts, where plant growth is limited by lack of moisture, primary production is low; plants of low stature dominate most landscapes. At higher latitudes, where there is more moisture and trees grow well, primary production is limited by low temperatures during much of the year. Production in aquatic systems is limited by light, which decreases rapidly with depth; by nutrients, which are scarce in open water; and by temperature.

Plants use most of the energy they capture to maintain themselves, to grow, and to reproduce. Some of this energy produces new tissues that can be eaten by herbivores or used by other organisms after the plants die. Because so much of the energy they capture goes to power their own metabolism, however, plants always contain much less energy than the total amount they have assimilated. Only the energy plants do not use to maintain themselves is available to be harvested by animals.

"The global distribution of net primary production is shown in Figure 56.5.

Energy flow through a series of organisms

Because energy flows through ecosystems when organisms eat one another, it is useful to group organisms according to their source of energy. The organisms in an ecosystem that obtain their energy from a common source constitute a trophic level (Table 56.1). Organisms at a particular trophic level occupy a position in an ecosystem that is determined

56.6 A Food Web Diagram for a Lake

This food web diagram summarizes the major predator-prey interactions within Gatun Lake, Panama. The arrows show who eats whom.

b\ the number of steps through which energy passes to reach them. Photosynthetic plants get their energy directly from sunlight. Collectively they constitute the trophic level called photosynthesizers or primary producers. They produce the energy-rich organic molecules upon which nearly all other organisms feed.

All other organisms consume, either directly or indirectly, the energy-rich organic molecules produced by photosynthetic organisms. Organisms that eat plants constitute the trophic level called herbivores. Organisms that eat herbivores are called primary carnivores. Those that eat primary carnivores are called secondary carnivores, and so on. Organisms that eat the dead bodies of organisms or their waste products are called detritivores or decomposers. The many organisms that obtain their food from more than one trophic level are called omnivores."

A sequence of linkages in which a plant is eaten by an herbivore, which is in turn eaten by a primary carnivore, and so on, is called a food chain. Food chains are usually interconnected in a food web, because most species in a community eat and are eaten by more than one other species."

A food web diagram is a useful summary of predator-prey interactions within a community. A simplified food web diagram (not including detritivores) for Gatun Lake, Panama, is shown in Figure 56.6. A complete food web diagram, showing the position of every species in a community, would be confusingly complex because most biological communities contain so many species. Therefore, similar species, especially those at lower trophic levels, are usually lumped together, as they are in the diagram of the Gatun Lake food web.

Photosynthetic organisms

Herbivores

Respiration

Much energy is lost between trophic levels

The energy that organisms use to maintain themselves is dissipated as heat, a form of energy that cannot be used by other organisms. For this reason, only a small portion of the energy captured at one trophic level is available to organisms at the next higher level. The energy content of an organism's net production—its growth plus reproduction—is available to organisms at the next trophic level (Figure 56.7).

56.7 Energy Flow through an Ecosystem

In this diagram, the width of each channel is roughly proportional to the amount of energy flowing through it. The arrows indicate directions of energy flow.

The efficiency of energy transfer through food webs depends on:

- The fraction of net production at one trophic level that is consumed by organisms at the next level
- How those organisms divide the ingested energy between production and maintenance ~"

Birds and mammals have very low production efficiencies because they expend so much energy maintaining constant high body temperatures. Herbivores are less efficient than carnivores because plant tissues generally take more energy to digest than animal tissues do, but because of the low efficiency of energy transfer between trophic levels, a given amount of primary production can support many more herbivores than carnivores.

The amount of energy reaching a trophic level is determined by net primary production in the ecosystem and by the efficiencies with which food energy is converted to biomass (the total weight of organisms) at the trophic levels below it. To show how energy decreases in moving from lower to higher trophic levels, ecologists construct diagrams called pyramids of energy. A pyramid of biomass, which shows the mass of organisms existing at different trophic levels, illustrates the amount of biomass that is available at a given moment in time for organisms at the next trophic level (Figure 56.8).

Pyramids of energy and biomass for the same ecosystem usually have similar shapes, but sometimes they do not. The shapes depend on the dominant organisms and how they allocate their energies. Terrestrial ecosystems may differ strikingly in patterns of energy flow depending on the life forms of the dominant plants.

In grassland ecosystems, for example, where plants produce few hard-to-digest woody tissues, animals are able to consume most of the annual production of plant tissues each year. In grasslands, mammals—wild or domestic—may consume 30-40 percent of the annual aboveground net primary production. Insects may consume an additional 5-15 percent. Soil organisms, primarily nematodes, may consume 6-40 percent of the belowground biomass (Figure 56.8a).

In forest ecosystems, the dominant plants allocate a great deal of their energy to forming wood, which accumulates at high rates in growing forests. Wood, which is constructed of difficult-to-digest material (such as cellulose and lignin), is rarely eaten unless a plant is diseased or otherwise weakened. In most forests, leaves fall to the ground relatively undamaged at the end of the growing season. Although there are outbreaks of defoliating insects in forests, browsing rates are generally so low that ecologists often ignore losses to herbivores when calculating forest production (Figure 56.8b).

In most aquatic communities, on the other hand, the dominant photosynthesizers are bacteria and protists.

These organisms have such high rates of cell division that a small biomass of photosynthesizers can feed a much larger biomass of herbivores, which grow and reproduce much more slowly. This pattern can produce an inverted pyramid of biomass, even though the pyramid of energy for the same ecosystem has the typical shape (Figure 56.8c).

Much of the energy ingested by organisms is converted to biomass that is eventually consumed by detritivores (see Figure 56.7). Detritivores transform the remains and waste products of organisms (detritus) into carbon dioxide, water, and free mineral nutrients that can be taken up by plants again. If there were no detritivores, most nutrients would eventually be tied up in dead bodies, where they would be unavailable to plants. Therefore, continued ecosystem productivity depends on rapid decomposition of detritus.

Under the warm, wet conditions found in tropical forests, detritus is decomposed within a few weeks or months, and no litter accumulates on the soil surface. Rates of decomposition are slower under colder, drier, or highly acidic conditions, such as those in many coniferous forests. At high altitudes and latitudes, decomposition of leaf litter

Most of the biomass in a grassland is found in the green plants, and most of the energy flows through them.

In forests, the majority of biomass is tied up in wood and is mostly unavailable to herbivores.

| Carnivores | Herbivores | Producers

A marine community produces an inverted pyramid of biomass. The producers are unicellular algae, which divide so rapidly that a small biomass can support a much larger biomass of herbivores.

v.

56.8 Pyramids of Biomass and Energy

Ecosystems can be compared in terms of the amount of material present in organisms at different trophic levels (left) and in terms of energy flow (right).

998 CHAPTER FIFTY-SIX

It can take decades, and decomposition of tree trunks may take more than a century.

Some ecosystems are not powered by direct sunlight

Most ecosystems are powered by sunlight falling directly on them, but some depend upon sunlight that falls elsewhere. For example, marine ecosystems deeper than the level at which enough light penetrates for photosynthesis depend on biomass produced in the well-lit zone above them. The productivity of most deep-sea ecosystems is low because only small amounts of detritus descend through the water column to reach them.

Some deep-sea ecosystems are totally independent of sunlight. The most striking are those around hydrothermal vents associated with seafloor spreading zones. The energy base of these ecosystems is chemosynthesis by sulfur-oxidizing

bacteria. These bacteria obtain energy by oxidizing hydrogen sulfide in the hot water emitted from the vents. Most other organisms in these ecosystems, such as vestimentiferans, live directly or indirectly on these sulfur-oxidizing bacteria.

Ecologists recently discovered a cave ecosystem in southern Romania that is now fed by bacteria that fix inorganic carbon by using hydrogen sulfide as an energy source. Chemoautotrophic production by these bacteria is the food base for 48 species of cave-adapted terrestrial and aquatic invertebrates. However, most cave ecosystems depend on imported photosynthetically produced organic matter.

(«)

Humans manipulate ecosystem productivity

Through agriculture, humans exploit ecosystems by replacing species of low economic value with species of high value. We do this by manipulating ecosystems so as to increase the yield of products useful to us. Agriculture has several intricately intertwined components:

- ▶ We eliminate competition between crops and unwanted plants by cultivating and by applying herbicides.
- ▶ We reduce competing herbivores and disease-causing organisms, usually by applying toxic chemicals.
- ▶ We augment photosynthesis by adding nutrients (fertilizing) and water (irrigating).
- ▶ We develop special high-yielding strains of plants that respond to additional fertilizer by increasing their growth or reproductive rates.

* —

All these manipulations must work together, because "miracle" strains of crops typically do not yield more than other strains unless they are provided with fertilizers and protected from competitors, herbivores, and pathogens. Agriculture also depends on energy from outside the system for cultivation and harvesting. In modern agriculture, this energy comes from fossil fuels (Figure 56.9).

Modern agricultural ecosystems have spectacularly increased food production per hectare, but they have also created problems. Herbicides and insecticides have polluted lakes, rivers, and groundwater in most industrialized countries. Many agricultural pests have evolved resistances to pesticides. New methods of pest control, collectively known as integrated pest management (IPM), are becoming more common. IPM combines chemical applications with cultural practices—crop rotation, mixed plantings of crop plants, and mechanical tillage of the soil—and biological methods—development of pest-resistant strains of

56.9 Agriculture Requires Energy Input

(a) In traditional agriculture, people and domesticated animals supply most of the energy, as in this Indian rice paddy, (b) Modern agriculture is based on the use of toxic chemicals and high rates of consumption of fossil fuels during site preparation, growth of the crop, and at harvest time. The large machines harvesting this wheat field are typical of much modern agriculture.

00

2f*

xT~

crops, use of natural predators and parasites, and use of chemical attractants, such as pheromones—to control insect herbivores. The reduced use of toxic chemicals avoids most pollution problems and reduces the chance that pests will evolve resistance to pesticides.

Cycles of Materials through Ecosystem Compartments

As we have just seen, energy flows through ecosystems according to the second law of thermodynamics. At each transformation, much of it is dissipated as heat, a form that cannot be used by organisms to power their metabolism. Chemical elements, on the other hand, are not lost when they are transferred among organisms; they cycle repeatedly through organisms and the physical environment. The carbon and nitrogen atoms of which life is composed today are the same atoms that made up dinosaurs, insects, and trees in the Mesozoic era. The amounts of carbon, nitrogen, phosphorus, calcium, sodium, sulfur, hydrogen, oxygen, and other chemical elements on Earth do not change, but the quantities that are available to organisms are strongly influenced by how organisms get them, how long they hold onto them, and what they do with them while they have them.

To understand the cycling of elements, it is convenient to divide the global ecosystem into four compartments: (1) oceans, (2) fresh water, (3) land, and (4) atmosphere. The physical environments in each compartment and the types of organisms living there are different. Therefore the amounts of elements found in the different compartments, what happens to those elements, and the rates at which they enter and leave the compartments differ strikingly. After we have described these compartments, we will consider them together to illustrate how elements cycle through the global ecosystem.

Oceans receive materials from the land and atmosphere

Oceans receive chemical elements from land as runoff from rivers. The immediate receivers of materials from land are often fresh waters and the atmosphere, but, on time scales of hundreds to thousands of years, oceans receive most of those materials, including those produced by human activity. Because of their huge size, and because oceans exchange materials with the atmosphere only at their surface, oceans respond very slowly to outside inputs.

Elements that enter the oceans from other compartments gradually sink to the seafloor and remain there, unless

something happens to bring them back to the surface. Most elements remain in the bottom sediments until they are elevated above sea level by movements of Earth's crust. This process may take many millions of years. For this reason, concentrations of mineral nutrients are very low throughout the ocean. Oxygen, however, is usually present at all depths, because even slow mixing suffices to replenish the oxygen consumed by the respiration and decomposition of the few organisms that live in the nutrient-poor ocean waters.

Except on the relatively shallow continental shelves, ocean waters mix very slowly and are strongly stratified by depth. Typically there is a well-defined depth zone—a thermocline—at which temperatures drop abruptly. Some elements are stirred to the surface by cool bottom water that rises up well. Much upwelling occurs near the coasts of continents where offshore winds push surface waters away from shore (Figure 56.10). Waters in these zones of upwelling are rich in nutrients, and most of the world's great fisheries

" $r' - 7^{\circ}$ ■ -.

are concentrated there.

Lakes and rivers contain only a small fraction of Earth's water

Lakes and rivers contain much less water than oceans do, and because these bodies of water are relatively small, most mineral nutrients entering them are not buried in bottom sediments for long periods of time. Some mineral nutrients enter fresh waters in rainfall, but most are released by the weathering of rocks and are carried to lakes and rivers via

Primary production (mg of carbon per m² per day)

□ <150 | 1150-250 H >25 °

56.10 Primary Production is High in Zones of Upwelling

Primary production in the oceans is highest near continents where surface waters, driven by prevailing winds, move offshore and are replaced by cool, nutrient-rich water upwelling from below.

1000 CHAPTER FIFTY-SIX

56.11 Annual Temperature and Oxygen Cycles in a Temperate Lake

These vertical temperature and oxygen profiles are typical of temperate zone lakes that freeze in winter.

Wind

Turnovers occur in the spring and fall and allow nutrients and oxygen to become evenly distributed in the water column.

g groundwater (the water that resides in soil and rocks) or by surface flow.

After entering rivers, mineral nutrients are usually carried rapidly to lakes or to the oceans. In lakes they are taken up by organisms and incorporated into their cells. These organisms eventually die and sink to the bottom, where decomposition of their tissues consumes the oxygen. Surface waters of lakes thus quickly become depleted of nutrients, while deeper waters become depleted of oxygen. However, this stratification process is countered by vertical movements of water—turnover—that bring nutrients and dissolved CO₂ to the surface and oxygen to deeper water. Wind is an important agent of turnover in shallow lakes, but in deeper lakes it usually mixes only surface waters.

Lakes in temperate regions turn over because water is most dense at 4°C; above and below that temperature it expands (Figure 56.11). In spring, the sun warms the surface layer of a lake. The depth of the warm layer gradually increases as spring and summer progress. However, there is still a well-defined thermocline where the temperature drops abruptly to about 4°C. Only if the lake is shallow enough to warm to the bottom does the temperature of the deepest water rise above 4°C.

In autumn, as the surface of the lake cools, the cooler surface water, which is denser than the warmer water below it, sinks, and is replaced by warmer water from below. This process continues until the entire lake has reached 4°C. At this point, the

density of the water is uniform throughout the lake, and even modest winds readily mix the entire water column. As colder weather then cools the surface water below 4°C, that water becomes less dense than the 4°C water below it. Therefore, it floats at the top. Another turnover occurs in spring, when the surface layers above the thermocline warm to 4°C and the water column, again being of uniform density throughout, is easily mixed by wind.

Deep tropical and subtropical lakes may be permanently stratified because they never become cool enough to have uniformly dense water. Their bottom waters lack oxygen because decomposition quickly depletes any oxygen that

reaches them. However, many tropical lakes are overturned at least periodically by strong winds so that their deeper waters are occasionally oxygenated. Arctic lakes turn over only once each year.

The atmosphere regulates temperatures close to Earth's surface

The atmosphere is a thin layer of gases surrounding Earth. About 80 percent of the mass of the atmosphere lies in its lowest layer, the troposphere, which extends upward from Earth's surface about 17 km in the tropics and subtropics, but only about 10 km at higher latitudes. Most global air circulation takes place within the troposphere, and virtually all atmospheric water vapor is located there.

The stratosphere, which extends upward from the top of the troposphere to about 50 km above Earth's surface, con-

tains about 99 percent of the remaining atmospheric mass, but it is extremely dry. Materials enter the stratosphere from the troposphere near the equator, where air rises to high altitudes. These materials tend to remain in the stratosphere for a relatively long time because stratospheric air circulation is horizontal. Ozone (O_3) in the stratosphere absorbs most incoming short-wavelength ultraviolet radiation, shielding organisms from its damaging effects.

The atmosphere is composed of 78.08 percent nitrogen as N_2 , 20.95 percent oxygen, 0.93 percent argon, and 0.03 percent carbon dioxide. It also contains traces of hydrogen gas, neon, helium, krypton, xenon, ozone, and methane. The atmosphere contains Earth's biggest pool of nitrogen and large supplies of oxygen. Although carbon dioxide constitutes a very small fraction of the atmosphere, it is the source of the carbon used by terrestrial photosynthetic organisms.

The atmosphere plays a decisive role in regulating temperatures at and close to Earth's surface. Without an atmosphere, the average surface temperature of Earth would be about -18°C, rather than the actual +17°C. The atmosphere is relatively transparent to visible light, but it traps a large part of the outgoing infrared radiation (heat) that is emitted by Earth. It traps heat at Earth's surface in a way analogous

The numbers give the relative amounts of water (expressed as units of 10^{18} g) held or exchanged.

ECOSYSTEMS

1001

Although rocks contain large quantities of water, this "locked-in" water plays a very small role in the hydrological cycle.

to the glass in a greenhouse, which is why this phenomenon is called the greenhouse effect. Water vapor, carbon dioxide, and ozone are especially important transmitters of infrared radiation. That is why, as we will see below, elevated concentrations of atmospheric carbon dioxide caused by human activities may lead to major climatic changes.

Land covers about one-fourth of Earth's surface

About one-fourth of Earth's surface, most of it in the Northern Hemisphere, is currently above sea level. Most of this land is covered by a layer of soil. Even though the global supply of nutrients is constant, regional and local deficiencies strongly affect ecosystem processes on land. Such deficiencies occur because, unlike their behavior in air and water, elements on land move slowly, and they usually move only short distances.

The terrestrial compartment is connected to the atmospheric compartment by terrestrial organisms that take chemical elements from and release them to the air. Chemical elements in soils are carried in solution into the ground-water and eventually into rivers and oceans where they are lost to organisms until geological processes raise marine sediments above sea level, and a new cycle of erosion and weathering begins. The type of soil that forms in an area and the elements it contains depend on the underlying rock, as well as on climate, topography, the organisms living there, and the length of time that soil-forming processes have been acting. Very old soils contain fewer nutrients than most young soils.

Biogeochemical Cycles

The chemical elements organisms need in large quantities—carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur—cycle through organisms to the physical environment and back again.

56.12 The Global Hydrological Cycle

The numbers show the relative amounts of water (expressed as units of 10^{18} g) held in or exchanged annually by ecosystem compartments. The widths of the arrows are proportional to the sizes of the fluxes.

environment and back again. The pattern of movement of a chemical element through organisms and compartments of the physical environment is called its biogeochemical cycle. Some chemical elements circulate continually, but large quantities of other elements are temporarily lost from circulation through deposition in deep-sea sediments.

Each chemical element used by organisms has a distinctive biogeochemical cycle whose properties depend on the physical and chemical nature of the element and how organisms use it. All chemical elements cycle quickly through organisms because no individual, even of the longest-lived species, lives very long in geological terms. Chemical elements, such as carbon and nitrogen, that exist in the atmosphere as a gas cycle faster than nongaseous elements. After discussing the movements of water, we discuss the cycling of the most abundant chemical elements in organisms.

Water cycles through the oceans, fresh waters, atmosphere, and land.

The cycling of water through the four ecosystem compartments is known as the hydrological cycle (Figure 56.12). Although water is a compound, not an element, we describe its cycle here together with those of individual elements because of its importance to life.

The hydrological cycle is driven by the evaporation of water, most of it from ocean surfaces. Some water returns to the oceans as precipitation, but much less falls back on the oceans than is evaporated from them. The remaining evaporated water is carried by winds over the land, where it falls as rain or snow.

Water also evaporates from soils, from freshwater lakes and rivers, and from the leaves of plants (transpiration), but the total amount evaporated is less than the amount that falls on land as precipitation. The excess water eventually returns to the oceans via rivers, coastal runoff, and subterranean flows.

Organisms profoundly influence the carbon cycle.

Organisms are triumphs of carbon chemistry. To survive, they must have access to carbon atoms. Nearly all the carbon in organisms comes from carbon dioxide (CO_2) in the atmosphere or dissolved carbonate ions (HCO_3^-) in water. In the cells of some bacteria, photosynthetic protists, and the leaves of plants, carbon is incorporated into organic molecules.

t

Q The two large reservoirs of carbon are carbon-containing minerals in rocks (including fossil fuels)...

1002 CHAPTER FIFTY-SIX

56.13 The Global Carbon Cycle

The numbers show the quantities of carbon (expressed as units of 10^{15} g) in organisms and in ecosystem compartments, and the amounts that move annually between them.

Deforestation:

(1-2)⁴

(yul es by pho tos ynthe sis. All organisms in Other groups get their carbon by consuming other organisms, their remains, or their waste products.

Although marine organisms contain a very little of Earth's total carbon, they have a profound influence on the distribution of carbon in the oceans. They convert soluble carbonate ions in seawater into insoluble ocean sediments by depositing carbon in their shells and skeletons, which eventually sink to the bottom.

Biological processes on land move carbon between the atmospheric and terrestrial compartments, removing it from the atmosphere during photosynthesis and returning it to the atmosphere during respiration (Figure 56.13). Growing plants at mid- and high latitudes in the Northern Hemisphere incorporate so much carbon into their bodies that they reduce the concentration of atmospheric CO_2 , from about 350 parts per million in winter to 335 parts per million in midsummer. This carbon is released back into the atmosphere by decomposition in autumn.

At times in the remote past, large quantities of carbon were removed from the cycling when organisms died in large numbers and were buried in sediments lacking oxygen. In such environments, detritivores do not reduce organic carbon to carbon

dioxide. Instead, organic molecules accumulate and eventually are transformed into oil, natural gas, coal, or peat (decomposed remains of plants in high-latitude bogs). Humans have discovered and used these deposits, known as fossil fuels, at ever increasing rates during the past 150 years. As a result, carbon dioxide, the final product of burning these fuels, is being released into the atmosphere faster than it is being transferred to the oceans and incorporated into terrestrial biomass (Figure 56.14).

Based on a variety of calculations, atmospheric scientists believe that 150 years ago, before the Industrial Revolution, the concentration of atmospheric CO₂ was probably about 265 parts per million. Today it is 350 parts per million. This increase has been caused primarily by combustion of fossil fuels and secondarily by the burning of forests. If current trends in both these activities continue, atmospheric CO₂ is expected to reach 580 parts per million by the middle of the twenty-first century. This CO₂ will eventually be transferred to the oceans and deposited in sediments as calcium carbonate (CaCO₃), but the rate of transfer is much slower than the rate at which humans are introducing CO₂ into the atmosphere.

Atmospheric CO₂ is the immediate source of carbon for terrestrial organisms.

The widths of the arrows are proportional to the size of the flux.

o...,in Tintin

d dissolved carbon the oceans.

Enough carbon is being released by the burning of fossil fuels to alter the heat balance of Earth. As we saw above, carbon dioxide is one of the components of the atmosphere that traps infrared radiation at Earth's surface. Scientists have measured the concentration of CO₂ in air trapped in the Antarctic and Greenland ice caps during the last Ice Age—between 15,000 and 30,000 years ago—when the climate was much colder. The CO₂ concentration then was as low as 200 parts per million. During a warm interval that occurred some 5,000 years ago, it may have been slightly higher than it is today. EXPERIMENT

Question: What effect do CO₂ levels have on a community of soil organisms?

ECOSYSTEMS

1003

METHOD

1. Establish multiple plots containing the same communities of organisms. Maintain half of the units at experimentally high levels of atmospheric CO₂, the others at normal atmospheric levels.
2. Maintain communities for three generations (9 months).
3. Measure abundances of three species of collembolans (springtails), prominent members of the community.

RESULTS With elevated CO₂, species 1 became more prevalent, while species 2 remained the same and species 3 dramatically decreased.

Conclusion: High levels of CO₂ dramatically changed the species composition of the experimental communities.

56.15 Increased Atmospheric CO₂ Concentrations Alter Soil Communities

After 9 months of exposure to elevated CO₂ concentrations, the relative abundances of three collembolan insect species (spring-tails) differed dramatically from those in communities exposed to normal atmospheric CO₂ concentrations.

It demonstrates a relationship between climate and atmospheric CO₂ levels, is a major reason why scientists expect global

warming as atmospheric CO₂ levels continue to increase.

A doubling of atmospheric CO₂ would shift climate zones toward the poles. Complex computer models predict there would probably be droughts in the central regions of continents while precipitation would increase in coastal areas.

Current evidence indicates such warming is already underway. The average global temperature has risen steadily over the past 20 years, and the sheets of sea ice surrounding the polar land masses have become smaller and thinner. The glaciers have risen by an average of a few centimeters worldwide, and some islands, such as Bermuda, have seen even greater effects. If global warming were to result in the melting of the Greenland and Antarctic ice caps, rising sea levels could flood coastal cities and agricultural lands.

In addition to studying the potential effects of global warming on ecosystem processes, ecologists are investigating

the direct effects of elevated CO₂ concentrations on ecosystems. Increases in CO₂ affect plants directly because CO₂ is the source of carbon for photosynthesis. Their effects on other organisms are indirect.

To determine how elevated concentrations of atmospheric CO₂ might influence soil biota, ecologists established and maintained sixteen 1-m² experimental plots, into which they introduced the same community of plants, herbivores, carnivores, and soil microorganisms. All sixteen plots were maintained under the same conditions, except that CO₂ levels were allowed to vary naturally in half of them but were kept high in the other half. After three plant generations, the abundance and species composition of soil microorganisms were about the same under the two conditions. However, populations of cellulose-decomposing fungi increased dramatically under the elevated CO₂ condition, and the species composition also changed. Populations of springtails—wingless insects that eat fungi—also increased, and different species dominated the biota (Figure 56.15). The sequence of these changes appeared to be:

- ▶ increased plant photosynthesis →
- ▶ increased transport of carbon belowground →
- ▶ increased dissolved organic carbon →
- ▶ changes in soil fungal assemblages →
- ▶ changes in abundances and species composition of springtails.

To ecologists, these changes are striking. However, these experiments inform us only about relatively short-term changes. Other experiments are being run to assess long-term changes in the functioning of ecological systems in response to elevated atmospheric concentrations of CO₂.

Few organisms can use elemental nitrogen

Although nitrogen gas (N₂) makes up about 78 percent of the atmosphere, it cannot be used by most organisms in this form. It can be converted into biologically useful forms only by a few species of bacteria and cyanobacteria, which convert N₂ into ammonia by a process called nitrogen fixation (see Chapter 36). So, despite the abundance of N₂, usable nitrogen is often in short supply in ecosystems.

Why don't nitrogen-fixing organisms increase in numbers so that nitrogen is no longer a limiting resource? Fixing nitrogen is energetically expensive; as a result, nitrogen-fixing organisms often lose out in competition with non-fixers when nitrogen becomes more readily available. Nitrogen tends to be lost rapidly from ecosystems by leaching, volatilization of ammonia, and denitrification (the return of nitrogen to the atmosphere as nitrogen gas, N₂ by some organisms), but is released only slowly by decomposition of detritus.

Organisms called nitrifiers neither take up nitrogen gas directly from the atmosphere nor respire nitrogen back to the atmosphere. Instead, they convert organic molecules containing nitrogen to inorganic molecules. This process is carried out in several stages by different organisms. Most of the resulting "nitrogen-containing compounds, such as nitro-

1004 CHAPTER FIFTY-SIX

56.16 The Global Nitrogen Cycle

The numbers show the quantities of nitrogen (expressed as units of 10⁹ kg) in organisms and in ecosystem compartments, and the amounts that move annually between compartments. The widths of the arrows are proportional to the sizes of the fluxes.

The several stages of inorganic nitrogen are nitrate (NO₃⁻), nitrite (NO₂⁻), and ammonium (NH₄⁺).

Nitrate or ammonia, are taken up by plants. This movement of nitrogen among organisms accounts for about 95 percent of all nitrogen flux on Earth (Figure 56.16).

Organisms drive the sulfur cycle

Emissions of volatile sulfur dioxide (SO_2) and hydrogen sulfide (H_2S) from volcanoes and fumaroles (vents for hot gases) are the primary significant natural nonbiological fluxes

of sulfur. These emissions release, on average, between 10 and 20 percent of the total natural flux of sulfur to the atmosphere, but they vary greatly in time and space. Large volcanic eruptions spread great quantities of sulfur over broad areas, but they are rare events.

Volatile sulfur compounds are also emitted by both terrestrial and marine organisms. Certain marine algae produce large amounts of dimethyl sulfide (CH_3SCH_3), which accounts for about half of the biotic component of the sulfur cycle. The other half is produced by terrestrial organisms.

Sulfur is apparently always abundant enough to meet the needs of living organisms. It also plays an important role in global climate patterns. Even if air is moist, clouds do not form readily unless there are small particles around which water can condense. Dimethyl sulfide is the major source of such particles. Therefore, increases or decreases in sulfur emissions can change cloud cover and hence climate.

Humans have altered the nitrogen and sulfur cycles, largely through the burning of fossil fuels. An important regional effect of this alteration is acid precipitation—rain or snow whose pH is lowered by the presence of sulfuric acid (H_2SO_4) and nitric acid (HNO_3). These acids enter the atmosphere, primarily from industrial smokestacks and automobile emissions, and may travel hundreds of kilometers before they settle to Earth in precipitation or as dry particles.

Acid precipitation now characterizes all major industrialized countries and is particularly widespread in eastern North America and Europe. The normal pH of precipitation in New England is about 5.6, but precipitation there now averages about pH 4.1, and there are occasional storms with a precipitation pH as low as 3.0. Precipitation with a pH of about 3.5 or lower causes direct damage to the leaves of plants and reduces photosynthetic rates. Fortunately, as a result of the establishment of a flexible regulatory system

under the 1990 Clean Air Act Amendments, precipitation in much of the eastern United States is less acid today than it was 15 years ago, primarily because of reductions in emissions of sulfur (Figure 56.17).

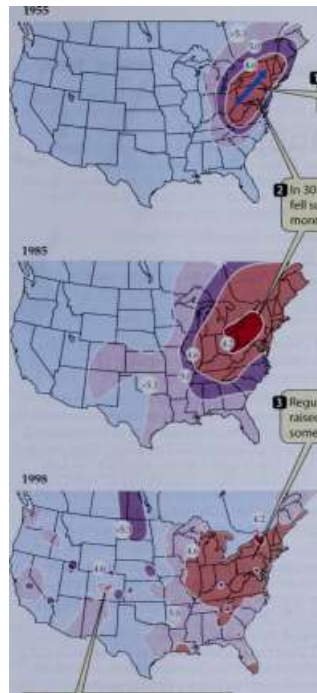

Ecologists in Canada studied the effects of acid precipitation by adding enough sulfuric acid to two small lakes to reduce their pH from about 6.6 to 5.2. In both lakes, nitrifying bacteria

ceased to function. As a result, the nitrogen cycle was blocked and ammonium accumulated in the water. When the ecologists stopped adding acid to one of the lakes, its pH increased to 5.4, and nitrification resumed. After about 1-year, the pH of the lake returned to its original value. These experiments show that lakes are very sensitive to acidification, but can recover quickly when pH returns to normal values.

The phosphorus cycle has no gaseous phase

The phosphorus cycle differs from the other biogeochemical cycles discussed in this section in that it lacks a gaseous phase. Some phosphorus is transported on dust particles, but in general the atmosphere plays a very minor role in the phosphorus cycle. Phosphorus exists mostly as phosphate (PO_4^{3-}) or similar compounds. Most phosphate deposits are of marine origin. On land, phosphorus becomes available through the slow weathering and dissolution of rocks and minerals.

Organisms need phosphorus as a component of the energy-rich molecules involved in cellular metabolism. Phosphorus is often a limiting nutrient in soils and lakes. That is why phosphate is a component of most fertilizers, and why adding phosphate to lakes causes marked increases in their biological productivity. The extra phosphorus from fertilizers and detergents that enters lakes through runoff allows algae and bacteria to multiply, forming blooms that turn water green. The decomposition of the extra biomass produced by this increased biological activity consumes all the oxygen in the lake, and anaerobic organisms come to dominate the sediments. These anaerobic organisms do not

Because of prevailing winds, acid rains affect areas far from the pollution sources.

ECOSYSTEMS 1005

56.17 Acid Precipitation is Decreasing in the Eastern United States

Thanks to emission controls, precipitation in many parts of the eastern United States is less acid than it was two decades ago. The figure shows the regional average pH of precipitation.

In 30 years, pH of precipitation fell substantially (became more acidic).

fj Regulation of emission sources has raised the pH of precipitation in some areas of the Northeast...

f

... but in many areas of the West, precipitation is becoming more acidic.

break down organic compounds all the way to carbon dioxide. Many of the end products of their activities have unpleasant odors.

Lake Erie is an example of such a ^utrophic (enriched) lake. Two hundred years ago it had only moderate levels of photosynthesis and clear, oxygenated water. Today more than 15 million people live in the Lake Erie basin. Nearby cities pour more than 250 billion liters of domestic and industrial wastes into the lake annually. The entire basin is intensely farmed and heavily fertilized.

In the early part of the twentieth century, nutrients in the lake increased greatly, and algae proliferated. At the water filtration plant in Cleveland, algae increased from 81 per milliliter in 1929 to 2,423 per milliliter in 1962. Algal blooms and populations of bacteria also increased. Numbers of the human fecal bacterium *Escherichia coli* increased enough to cause the closing of many of the lake's beaches as health

As a result, the amount of phosphate added to Lake Erie has decreased more than 80 percent from the maximum level, and phosphorus concentrations in the lake have declined substantially. ^Tre~deeper waters of Lake Erie still become poor in oxygen during the summer months, but the rate of oxygen depletion is declining. Algal blooms have decreased, as have populations of small fishes that feed on algae.

The rate at which a eutrophic lake recovers depends on the replacement rate of its waters. Because water flows slowly through Lake Erie, it will take many years for the lake to recover from the heavy pollutant loads it has received. By contrast, the water in Lake Washington, a smaller lake adjacent to the city of Seattle, is replaced every 3 years. When sewage was diverted away from Lake Washington, the lake returned to its former condition within a decade.

Humans influence other biogeochemical cycles

In addition to modifying the great natural biogeochemical cycles we have just described, human activities are increasing the cycling of elements such as lead and creating cycles of synthetic chemicals, such as DDT. These changes are large enough to cause serious environmental problems. However, the results of experiments show [■]tha ecosystems have the capacity to recover from many disturbances*! the alterations have not been too great and the disturbing forces are reduced or eliminated. Controlling our manipulations of biogeochemical cycles so that ecosystems can continue to provide the goods and services upon which humanity depends is one of the major challenges facing modern societies.

Since 1972, the United States and Canada have invested more than 8 billion dollars to improve municipal waste facilities and reduce discharges of phosphorus into Lake Erie.

Chapter Summary

► The organisms living in a particular area, together with the physical environment with which they interact, constitute an ecosystem. At a global scale, Earth is a single ecosystem.

Climates on Earth

- Air and water movements on Earth are driven primarily by solar radiation.
- Climates determine the amount of heat, moisture, and sunlight available to living organisms in different places on Earth.
- Rising air expands and cools, releasing moisture. Descending air warms and dries and takes up moisture, creating rain shadows. Review Figure 56.1
- Global air circulation is driven by solar radiation and the spinning of Earth on its axis. Review Figure 56.2

1006 CHAPTER FIFTY-SIX

- Oceanic currents are driven primarily by prevailing winds. Review Figure 56.3

Energy Flow through Ecosystems

- The capture of solar radiation by photosynthesis powers ecosystem productivity.
- The annual production of an area is determined primarily by temperature and moisture. Review Figures 56.4, 56.5
- Energy flows through ecosystems as organisms capture and store energy and transfer it to other organisms when they are eaten. Organisms are grouped into trophic levels according to the number of steps through which energy passes to get to them. Review Table 56.1
- Who eats whom in an ecosystem can be diagrammed as a food web. Review Figure 56.6
- The amount of energy flowing through an ecosystem depends on net primary production and on the efficiency of transfer of energy from one trophic level to another. Review Figures 56.7, 56.8
- A few deep-sea and cave ecosystems are powered by chemosynthesis rather than photosynthesis.
- Through agriculture, humans manipulate ecosystem productivity so as to increase the yield of products useful to us. In modern agriculture, the energy required to do this is provided by fossil fuels.

Cycles of Materials through Ecosystem Compartments

- The main compartments of the global ecosystem are the oceans, fresh waters, land, and atmosphere, among which materials are constantly being exchanged.
- Primary production in the oceans is highest adjacent to continents in zones of upwelling, where nutrient-rich waters rise to the surface. Review Figure 56.10
- Temperate-zone lakes turn over twice each year as water cools and warms. Review Figure 56.11

Biogeochemical Cycles

- The elements organisms need in large quantities cycle through organisms to the environment and back again.
- The hydrological cycle is driven by evaporation of water, most of it from ocean surfaces. Review Figure 56.12

* ■ Atmospheric carbon dioxide is the immediate source of carbon for terrestrial organisms, but only a small part of Earth's carbon is found in the atmosphere. Review Figure 56.13

^ Increasing concentrations of carbon dioxide in the atmosphere are changing climates and influencing ecological processes. Review Figures 56.14, 56.15

- Although nitrogen makes up 78 percent of Earth's atmosphere, nitrogen can be converted into biologically useful forms only by a few species of bacteria and cyanobacteria. Review Figure 56.16
- Acid precipitation, an important regional consequence of human modifications of the nitrogen and sulfur cycles, is being addressed in the United States by flexible regulations. Review Figure 56.17

- The phosphorus cycle differs from the cycles of carbon and nitrogen in that it lacks a gaseous phase.
- The most striking effect of altering the phosphorus cycle is lake eutrophication.

For Discussion

1. Continental climates are largely confined to the Northern Hemisphere. Why are there so few continental climates in the Southern Hemisphere?
2. The amount of energy flowing through a food chain declines more or less rapidly depending upon the nature of the organisms in the chain. Which of the following simplified food chains is likely to be more efficient? Why? What criteria of efficiency are you using?
 - a. phytoplankton → zooplankton → herring
 - b. shrubs → moose → wolf
3. What principles of ecosystem functioning underlie modern agricultural practices? Which components of those practices are most likely to be unsustainable in the long term?
4. How would you expect temperature and oxygen profiles to appear in a broad, shallow tropical lake? In a very deep tropical lake? A subarctic lake? Why?
5. The waters of Lake Washington, adjacent to the city of Seattle, rapidly returned to their preindustrial condition when sewage was diverted from the lake to Puget Sound, an arm of the Pacific Ocean. Would all lakes being polluted with sewage clean themselves up as rapidly as Lake Washington if pollutant input were stopped? What characteristics of a lake are most important to its rate of recovery following removal of pollutant inputs? What are the likely ecological effects of the diverted sewage in Puget Sound?

Tropical forests currently are being cut at a very rapid rate. Does this necessarily mean that deforestation is a major source of input of carbon dioxide to the atmosphere? If not, why not?

Why do elevated atmospheric concentrations of carbon dioxide have direct effects on plants but not on animals? What are the most important indirect effects on animals, and by what ecological pathways do they operate?

The two drawings below represent pyramids of biomass for (a) an old field in Georgia and (b) the English Channel. Explain the significance of the inversion of the second pyramid compared with the first.

Which of the ecological results you have just outlined would still happen?

57

Biogeography

When the first Europeans arrived in Australia, they saw plants and animals that differed

in perplexing ways from the ones they knew at home. Among the oddities they found were flowers pollinated by brush-tongued parrots and mammals that hopped around on their hind legs, carrying their offspring in pouches. The first Europeans to visit North America felt more at home because the plants and animals of North America were more similar to those of Europe.

During their worldwide travels, European explorers found many vegetation types—tropical forests, mangrove forests, and deserts with tall cacti—that were unfamiliar to them, but they also found many areas where the vegetation forms and species were similar to what they knew back home. The study of the distribution of organisms over Earth's surface began when those eighteenth-century travelers first noted intercontinental differences in biotas and attempted to understand them.

Biogeography is the science that attempts to explain patterns of variation among individuals, populations, species, and communities across Earth. In this chapter, we will show how biogeographers study both events in the remote past and current ecological processes to discover how they influence the distribution patterns we see today.

Why Are Species Found Where They Are?

Explaining species' distributions might seem to be a simple matter because the question of why a species is or is not found in a certain location has only a few possible answers:

- If a species occupies a particular area, either it evolved there, or it evolved elsewhere and dispersed to that area.
- If a species is not found in a particular area, either it evolved elsewhere and never dispersed to that area, or it was once present in that area but no longer lives there.

Unfortunately, determining which of these answers is correct turns out to be far from simple.

To explain the distributions of organisms, biogeographers must draw upon and interpret a broad array of know-

Strange Organisms in New Places

Kangaroos that hopped on large hind legs and carried their offspring in pouches were novel sights to the Europeans who colonized Australia.

Answering the questions listed above requires information about the evolutionary histories of species, which comes from fossils and from knowledge of their phylogenetic relationships. It also requires information about changes in Earth itself—continental drift, glacial advances and retreats, sea level changes, and mountain building—during the time the organisms were evolving. Such geological information can tell us whether organisms evolved where they are currently found or dispersed to colonize new areas from a distant area of origin. In this section we show how the acceptance of continental drift and the use of new methods of reconstructing phylogenies changed the science of biogeography:

1008 CHAPTER FIFTY-SEVEN

Ancient events influence current distributions

Early biogeographers believed in an unchanging Earth that was too young to account for the diversity and distribution of life by any means except divine creation. Linnaeus, for example, believed that all organisms had been created in one place—which he called Paradise—from which they later dispersed. Indeed, because most people believed that the continents were fixed in their positions, the only way to account for current distributions was to invoke massive dispersal.

The notion that the continents might have moved was not seriously considered until 1912. Alfred Wegener, the German meteorologist who proposed the idea of continental drift, based his theory on several observations:

- the shapes of continents (the outlines of Africa and South America seemed to fit together like pieces of a puzzle)
- the alignment of mountain chains, rock strata, coal beds, and glacial deposits on different continents
- the distributions of organisms (the distributions of species in Africa and South America were hard to explain if one

assumed that the continents had never moved)

When Wegener proposed his ideas, few scientists took them seriously, primarily because there were no known mechanisms to move continents and because no convincing geological evidence of such movements existed. As we learned in Chapter 20, geological evidence and plausible mechanisms were eventually discovered, and the broad pattern of continental movement is now clear.

About 280 million years ago—the continents were united

to form a single land mass, Pangaea (see Figure 20.13). By the early Mesozoic era (about 245 million years ago), when the continents were still very close to one another, many groups of organisms in each of the

warm tropical regions and various polar regions

evolved. The ancestors of some organisms that live on widely separated continents today were probably present on those land masses when they were part of Pangaea.

By 100 million years ago, Pangaea had separated into northern (Laurasia) land masses, and the southern continents were drifting away from each other (see Figure 20.15). Eventually, continental drift, which continues today, brought India from Africa to southern Asia, Australia closer to Southeast Asia, and South America, which had drifted as an island for 60 million years, into contact with North America. Continental drift has thus influenced the evolution and mixing of species throughout the history of life on Earth.

Modern biogeographic methods

As the great age of Earth and the fact of evolution began to be understood, two groups of investigators developed new methods for generating testable hypotheses about geographic distribution. One group of biogeographers

current distributions are influenced by interactions

among species and by interactions between species and their physical environments. They examine species interactions of the types discussed in Chapter 55 to explain patterns of local and regional species diversity. We will see

some examples of their work later in this chapter

The other group of investigators consists of historical biogeographers who concentrate on longer time frames and larger spatial scales. They ask questions such as

- Where and when did evolutionary lineages originate?
- How did they spread?
- What do the present-day distributions of organisms tell us about their past histories?

An important technique developed by historical biogeographers was the transformation of taxonomic phylogenies into "area phylogenies" by substituting the taxa's geographic distributions for their names. Distribution patterns identified in this manner may suggest routes of dispersal or point to the splitting of biotas due to the appearance of barriers to dispersal. For example, by combining the phylogenetic relationships and current distribution pattern of the horse family, we can better understand why its members are found where they are and where past barriers probably influenced speciation events among them (Figure 57.1).

If we compare the distribution patterns of many evolutionary lineages, we may detect similarities and differences. Similarities suggest common responses to physical events, such as continental drift, mountain building, and sea-level changes. Differences suggest that organisms in different lineages responded in different ways or at different times, or that they dispersed in different ways and at different times.

The Role of History in Biogeography

Past events influence today's patterns of distribution. We can never know past events with complete certainty, but by using a variety of types of evidence, historical biogeographers can develop and test hypotheses in which they eventually have a high degree of confidence. As we have just seen, biogeographers often base their interpretations on phylogenies, which show the evolutionary relationships among the organisms in a lineage (see Chapter 23). Phylogenies are most useful to biogeographers if the approximate times of evolutionary and geographic separations of lineages can be estimated.

Biogeographers use several approaches to infer the approximate times of separation of taxa within a lineage. First, if a taxon has been ticking at a relatively constant rate, the degree of difference in the molecules of species will be strongly correlated with time their lineages have been evolving independently (see Chapter 24). Second, fossils can help to show how long a taxon has been present in an area and whether its members formerly lived in areas where they are no longer found. The fossil record is helpful, but it is always incomplete. The first and

3.9

3 2 1

Millions of years ago (mya)

last members of a taxon to live in an area are extremely unlikely to have become fossils that are discovered and described. Therefore, dates of colonization and extinction cannot be estimated accurately. A third valuable source of information is the distributions of living species. Much more complete and extensive information can be gathered on current distributions than will ever be available from fossils. Much can be learned by examining the distribution patterns of many different groups of living organisms. Similarities in their distributions provide clues about past events that affected many of them.

Vicariance and dispersal can both explain distributions

As we have seen, a species may be found in an area either because it evolved there or because it dispersed to that area. But what if a species is found in two or more different places? What accounts for such a split distribution? There are two possibilities.

► A barrier may appear that splits a species' distribution. The barrier may be a physical barrier and dispersal need be postulated to account for a split distribution.

► Members of a species may cross an already existing barrier and establish a new population. In this case, the species' split range must be attributed to dispersal.

By studying a single evolutionary lineage, a biogeographer may discover evidence suggesting that the distributions of its ancestors were influenced by a vicariant event, such as a change in sea level, mountain building, or continental movement. If that inference is correct, species in other lineages are likely to have been influenced by the same event and should therefore have similar distribution patterns.

Differences in distribution patterns among lineages indicate either that the lineages responded differently to the same vicariant events, that they separated at different times, or that they have very different dispersal abilities. By analyzing such similarities and differences among lineages, biogeographers can discover the relative roles of vicariant events and dispersal in determining today's distribution patterns.

Species, genera, and families found in only one place are said to be endemic to that location. As far as we know—all species are endemic to Earth. Some species are endemic to one continent. Others are restricted to very small areas, such as tiny islands or single mountaintops. Because a species may disperse widely and then die out where it originated,

Prior to modern times, Cook Strait separated South Island and this peninsula, which then became part of North Island.

57.2 A Vicariant Distribution Explained

Blue circles indicate the current distribution of the weevil *Lyperobius huttoni*. Compare New Zealand's present geography with that of the Pliocene (inset), when the southern part of today's North Island was part of South Island.

quires the smallest number of unobserved events to a c-cojintior-itr-To see the application of the parsimony principle to biogeography, consider the distribution of the New Zealand flightless weevil *Lyperobius huttoni*, a species that is found in the mountains of South Island and on sea cliffs at the extreme southwestern corner of North Island (Figure 57.2). If you knew only its current distribution and the current positions of the two islands, you might guess that, even though this weevil cannot fly, *L. huttoni* had somehow managed to cross Cook Strait, the 25-km body of water that separates the two islands.

However, more than 60 other animal and plant species, including other species of flightless insects, live on both sides of Cook Strait. It is unlikely that all of these species made the same ocean crossing. In fact, that assumption is unnecessary to explain the distribution patterns. Geological evidence indicates that the present-day southwestern tip of North Island was formerly united with South Island. Therefore, none of the 60 species need have made a water crossing. A single vicariant event—the separation of the northern tip of South Island from the remainder of the Island by the newly formed Cook Strait—could have split aU of the

distributions. Although organisms do cross oceanic and terrestrial barriers, biogeographers often apply the parsimony principle when interpreting distribution patterns, just as evolutionists do when reconstructing phylogenies.

biogeographers cannot assume that a species now endemic to a location originated there. Endemic taxa can be very old ones that are in the process of becoming extinct, or very young taxa that have recently evolved in a restricted area.

The longer an area has been isolated from the rest of the world,

by a vicariant event, the more endemic taxa it is likely to

have, because there has been more time for evolution to take place.

Australia, which has been separated the longest from the other continents (about 65 million years), has the most distinct biota. South America has the next most distinct biota, having been isolated from other continents for nearly 60 million years. North America and Eurasia, which were joined together for much of Earth's history, have very similar biotas. That is why the early European travelers felt more at home in North America than in Australia.

Biogeographers use parsimony to explain distributions

When several hypotheses can explain a pattern, scientists typically prefer the most parsimonious one—the one that requires the fewest evolutionary changes.

57.3 Protead Distributions Reveal a Gondwana Ancestry

(a) Proteads from South Africa (left) and Australia (right).

(b) Current distribution (green) of the family Proteaceae.

Biogeographic histories are reconstructed from various kinds of evidence

Biogeographers use distribution maps, phylogenies, and knowledge of ancient climates and ancient geography to reconstruct the biogeographic histories of taxa. These kinds of information suggest, for example, that distributions of the proteads (family Proteaceae; Figure 57.3) have been influenced by continental drift many millions of years ago. These plants are found in Africa, but the African species are highly specialized members of an endemic subfamily. The South American species are members of a different subfamily, whose closest relatives are found in the Australian region. The phylogeny and distribution of proteads suggests that they had a broad distribution in Gondwana before that large continent began to break up, and that populations were carried by drifting land masses to their current locations. Protead lineages have been separated on the different continents long enough to have evolved major differences from one another.

Earth can be divided into biogeographic regions

Although the drifting continents carried many kinds of organisms with them, they have been isolated from one another long enough for distinct biotas to have evolved on them. Differences among continental biotas form the basis for dividing Earth into six major biogeographic regions: the Nearctic, Neotropical, Palearctic, Ethiopian, Australian, and Antarctic regions. Biogeographers drew the boundaries of these regions where species compositions change

dramatically over short distances (Figure 57.4). These biogeographic regions are based on taxonomic similarities among the organisms living in them, not on their appearances, and should not be confused with the biomes we will discuss later in this chapter.

Biogeographers agree on the boundaries of many of these regions, but plant biogeographers recognize two regions not used by zoogeographers: southern South America and the Cape Region of South Africa. The floras of these two regions are distinct from those of adjacent areas on those continents, but the faunas of southern South America and the Cape Region are very similar to those of the remainder of those continents.

Except for the Australasian region, the biogeographic regions are no longer separated from each other by water as they were in the past. The biological distinctness of these biogeographic regions is maintained today in part by mountain and desert barriers to dispersal and in part by major climatic changes over short distances.

Ecology and Biogeography

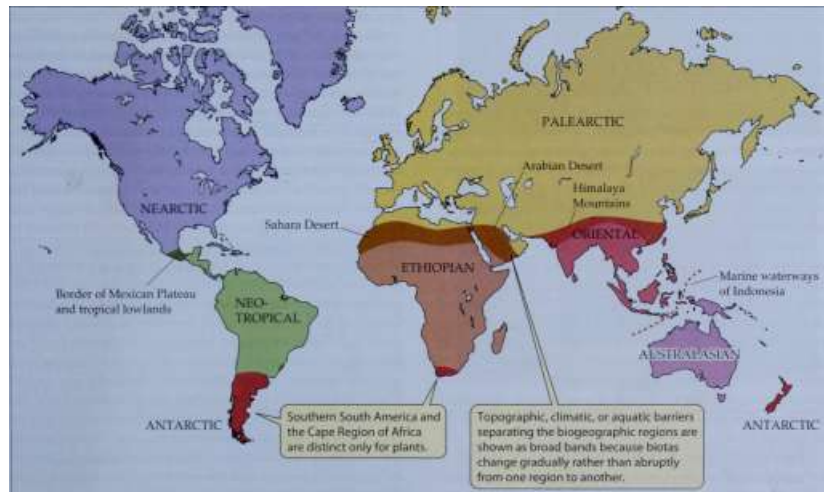

Ecological biogeographers use the wealth of available information on current distributions of organisms to test theories that explain the numbers of species in different com-

Island near mainland

Small island

Number of species

57.5 A Model of Species Richness on Islands

Rates of arrival of new species and extinction of species already present determine the equilibrium species richness.

munities, the ways in which species disperse, and the effects of different types of barriers to dispersal. They can also use experiments to test some hypotheses. Here we describe an influential biogeographic model that attempts to account for the number of species living in an area—its species richness—and then look at experiments conducted to test this model.

The species richness of an area is determined by rates of colonization and extinction

Over periods of a few hundred years (a time span during which speciation is unlikely), the species richness of an area depends on the immigration of new species and the extinction of species already present. It is easiest to visualize the effects of these two processes if we consider, as did Robert MacArthur and Edward Wilson, an oceanic island that initially has no species.

Imagine a newly formed oceanic island that receives colonists from a mainland area. The list of species on the mainland that might possibly colonize the island is called the species pool. The first colonists to arrive on the island are all "new" species because no species live there initially. As the number of species on the island increases, a larger fraction of colonists will be members of species already present. Therefore, even if the same number of species arrive as before, the rate of arrival of new species decreases, until it reaches zero when the island has all the species in the species pool.

Now consider extinction rates. First there will be only a few species on the island, and their populations may grow large. As

more species arrive and their populations in-

$S_{sf} S_{lf}^{sn} \ln$

Number of species

crease, the resources of the island will be divided among more species. We therefore expect the average population size of each species to become smaller as the number of species increases. The smaller a population, the more likely it is to become extinct. In addition, the number of species that can become extinct increases as species accumulate on the island. New arrivals to the island may include pathogens and predators that increase the probability of extinction of other species, further increasing the number of species becoming extinct per unit of time.

Because the rate of arrival of new species (i.e., colonization) decreases and the extinction rate increases as the number of species increases, eventually the number of species should reach an equilibrium at which the rates of arrival and extinction are equal (Figure 57.5a). If there are more species than the equilibrium number, extinctions should exceed arrivals, and species richness should decline. If there are fewer species than the equilibrium number, arrivals should exceed extinctions, and species richness should increase. The equilibrium is dynamic because if either rate fluctuates—as they generally do—the expected number of species shifts up and down.

Even if extinction and colonization rates are assumed to fluctuate somewhat, the model can be used to predict how species richness should differ among islands of different sizes and different distances from the mainland species pool. We expect extinction rates to be higher on small islands than on large islands because species' populations will, on average, be smaller there. Similarly, we expect fewer colonists to reach islands more distant from the mainland. Figure 57.5b gives hypothetical relative species richnesses for islands of different sizes and distances from the mainland. As you can see, the number of species should be highest for islands that are relatively large and relatively close to the mainland.

57.6 Small, Distant Islands Have Fewer Species

The dots show the numbers of land and freshwater bird species on islands of different sizes in the Moluccas, Melanesia, Micronesia, and Polynesia. These islands have been divided into three groups according to their distance from the "mainland," which is New Guinea.

The island biogeographic model has been tested

The island biogeographic model we have just described predicts that the number of species should increase with island size and decrease with distance from the mainland. Ecological biogeographers have tested the model using counts of species on real islands. New Guinea, which is large enough to function as a small continent, supplies the mainland species pool for islands farther east in the Pacific Ocean. The number of bird species found on those islands corresponds to the predictions of the model (Figure 57.6). The species richness patterns of plants, insects, lizards, and mammals on those islands are similar to those of birds.

The predictions of the island biogeographic model are based on assumptions about rates of colonization and extinction. Major disturbances, which serve as "natural experiments," sometimes permit colonization and extinction rates to be estimated directly. The eruption of Krakatau in August 1883, described in Chapter 20, destroyed all life on the island's surface. After the lava cooled, Krakatau was colonized rapidly by plants and animals from Sumatra to the east and Java to the west.

PERIOD

NUMBER OF SPECIES

EXTINCTIONS COLONIZATIONS

17 4

7 7

During the 1920s, a forest canopy was developing, and there were high rates of colonization by both birds (Table 57.1) and plants. Birds probably brought the seeds of many plants because, between 1908 and 1934, both the percentage (from 20 to 25 percent) and the absolute number (from 21 to 54 species) of plant species with bird-dispersed seeds increased. By 1933, Krakatau was again covered with a tropical evergreen forest, and 271 species of plants and 29 species of resident land birds were found there. Today the numbers of species of plants and birds are not increasing as fast as they did during the 1920s, but there are still colonizations and extinctions, as predicted by the model.

A manipulative experiment to test the island biogeographic model was carried out in the Florida Keys, a region dotted with thousands of small islands consisting entirely of red mangrove trees rooted in shallow water. Six tiny islands were fumigated with methyl bromide, which destroyed all arthropods living on them (Figure 57.7). Methyl bromide decomposes rapidly and does not inhibit recolonization.

The design of this experiment permitted the investigators to measure colonization and extinction rates directly.

RESEARCH METHOD

Scaffolding was erected to enclose a small mangrove island in the Florida Keys.

• v - ' - :

-

. II

Methyl bromide introduced into the enclosure killed all arthropods inside it.

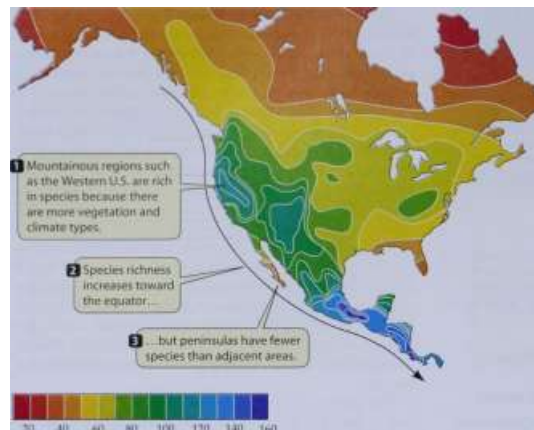

Over about a year, investigator observed and measured the rates of recolonization.

57.7 Experimental Island Biogeography

Scientists removed all species of arthropods from several small mangrove islands in the Florida Keys by enclosing them and fumigating them with methyl bromide. When the enclosures were removed, arthropods quickly recolonized the islands.

1014 CHAPTER FIFTY-SEVEN

40 60 80 100 120 140 160 Number of mammal species

They found that rates of colonization of the islands by arthropods were very high. Within a year the fumigated islands had about their original number of species, and each census revealed considerable turnover in the number of species present. Both results support the island biogeographic model.

Species richness varies latitudinally

A nearly universal pattern in the distribution of species is that more species live in tropical than in high-latitude regions. Figure 57.3 shows the latitudinal gradient in mammal species richness in North and Central America. Similar patterns exist for birds, frogs, and trees, and for many marine taxa.

The figure also shows two other general patterns of species richness. First, more species are found in mountainous regions than in relatively flat areas because more vegetation types and climates exist within topographically complex regions. Second, species richness declines on peninsulas, such as Florida and Baja California, probably because colonization is possible from only one direction.

®

Terrestrial Biomes

Another way in which ecologists describe the distribution patterns of organisms is by classifying ecosystems. They apply the name biome to a major ecosystem type that differs from other types in the structure of its dominant vegetation. The vegetation of a biome has a similar appearance wherever on Earth that biome is found, but the plant species in these communities, despite their physical similarity,

57.8 Latitudinal Gradient of Species Richness of North American Mammals

Lines on the figure connect regions with equal numbers of species. An increase in species richness toward the equator typifies many other taxa, such as birds, amphibians, and trees, as well as mammals.

ities, may not be evolutionarily closely related. Although biomes are named for and identified by their characteristic plants, sometimes supplemented by their location or climate, each biome contains many other kinds of organisms. The geographic distribution of biomes is shown in Figure 57.9.

Biomes are identified by their distinctive climates and dominant plants

Because climate plays a key role in determining which types of plants live in a given place, the distribution of biomes on Earth is strongly influenced by annual patterns of temperature and rainfall. In some biomes, such as temperate deciduous forest, precipitation is relatively constant throughout the year, but temperature varies strikingly between summer and winter. In other biomes, both temperature and precipitation change seasonally. In certain biomes, such as tropical rainforest, temperatures are nearly constant, but rainfall varies seasonally.

In the tropics, where seasonal temperature fluctuations are small, annual climatic cycles are dominated by wet and dry seasons. In general, the number of months during which a region is close to the intertropical convergence zone (and hence receives rainfall) increases toward the equator (see Chapter 56). The intertropical convergence zone shifts latitudinally in a seasonally predictable way, resulting in a characteristic latitudinal pattern of distribution of rainy and dry seasons in tropical and subtropical regions (Figure 57.10).

Pictures and graphs capture the essence of terrestrial biomes

It is easiest to grasp the similarities and differences among terrestrial biomes by means of a combination of photographs and graphs of temperature, precipitation, and biological activity, supplemented by a brief description of the species richness and other attributes of those biomes. We use this method in the following pages to describe the major terrestrial biomes of the world.

► Each biome is represented by two photographs that show either the biome at different times of year or representatives of the biome in different places on Earth.

57.9 Biomes Have Distinct Geographic Distributions

Compare these biomes with the patterns of net primary production shown in Figure 56.5.

► The first set of graphs plots seasonal patterns of temperature and precipitation at a typical site in the biome.

► Other graphs show how active different kinds of organisms are during the year. Levels of biological activity (shown by the width of horizontal bars) change either because resident organisms become more active (produce leaves, come out of hibernation, hatch, or reproduce) or because organisms migrate into and out of the biome. (The patterns shown are for the Northern Hemisphere; for high-latitude biomes, patterns in the Southern Hemisphere are 6 months out of phase with those illustrated.)

► A small box describes the dominant growth forms of plants in the biome and patterns of species richness there.

These descriptions are very general; they cannot capture the variation that exists within each biome.

Tropical alpine tundra: Teleki Valley, Mt. Kenya

Tundra is found at high latitudes and in high mountains

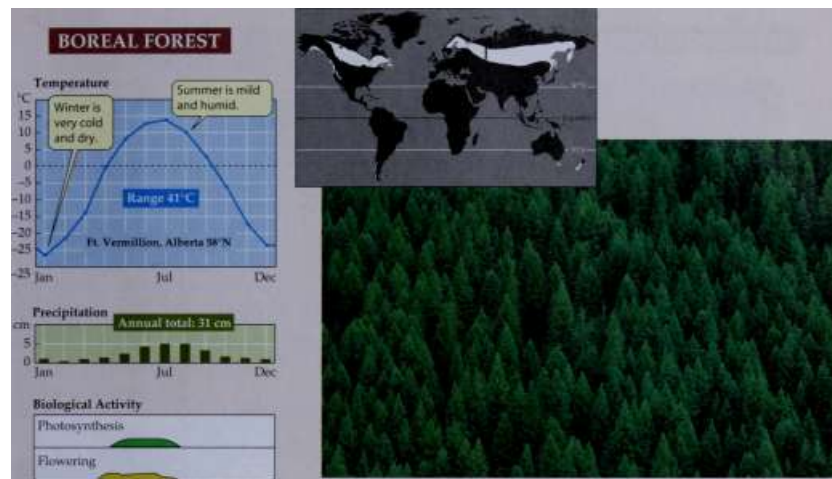

The tundra biome is found at high latitudes in the Arctic, Antarctic, and high in mountains at all latitudes (where it is called alpine tundra). There are no trees; the vegetation is dominated by short perennial plants.

Permanently frozen soil—permafrost—underlies tundra

vegetation. The top few centimeters of soil thaw during the short summers, when the sun shines 24 hours a day. Even though there is little precipitation, Arctic tundra is very wet because water cannot drain down through the frozen soil. Plants grow for only a few months each year. Most Arctic tundra animals either migrate into the area only for the summer or are dormant for most of the year.

Boreal forests are dominated by evergreen trees

The boreal forest biome is found equatorward from, or at lower elevations on temperate-zone mountains than, tundra. Winters are long and very cold, and summers are short (although often warm). The short summers favor trees with evergreen leaves because these trees are ready to photosynthesize as soon as temperatures warm in spring.

The boreal forests of the Northern Hemisphere are dominated by coniferous evergreen gymnosperms. In the

Southern Hemisphere, the dominant trees are southern beeches (*Nothofagus*). Evergreen forests also grow along the west coasts of continents at middle to high latitudes, where winters are mild but very wet and summers are cool and dry. These forests are home to Earth's tallest trees.

Boreal forests have only a few tree species. The dominant animals—such as insects, moose, and hares—eat leaves. The seeds in the cones of conifers also support a fauna of rodents and birds.

Temperate deciduous forests change with the seasons

The temperate deciduous forest biome is found in eastern North America, eastern Asia, and western Europe. Temperatures in these regions fluctuate dramatically between summer and winter. Precipitation is relatively evenly distributed throughout the year. Deciduous trees, which dominate these forests, produce leaves that photosynthesize rapidly

during the warm, moist summers and lose their leaves during the cold winters.

There are many more tree species here than in boreal forests. The temperate forests richest in species are in the southern Appalachian Mountains of the United States and in eastern China and Japan, areas that were not disturbed by Pleistocene glaciers. Many birds migrate into this biome in summer, when insects are abundant.

The Veldt, Natal, South Africa

Temperate grasslands are widespread

The temperate grassland biome is found in many parts of the world, all of which are relatively dry much of the year. Most grasslands have hot summers and relatively cold winters. In some grasslands most of the precipitation falls in winter; in others the majority falls in summer. Such regions as the pampas of Argentina, the veldt of South Africa, and the Great Plains of the United States are components of the

temperate grassland biome. Most of this biome has been converted to agriculture.

Grasslands are structurally simple, but they are rich in species of perennial grasses, sedges, and forbs. Grasses are well adapted to grazing and fire because they store much of their energy underground and quickly resprout after they are burned or grazed. As we saw in Chapter 56, many grasslands support large populations of grazing mammals.

Cold deserts are high and dry

The cold desert biome is found in dry regions at middle to high latitudes, especially in the interiors of large continents. Cold deserts also are found at fairly high altitudes in the rain shadows of mountain ranges. Seasonal changes in temperature are great.

Los Glaciers National Park, Argentina

Cold deserts are dominated by a few species of low-growing shrubs. The surface layers of the soil are recharged with moisture in winter, and plant growth is concentrated in spring. Cold deserts are relatively poor in species in most taxonomic groups, but the plants of this biome tend to produce large numbers of seeds, supporting a rich fauna of seed-eating birds, ants, and rodents.

Hot deserts form around 30° latitude

The hot desert biome is found in two belts, centered around 30°N and 30°S latitudes, respectively. These are the regions where dry air descends, warms, and picks up moisture (see Chapter 56). The driest large regions within this biome are in the center of Australia and the middle of the Sahara Desert of Africa.

Except in these driest regions, hot deserts have a richer and structurally more diverse vegetation than cold deserts. Succulent plants that store large quantities of water in their stems are conspicuous. Annual plants germinate and grow when rain falls. Pollination and seed dispersal by animals are common. Rodents and ants are often remarkably abundant, and lizards and snakes typically are rich in species and common.

The chaparral climate is dry and pleasant

The chaparral biome is found on the west sides of continents at moderate latitudes, where cool ocean waters flow offshore. Winters in this biome are cool and wet; summers are hot and dry. Such climates are found in the Mediterranean region of Europe, coastal California, central Chile, extreme southern Africa, and southwestern Australia.

Chaparral is dominated by low-growing shrubs and trees that have tough, evergreen leaves. The shrubs carry out most of their growth and photosynthesis in early

spring, which is when insects are active and birds breed. Annual plants are abundant, producing seeds that are deposited in soil "seed banks." This biome thus supports large populations of small rodents, most of which store seeds in underground burrows.

Chaparral vegetation is naturally adapted to survive periodic fires. Many shrubs of Northern Hemisphere chaparral produce bird-dispersed fruits that ripen in the late fall, when large numbers of migrant birds arrive from the north.

Savanna in Tanzania

Thorn forests and savannas have similar climates

Thorn forests are found on the equatorial sides of hot deserts. The climate is semiarid; little or no rain falls during the winter, but rainfall may be heavy during the summer. Thorn forests contain many plants similar to those found in hot deserts. The dominant plants are spiny shrubs and small trees. Members of the genus *Acacia* are common in thorn forests worldwide.

The dry tropical and subtropical regions of Africa, South

America, and Australia have extensive areas of savannas — expanses of grasses and grasslike plants punctuated by scattered trees. The largest savannas are found in central and eastern Africa, where this biome supports huge numbers of grazing and browsing mammals that serve as prey for many large carnivores.

Grazers and browsers maintain the savannas. If savanna vegetation is not grazed, browsed, or burned, it typically reverts to

dense thorn forest.

Rich, but poorly known

...and in the dry season

Tropical deciduous forests occur in hot lowlands

As the length of the rainy season increases toward the equator, thorn forests are replaced by tropical deciduous forests. These forests have taller trees and fewer succulent plants than thorn forests, and they are much richer in species. Most of the trees, except for those growing along rivers, lose their leaves during the long, hot dry season.

Many of them flower while they are leafless. This biome is very rich in species of both plants and animals.

The soils of the tropical deciduous forest biome are some of the best soils in the tropics for agriculture because they are less leached of nutrients than the soils of wetter areas. As a result, most tropical deciduous forests have been cleared for grazing cattle and growing crops.

Knowledge

Very rich but poorly known

Biological activity is essentially constant year round.

Tropical evergreen forests are rich in species

Tropical evergreen forests are found in equatorial regions where total rainfall exceeds 250 cm annually. This biome is the richest of all in species of both plants and animals, with up to 500 species of trees per km². Many of these species are rare. Food webs are extremely complex.

Tropical evergreen forests have the highest overall productivity of all terrestrial ecological communities. However, most mineral nutrients are tied up in the vegetation. The

soils usually cannot support long-term agriculture.

On the slopes of tropical mountains, temperature decreases about 6° for each 1,000 m of elevation. The trees are shorter than lowland tropical trees. Their leaves are smaller, and there are more epiphytes—plants that grow on other plants and derive their nutrients and moisture from air and water rather than soil. Epiphytes thrive in tropical mountain forests where clouds form, bathing the forest in moisture.

1026 CHAPTER FIFTY-SEVEN

Aquatic Biogeography

The coastal zone affected by wave action constitutes the littoral zone.

The column of water above the ocean floor constitutes the pelagic zone.

The ocean floor constitutes the benthic zone.

The abyssal and benthic zones coincide below the penetration of light.

Three-fourths of Earth's surface is covered by water, most of it in the oceans. Earth's oceans form one large, interconnected water mass with no obvious barriers to dispersal. Fresh waters, in contrast, are divided into river basins and thousands of relatively isolated lakes. For freshwater organisms that cannot survive out of water, terrestrial habitats are barriers to dispersal. However, some aquatic species have flying adults that can disperse widely among water bodies. Others have windborne, desiccation-resistant spores and seeds. Still others are small enough to be transported by means such as mud on the feet of birds. Many freshwater taxa that are capable of dispersing across terrestrial barriers are distributed widely over several continents.

Freshwater ecosystems have little water but many species

Although only about 2.5 percent of Earth's water is found in ponds, lakes, and streams, about 10 percent of all aquatic species live in freshwater habitats. Prominent among these are the more than 25,000 species of insects that have at least one aquatic stage in their life cycle. Most commonly, eggs and larvae are aquatic and adults have wings. Adults of some of these insects, such as dragonflies, are powerful flyers, but adults of mayflies and some other species are weak flyers, desiccate rapidly in air, and live no longer than a few days. As you would expect, oceanic islands have no or very few species of these weak flyers.

Similarly, fishes unable to live in salt water can disperse only within the connected streams and lakes of a river basin. Most families of freshwater fishes are restricted to a single continent. Those families with species distributed on both sides of major saltwater barriers are believed to be ancient lineages whose ancestors were distributed widely in Laurasia or Gondwana.

Marine biogeographic regions are determined primarily by water temperature and nutrients

Ocean water moves in great circular patterns—clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere (see Figure 56.3) These movements disperse organisms with limited swimming abilities. Nevertheless, most marine organisms have restricted ranges, indicating that important environmental limits to their distributions exist in the oceans.

We can divide the oceans into zones based on sharp horizontal and vertical environmental gradients (Figure 57.11). At all depths, the bottom of the ocean is called the benthic zone, and the open water column is called the pelagic zone. The ocean floor below the level of sunlight penetration is called the abyssal zone. The coastal zone from the most limits of tidal action down to the depth where

Limit of sunlight penetration

The ocean floor below the depth of sunlight penetration is also called the abyssal zone.

Zones of the ocean are shown schematically in relation to depth and sunlight penetration.

the water is thoroughly stirred by wave action is called the littoral zone.

Water temperatures, hydrostatic pressures, and food supplies all change with depth and distance from shore, influencing biotic distributions. Food is scarce, for example, in the permanently dark, cold waters of the deep sea. Living successfully in different zones of the ocean requires different physiological tolerances and morphological attributes. Not surprisingly, even though many organisms can disperse between these zones, organisms from one zone survive poorly if they attempt to live in another.

Ocean temperatures are barriers to colonization because many marine organisms are well adapted to only relatively narrow temperature ranges. The main biogeographic divisions of the pelagic zone coincide with regions where the temperature of surface waters changes relatively abruptly as a result of horizontal and vertical ocean currents (Figure 57.12). These temperature changes, in combination with seasonal changes in the amount of daylight, determine the seasons of maximum primary production. Species of marine algae tend to be adapted to photosynthesize either in summer or in winter, but not during both seasons.

Because nutrients gradually sink to the ocean bottom, high concentrations of nutrients in the pelagic zone are restricted to areas where upwelling currents bring nutrient-rich bottom waters to the surface (see Figure 56.10). Most marine organisms that grow and reproduce well in nutrient-rich waters perform relatively poorly in nutrient-poor waters. Therefore, nutrient-rich waters typically have biotas that differ considerably from those of nutrient-poor waters in the same region.

Deep ocean waters are barriers to the dispersal of marine organisms that live only in shallow water. Eggs and larvae of marine organisms can be carried great distances

demonstrated by the richness of reef-building corals in the intertidal and sub-tidal zones of isolated islands in the Pacific Ocean, which decreases with distance from New Guinea (Figure 57.13).

Marine vicariant events influence species distributions

Ancient vicariant events associated with continental drift do not influence current distributions of marine organisms, but more recent events have left biogeographic traces. An important recent vicariant event was the formation of the Isthmus of Panama about 3 million years ago. The isthmus separated the Pacific Ocean from the Caribbean Sea for the first time in more than 100 million years. Distinct marine biotas are now evolving on opposite sides of the isthmus. It forms a barrier to the dispersal of Pacific species, such as sea snakes, which reached the west coast of the Americas after the isthmus formed (Figure 57.14). Currently the fresh waters of Gatun Lake form a barrier to the dispersal of marine organisms through the Panama Canal. If a sea-level canal were constructed across the isthmus, poisonous sea snakes and other marine organisms would be able to disperse into the Caribbean.

by ocean currents, but the distance they can disperse is determined in large part by the duration of the larval life span. Relatively few species have eggs and larvae that survive long enough to disperse across wide barriers of deep water and settle in new areas. The effect of these barriers is

Larvae of many species cannot reach islands distant from New Guinea.

57.13 Generic Richness of Reef-Building Corals Declines with Distance from New Guinea

The existence of the Isthmus of Panama prevents poisonous sea snakes from entering the Caribbean Sea from the Pacific Ocean.

1028 CHAPTER FIFTY-SEVEN

Biogeography and Human History

The distributions of land masses and species on Earth have had a strong influence on human history. The Old World happened to have a large number of species of plants and animals that were suitable for domestication. Eurasia was home to 39 species of large-seeded grasses, many more than were found in Africa or the Americas. Eurasia had 72 species of large mammals, compared with 51 in sub-Saharan Africa and 24 in the New World. Thirteen large mammal species, including pigs, horses, cattle, sheep, goats, and camels, were domesticated in Eurasia. None were domesticated in Africa, and only one, the llama, in the Americas.

To be amenable to domestication, large mammals needed to have three important social characteristics: They needed to live in herds, have well-developed male dominance hierarchies, and be nonterritorial. These traits enabled humans to tame the animals, exert dominance over them, and keep them in herds. All the large mammals of Africa lacked one or more of these traits. They have never been domesticated. The domesticated large mammals found in Africa today all came from Asia.

Domestication of large mammals had other important influences on human history. Many human diseases, such as smallpox and measles, were acquired from domesticated mammals. Eurasian people acquired immunity to these diseases. People on other continents did not. Thus when Europeans colonized the New World, they brought with them diseases that devastated the indigenous people—who transmitted no fatal diseases to the Europeans in turn. In addition, Europeans had horses, a domesticated mammal capable of carrying a person at high speeds. Horses have played a major role in human history, because cultures with horses have readily conquered cultures without them.

In the Old World, most mountain ranges are oriented in an east-west direction. Therefore, dispersal of people and their domesticated plants and animals was relatively easy, and dispersing individuals remained within climates with similar temperatures and day lengths. Humans dispersed into the New World only recently, across the high-latitude Bering land bridge. They brought with them no domesticated plants or animals. North America, as we have seen, had few species of grasses with large seeds. Maize, the grass that came to dominate American agriculture, was difficult to domesticate. Its eventual spread northward from its center of domestication in Mexico was possible only after extensive genetic changes that adapted the plants to the very different day lengths and climates of temperate North America.

Chapter Summary

► Biogeography is the science that attempts to explain patterns in the distribution of life on Earth.

Why Are Species Found Where They Are?

- ▶ If a species occupies an area, either it evolved there, or it evolved elsewhere and dispersed to that area.
- ▶ If a species is not found in a particular area, either it evolved elsewhere and never dispersed to that area, or it was once present in that area but no longer lives there.
- ▶ Continental drift has influenced the distributions of organisms throughout Earth's history.
- ▶ Ecological biogeographers seek to understand how current ecological interactions influence where species are found today.
- ▶ Historical biogeographers attempt to determine the influence of past events on today's patterns of species distributions.
- ▶ Historical biogeographers often analyze species distributions by converting phylogenies into "area phylogenies." Review Figure 57.1

The Role of History in Biogeography

- ▶ Biogeographers use the parsimony principle when they attempt to explain distribution patterns. Review Figure 57.2
- ▶ Vicariance and dispersal events have both influenced current distributions. Review Figure 57.3
- ▶ Animal biogeographers divide Earth into six major biogeographic regions. Plant biogeographers recognize two additional regions. Review Figure 57.4

Ecology and Biogeography

- ▶ Ecological biogeographers test theories that explain the numbers of species in different communities, how species disperse, and the effectiveness of barriers to movement.
- ▶ The island biogeographic model, which predicts the equilibrium species richness on islands, has been tested by examining patterns of distribution and by performing experiments. Review Figures 57.5, 57.6; Table 57.1
- ▶ The number of species in most lineages increases from polar to tropical regions. Review Figure 57.8

Terrestrial Biomes

- ▶ Terrestrial biomes are major ecosystem types that differ from one another in the structure of their dominant vegetation.
- ▶ The distribution of biomes on Earth is strongly influenced by annual patterns of temperature and rainfall. Review Figures 57.9, 57.10
- ▶ The major terrestrial biomes are tundra, boreal forest, temperate deciduous forest, temperate grassland, cold desert, hot desert, chaparral, thorn forest, savanna, tropical deciduous forest, and tropical evergreen forest.

Aquatic Biogeography

- ▶ No absolute barriers to the movement of marine organisms exist within the oceans, but most marine organisms have restricted ranges.
- ▶ Conditions in the oceans change dramatically with depth and sunlight penetration. Review Figure 57.11
- ▶ Boundaries between many pelagic regions are determined by ocean currents. Review Figure 57.12
- ▶ Species that live in shallow waters disperse with difficulty across wide deep-water barriers. Review Figure 57.13

Biogeography and Human History

- ▶ The distributions of plants, animals, and continents have exerted powerful influences on human history.

For Discussion

1. Horses evolved in North America, but subsequently became extinct there. They survived to modern times only

BIOGEOGRAPHY 1029

in Africa and Asia. In the absence of a fossil record, we would probably infer that horses originated in the Old World. Today, the Hawaiian Islands have by far the greatest number of species of fruit flies (*Drosophila*). Would you conclude that the genus *Drosophila* originally evolved in Hawaii and spread to other regions? Under what circumstances do you think it is safe to conclude that a group of organisms evolved close to where the greatest number of species live today?

2. The island biogeographic model we described incorporates almost nothing about the biology of the species involved. What traits of species should be incorporated into more realistic models of rates of colonization and extinction of species on islands?

3. Experiments to test theories of species richness are necessarily short-term. What long-term consequences of colonization and extinction are likely to be undetected by these experiments? How could they be studied?
4. In nearly every ecological community, the number of species present is much smaller than the number potentially available to colonize it. What inferences can be drawn from this pattern?
5. A well-known legend states that Saint Patrick drove the snakes out of Ireland. Give some alternative explanations, based on sound biogeographic principles, for the absence of indigenous snakes in that country.
6. Why are there so few species of trees in boreal forests? Why do few species of trees of boreal forests have animal-dispersed seeds?
7. What are some significant present-day human problems whose solutions involve biogeographic considerations? What kinds of biogeographic knowledge are most important for addressing each one?
8. Most of the world's flightless birds are either nocturnal and secretive (such as the kiwi of New Zealand) or large, swift, and well armed (such as the ostrich of Africa). The exceptions are found primarily on islands. Many flightless island species have become extinct with the arrival of humans and their domestic animals. What special biogeographic conditions on islands might permit the survival of flightless birds? Why has human colonization so often resulted in the extinction of such birds? The power of flight has been lost secondarily in representatives of many groups of birds and insects; what are some possible evolutionary advantages of flightlessness that might offset its obvious disadvantages?

Conservation Biology

When Polynesian people settled in Hawaii about 2,000 years ago, they exterminated—

probably by overhunting—at least 39 species

of land birds. Among them were 7 species of

Mallards, 2 species of flightless ibises, a sea eagle,

a small hawk, 7 flightless rails, 3 species of owls, 2 large

crows, a honeyeater, and at least 15 species of finches.

No people lived in New Zealand until about 1,000 years ago, when the Maori colonized the islands. Hunting by the Maori caused the extinction of 13 species of flightless moas, some of which were larger than ostriches.

When humans arrived in North America over the Bering land bridge, about 20,000 years ago, they encountered a rich fauna of large mammals. Most of those species were exterminated within a few thousand years. A similar extermination of large animals followed the human colonization of Australia, about 40,000 years ago. At that time Australia had 15 genera of marsupials larger than 50 kg, a genus of gigantic lizards, and a genus of heavy, flightless birds. All the species in 13 of those 15 genera had become extinct by 18,000 years ago.

The accelerating pace of human-caused extinctions of species, which raises serious concerns about the future of biological diversity on Earth, has led to the rapid development of the applied discipline of conservation biology—the scientific study of how to preserve the diversity of life. Conservation biologists study the causes of endangerment and extinction and develop methods to help preserve genes, species, communities, and ecosystems. The science of conservation biology draws heavily on concepts and knowledge from population genetics, evolution, ecology, biogeography, wildlife management, economics, and sociology. In turn, the needs of conservation are stimulating new research in those fields.

In this chapter we will see how biologists estimate rates of species extinction and the causes of endangerment, and learn how management plans can be used to reduce extinction rates and restore endangered species and communities to states in which they are likely to persist for a long time.

Extinct Flightless Hawaiian Birds

This artist's reconstruction of a flightless Hawaiian goose shows one of the many bird species exterminated by the Polynesian settlers of the islands.

Estimating Current Rates of Extinction

Most human activities that are causing extinctions are not new, but there are many more of us doing those things than ever before (see Figure 54.16). We have also added the results of our advancing technology, such as pesticides and climate change, to the array of pressures created by human activities.

We do not know how many species will become extinct during the next 100 years, first, because we do not know how many species there are on Earth, and second, because the number of extinctions will depend both on what we do and on

unexpected events. However, several methods exist for estimating probable rates of extinction resulting from human actions. In this section we will discuss how conservation biologists estimate current rates of extinction and identify species at risk of extinction.

Species-area relationships are used to estimate extinction rates

When we described the island biogeographic model in Chapter 57, we saw that the number of species on an island increases with the size of the island (see Figure 57.6). This species-area relationship can be applied to habitat patches

Green areas indicate dense forest cover.

58.1 Deforestation Rates Are High in Tropical Forests

Central America provides an example of the high rate of destruction of tropical forests that has taken place in recent years. As the forests are lost, so are the many species that live in them.

on mainlands as well. Conservation biologists often use the well-established relationship between the size of an area and the number of species present to estimate numbers of species extinctions resulting from habitat destruction.

The rate at which tropical forests are being logged and converted to cropland and pasture is not precisely known, but it is currently very high (Figure 58.1). These forests are Earth's richest biomes, home to perhaps one-half of all the species on the planet. Calculations using the species-area relationship applied to tropical forests are far from exact, but can result in estimates of over 1 million species extinctions in the next few decades.

Even the lowest estimates of current extinction rates predict that at least 10 percent of Earth's species are likely to become extinct during the next two decades. Some estimates predict extinction of 50 percent of Earth's species

CONSERVATION BIOLOGY 1031

during the next 50 years. Extinction rates have been much higher on islands than in mainland areas during the past 400 years (Figure 58.2), but extinction rates on continents are also rising fast.

Population models are used to estimate risks of extinction

To estimate the risk that a population will become extinct, conservation biologists analyze information about interactions between a population's genetic variation, morphology, physiology, and behavior and its environment, both physical and biological. Although rarity itself is not always a cause for concern, species whose populations are shrinking rapidly usually are at risk. Species with only a few individuals confined to a small range are likely to become extinct because they can be eliminated by local disturbances such as fires, unusual weather, disease, and predators.

Both demographic and genetic information were used in assessing the risk of extinction of Furbish's lousewort, a plant that is restricted to the banks of the St. John River in northern Maine. The Furbish's lousewort population is divided into discrete subpopulations growing at separate sites. These subpopulations are found where periodic disturbance, often caused by spring ice scour when blocks of floating ice scrape the stream banks, prevent establishment of trees and shrubs that would outcompete the louseworts (Figure 58.3). Data on annual rates of survival, growth, and reproduction were gathered by following more than 6,000 individually marked plants between 1983 and 1986. Extinctions of subpopulations and foundings of new subpopulations were estimated by counting plants over the entire range of the species.

Although Furbish's lousewort depends on regular disturbance to suppress the growth of shrubs and trees, distur-

Extinction rates are higher on islands than on the mainland.

1032 CHAPTER FIFTY-EIGHT

58.3 Furbish's Lousewort Exists as a Metapopulation

Small populations of Furbish's lousewort exist along the St. John River, where ice scour and bank slumping eliminate shrubs and trees. Dispersing individuals colonize newly disturbed sites.

bances can also eliminate subpopulations. Between 1983 and 1984, three of ten study subpopulations were completely destroyed by ice scour and bank slumping, and none of the disturbed sites were recolonized during succeeding years. Thus if disturbance rates were too high, extinction rates of subpopulations are likely to be higher than rates of establishment of new subpopulations. Under current disturbance regimes, the two rates are about equal. Local subpopulations became extinct and new subpopulations were founded at an annual rate of about 3 percent during the study.

The investigators concluded that the persistence of Furbish's lousewort depends on disturbance events at sites currently having subpopulations and also at sites that are currently unoccupied. Clearly a strategy that protected only sites with current subpopulations would not maintain the species for many years. Preserving Furbish's lousewort depends on maintaining disturbance regimes along an entire stretch of the St. John River. If the St. John River continues to flow naturally and spring ice scouring continues, Furbish's lousewort is likely to persist for a long time.

Why Do We Care about Species Extinctions?

We care about species extinctions in part because humans depend on other species in many ways. For example, more than half the medical prescriptions written in the United States contain a natural plant or animal product (Figure 58.4). The search for and use of such products from the living world has hardly begun. Many species may be eliminated by tropical

forest destruction before we find out whether they might be sources of useful products.

Extinctions deprive us of opportunities to study and understand ecological relationships among organisms. The

more species are lost, the more difficult it will be to understand the rules that govern the structure and functioning of ecological communities.

We also derive enormous aesthetic pleasure from interacting with other organisms. Many people would consider a world with far fewer species as a less desirable one in which to live. Living in ways that cause the extinction of other species also raises serious moral and ethical issues that are receiving increased attention.

Ecosystem processes, as well as individual species, produce many benefits to humanity. Among them are the generation and maintenance of fertile soils, prevention of soil erosion, detoxification and recycling of waste products, regulation of hydrological cycles and the composition of the atmosphere, control of agricultural pests, pollination, and maintenance of the species richness upon which humanity depends. It is easy to list these ecosystem services, but to justify the allocation of scarce public resources to maintain them, we need quantitative estimates of their value.

A detailed study by economists, ecologists, and land managers in Western Cape Province, South Africa, has shown that an intensive program to eradicate invasive alien plants in the highlands of the region is a cost-effective way of maintaining a reliable regional supply of high-quality water. The native vegetation of these highlands is a species-rich community of shrubs, known as fynbos (pronounced "fainbos"). Fynbos can survive regular summer drought, nutrient-poor soils, and the fires that periodically sweep through the highlands (Figure 58.5a).

The fynbos-clad highlands provide about two-thirds of the Western Cape's water requirements. In addition, the flora is harvested for cut and dried flowers and thatching

grass. The combined value of these harvests in 1993 was about \$19 million. Some of the income from tourism in the region comes from people who want to see the fynbos vegetation. About 400,000 people visit the Cape of Good Hope Nature Reserve each year, primarily to see the many unique plants.

During recent decades, a number of plants introduced into South Africa have invaded the fynbos highlands. Be-

58.5 Water Flows from Fynbos

{a) The fynbos of South Africa, (b) Stream flow from fynbos watersheds is inversely proportional to plant biomass. (c) A computer simulation of stream flows from watersheds that have and have not been invaded by trees from outside the region.

cause they are taller and grow faster than the native plants, the exotics increase the intensity and severity of fires. By transpiring larger quantities of water, they decrease stream flows to less than half the amount flowing from mountains covered with native plants (Figure 58.5b,c).

Removing the exotic plants by felling and digging out invasive trees and shrubs and managing fire is estimated to cost between \$140 and \$830 per hectare, depending on the densities of invasive plants. Annual follow-up operations will cost about \$8 per hectare. The costs of alternative methods to replace the water lost from watersheds taken over by exotic plants are much higher. A sewage purification plant that would deliver the same volume of water as a well-managed watershed of 10,000 hectares would cost \$135 million to build and \$2.6 million per year to operate. Desalination of seawater would cost four times as much. Thus, the available alternatives would deliver water at a cost between 1.8 and 6.7 times more than the costs of maintaining natural vegetation in the watershed.

Modern industrial societies often favor technologically sophisticated methods of substituting for lost ecosystem services. The study of water resources in the Western Cape Region shows that simple but labor-intensive methods—cutting and burning—can be cheaper. In addition, they preserve other ecosystem values, such as tourism and commercial plant products.

Some ecosystem values, such as aesthetic benefits, cannot be replaced with technological inventions. Aesthetic benefits may contribute much to a country's economy. One of the largest sources of foreign income in Kenya is nature tourism. The loss of a single species probably would not reduce the flow of tourists to Kenya, but if elephants, rhinoceroses, lions, leopards, and buffalo were all to disappear, fewer people would pay the high price of a Kenyan vacation. Populations of these species can be maintained only if large tracts of the ecosystems in which they live are preserved.

Determining Causes of Endangerment and Extinction

Rare species are more likely to become extinct than common species. Species may be rare for any of several reasons. They may live in a habitat that is rare, such as desert lakes with high salt concentrations or caves (Figure 58.6). Another reason for rarity is trophic level—secondary carnivores are usually rare because so little energy is available to support their populations,

as we saw in Chapter 56. Being rare increases a species' chance of becoming extinct, but common species can also become extinct.

58.6 The Habitat of Cave Animals Is Patchy and Restricted

The map shows the distribution of subterranean limestone (karst) in which caves with running water are found. The caves that can actually be inhabited by cave animals covers a much smaller area.

An analysis by The Nature Conservancy revealed that habitat loss is the most important cause of endangerment of species in the United States (Figure 58.7), but that other factors, such as exotic species, pollution, overexploitation, and disease, also threaten species. In this section we will examine some of these major threats to species.

Habitat destruction and fragmentation are important causes of extinction today

The 6 billion humans that live on Earth today are fed, clothed, and housed by the agricultural and forestry industries, which convert natural ecological communities containing many species into highly modified communities dominated by one or a few species of plants. Within these communities, humans discourage the presence of other species by killing competing plants, bacteria, fungi, nematodes, insects and other arthropods, and vertebrates.

Although agricultural ecosystems have always harbored fewer species than the complex natural ecosystems they replaced, only recently have farmers planted large tracts of land in single crops. Traditional farmers planted many different crops together, maintaining some of the diversity that is key to the functioning of natural communities. Many species that cannot survive in intensive modern agricultural systems live in traditional agricultural ones. In traditional coffee plantations, for example, coffee bushes are grown in the shade of large trees (Figure 58.8f). These structurally rich plantations support populations of many species of birds, and few pesticides need to be applied to them. Some recently developed high-yielding strains of coffee, however, grow best in full sunlight. Pure plantations of these coffee bushes require heavy applications of pesticides and support almost no birds (Figure 58.8b).

Agriculture and forestry today are so extensive that more than 30 percent of all net terrestrial primary production is diverted for human use. All other species on Earth must survive on only two-thirds of the total global terrestrial production, and the fraction people divert is steadily increasing.

As natural habitats are progressively destroyed, the remaining patches increasingly become smaller and more isolated. Small habitat patches are qualitatively different from larger patches of the same habitat in ways that affect the

survival of species. Small patches cannot maintain populations of species that require large areas, and they support only small populations of many of the species that can survive in them.

In addition, the fraction of a patch that is influenced by conditions in adjacent habitats—resulting in edge effects — increases rapidly as patch size decreases (Figure 58.9). Close to the edges of forest patches, for example, winds are stronger, temperatures are higher, humidity is lower, and light levels are higher than they are farther inside the forest. Species from surrounding habitats often colonize the edges of patches to compete with or prey upon the species living there.

This area is influenced by edge effects.

This area is not influenced by edge effects.

Because the width of the edges is relatively constant, as the total area becomes smaller, the edge becomes proportionately

larger.

Usually we do not know which organisms lived in an area before its habitats became fragmented. To address this problem, a major research project near Manaus, Brazil, was launched in an area of tropical forest before logging took place. The landowners agreed to preserve forest patches of certain sizes and locations (Figure 58.10V?).

Biologists conducted censuses of those patches while the areas were still part of the continuous forest. Soon after the surrounding forest was cut, species began to disappear from the isolated patches. The first species to be eliminated were monkeys with large home ranges, such as the black spider monkey, the tufted capuchin, and the bearded saki, and antbirds that follow raiding army ant swarms to capture insects flushed by the ants (Figure 58.10b,c).

Species that become extinct in small fragments are unlikely to become reestablished because individuals dispersing from other locations are less likely to find isolated patches. Even if they find them, the patches may be too small to support their populations on a long-term basis. The persistence of species in small patches may be improved if the patches are connected by corridors of suitable habitat through which individuals can disperse.

The role of corridors in sustaining populations of species was studied by creating patches of mosses on the surface of a large rock. Eight experimental "landscapes" were established by scraping away the moss to create patches of equal size. Some patches were isolated, others were connected by narrow moss corridors, and still others were connected by pseudocorridors

that were interrupted by a 10 mm break (Figure 58.11). The abundance and species richness of tiny arthropods were measured at 2-month intervals over the course of a year—a time period equivalent to many generations for most of the small animals living in the moss.

Remarkably/ barriers as narrow as 10 mm were sufficient to greatly reduce the dispersal rates of arthropods between moss patches. Isolated patches and patches connected by pseudocorridors had only about 60 percent as many species of springtails (tiny, wingless insects) and mites as the patches connected by complete corridors.

...than patches connected to the main forest.

Even larger patches are strongly influenced by edge effects.

58.11 An Experiment Demonstrates the Value of Corridors

A small-scale experiment in which patches were created by removing moss from a rock surface demonstrated that even small gaps between suitable habitats can reduce the number of species that persist in patches.

58.12 Galapagos Tortoises Are Reared in Captivity

Conservationists at the Charles Darwin Research Station remove tortoise eggs from nests. When the eggs hatch, the young are reared in captivity until they are large enough to be invulnerable to predation by introduced pigs and rats. Populations of tortoises on some Galapagos islands would be extinct if they were not propagated in captivity.

CONSERVATION BIOLOGY 1037

cause by removing most of the algae from the water, thereby clarifying it, zebra mussels allow sunlight to penetrate more deeply into the water column. As a result, in areas of high mussel densities, populations of submerged vascular plants and some invertebrates have increased. Not until after many years will we know the full effects of the colonization of North America by zebra mussels.

Some pests proliferated quickly following their introduction to new continents, with destructive consequences. Forest trees in eastern North America, for example, have been attacked by several European diseases. The chestnut blight, caused by a European fungus, virtually eliminated the American chestnut, formerly a dominant tree in forests of the Appalachian Mountains. Nearly all American elms over large areas of the East and Midwest have been killed by Dutch elm disease (caused by a different fungus), which reached North America in 1930. Ecologists suspect that intercontinental movement of disease organisms has caused extinctions throughout life's history, but evidence of disease outbreaks is not usually preserved in the fossil record.

Introduced pests, predators, and competitors have eliminated many species

Deliberately and accidentally, people move many organisms from one continent to another. Pheasants and partridges were introduced into North America for hunting. Europeans introduced rabbits and foxes to Australia for sport. Many plants have been introduced as ornamentals. Weed seeds have been accidentally carried around the world in soil used as ballast in sailing ships and as contaminants in sacks of crop seeds. Despite quarantines, disease organisms have spread widely, carried by infected plants, animals, and people.

A species that has evolved over time in a community with certain predators and competitors may be driven to extinction by newly introduced predators and competitors. Nearly half of the small to medium-sized marsupials and rodents of Australia have been exterminated during the last 100 years by a combination of competition with introduced rabbits and predation by introduced cats and foxes. On the Galapagos archipelago, introduced pigs and rats had exterminated several races of tortoises even before Darwin visited the islands. Populations of tortoises on some islands are maintained today only because conservationists remove eggs and rear the young tortoises in captivity (Figure 58.12).

The zebra mussel, whose larvae were carried in ships' ballast water from Europe, became established in the Great Lakes in about 1985. Zebra mussels dispersed rapidly and today occupy much of the Great Lakes and Mississippi River drainage (Figure 58.13). In some places these mussels have reached densities as high as 400,000 per square meter! Some species of native clams are being covered and smothered by zebra mussels. Zebra mussels have also caused millions of dollars of damage to water intake structures. On the other hand, some native species have benefited, be-

I Zebra mussels entered North American waters when ballast water from European ships was pumped into Lake Ontario.

I The mussels became established and rapidly spread via rivers through eastern North America.

58.13 Introduced Zebra Mussels Spread Rapidly

Between 1986 and 1988 the range of zebra mussels in North America nearly doubled. This introduced species spreads rapidly because zebra mussel larvae are free-swimming and adults can attach to moving objects, such as boat hulls.

Dreissena polymorpha

1038 CHAPTER FIFTY-EIGHT

The curved bill of the iiwi matches the shape of the Lobelia flower.

58.74 Coevolved Mutualists

Declining populations of the iiwi (*Vestiaria coccinea*), a Hawaiian honeycreeper, also threaten the Lobelia plant, which has no other pollinator.

Overexploitation has driven many species to extinction

Until recently, humans caused extinctions primarily by overhunting. The passenger pigeon, the most abundant bird in North America in the early 1800s, became extinct by 1914, largely due to overhunting. Russian whalers exterminated the unusual Steller's sea cow of the North Pacific in the late 1800s, just 37 years after it was first described. Such overex-

(a)

If the climate of eastern North America warms by as little as 4°C, about half the potential future range of beech trees will be beyond the northernmost extent of the current range.

Exploitation continues today. Elephants and rhinoceroses are threatened in Africa because poachers kill them for their tusks and horns. Unfortunately, these animals are not slaughtered for medical or other useful purposes; rather, they are killed for ornaments and because some men believe that powdered horn enhances their sexual potency. Many species of orchids, parrots, reptiles, and tropical reef fishes are currently threatened by lucrative pet and houseplant trades.

Loss of mutualists threatens some species

Many plants have mutualistic relationships with pollinators, but most of these mutualisms are not highly species-specific. On islands, however, where ecological communities contain relatively few species, plant-pollinator interactions often evolve to be highly specific. For example, a single species of the plant *Lobelia* colonized the Hawaiian Islands, where it eventually gave rise to 110 daughter species. A single colonizing species of songbird gave rise to at least 47 species of Hawaiian honeycreepers, some of which have long, slender, curved bills. These nectar-feeding birds were the only pollinators of many species of Hawaiian lobelias (Figure 58.14).

Today, half of the nectar-feeding birds of Hawaii are extinct, leaving many lobelias without pollinators. Many of these lobelias still survive, but populations of some species have been reduced to only a few individuals. A few species survive only because biologists artificially pollinate them.

Global warming may cause species extinctions

Atmospheric scientists predict that, as a result of increasing concentrations of CO₂ and other greenhouse gases in the atmosphere (see Chapter 56), average temperatures in North America will increase 2°-5°C by the end of the twenty-first century. If the climate warms by only 1°C, the average temperature currently found at a certain location will shift 150 km to the north. To remain in the temperature regime to which they are accustomed, species will have to shift their ranges 150 km to the north. Species will need to shift their ranges as much as 500-800 km in a single century if the climate warms 2-5°C. Some habitats, such as alpine tundra, could be eliminated from many areas as forests expand up the mountain slopes.

58.15 Threatened by Global Warming

(a) Seedlings and saplings abound in this beech forest, (b) Beeches would need to migrate 40 times faster than they have in the past to keep up with the anticipated rates of climate change.

Conservation biologists are attempting to predict the effects of global warming on North American species. Trees might be especially vulnerable to climate change because they grow for long periods before they begin to reproduce, and their seeds typically move only very short distances (Figure 58.15).

If Earth warms as predicted, climatic zones will not simply shift northward. New climates will develop, and some existing climates will disappear. New climates are certain to develop at low elevations in the tropics because a warming of even 2°C would result in climates near sea level that are hotter than those found anywhere in the humid tropics today. Adaptation to those climates may prove difficult for many tropical organisms.

Preventing Species Extinctions

Designing recovery plans

Once the causes of endangerment of species have been identified, appropriate remedies can be designed. In the United States, when a species is listed as threatened or endangered under the Endangered Species Act, a recovery plan is typically prepared to guide efforts to improve the status of the species. In this section we will describe how good diagnoses have been used to design management actions to prevent species from becoming extinct.

kirtland's warbler. The Kirtland's warbler is an endangered bird that nests only in 8-18-year-old stands of jack

Areas with sandy soils are absent north of the current breeding range.

pine growing on sandy soils in Michigan (Figure 58.16). The current population of Kirtland's warblers is less than 1,000 individuals. Field studies determined that the Kirtland's warbler is at risk from both loss of habitat and nest parasitism by brown-headed cowbirds. Fire suppression has reduced the area of young jack pine stands, and cowbirds, which lay their eggs in other birds' nests, have greatly increased in abundance in the area. To prevent further threats to the warblers, conservation biologists ignite controlled fires in jack pine forests to maintain a steady supply of trees of the right age. They are also removing brown-headed cowbirds to reduce nest parasitism rates.

the California sea otter. Populations of the California sea otter were hunted nearly to extinction during the nineteenth century. After receiving legal protection in 1911, the species increased steadily to about 2,400 individuals today. The Southern Sea Otter Recovery Team was charged with developing a recovery plan for the sea otter under the U.S. Endangered Species Act. They determined that ample habitat and food supplies are present and that the otters are reproducing and surviving well. They judged that a major oil spill poses the most serious threat to the otters.

A demographic model suggested that the otter population would be endangered if it dropped below 1,850 individuals. A model designed to assess whether a major oil spill could reduce the population to that size suggested that fewer than 800 otters would be killed by 90 percent of the simulated spills. Therefore, the team set the "delisting" criterion at 2,650 individuals (1,850 + 800). Because the California sea otter population has nearly reached this size, it may soon be removed from the list of endangered species.

Captive propagation has a role in conservation

Species being threatened by overex-ploitation, loss of habitat, or environmental degradation through pollution can sometimes be maintained in captivity while the external threats to their existence are reduced or removed. Captive propagation is only a temporary measure that buys time. Existing zoos, aquariums, and botanical gardens do not have enough space to maintain adequate populations of more than a small fraction of Earth's rare and endangered species. Nonetheless, captive propagation can play an important role by maintaining species during critical periods and by providing a source of individuals for reintroduction into the wild. Captive propagation projects in zoos also have raised public awareness of species that are threatened with extinction.

1040 CHAPTER FIFTY-EIGHT

58.77 Peregrine Falcon Populations Have Been Reestablished

(a) Peregrine falcons have responded well to captive propagation. Some individuals have adapted to urban life, nesting on the tall buildings of cities and feeding on pigeons, (b) Throughout the eastern United States, many pairs of peregrine falcons now

attempt to reproduce. Most of them are successful.

THE PEREGRINE FALCON. In 1942,

about 350 pairs of peregrine falcons bred in the United States east of the Mississippi River. This breeding population disappeared entirely by 1960. The cause of the falcon's disappearance was the widespread use of organochlorine pesticides, such as DDT and dieldrin. These pesticides degrade very slowly in the environment and become concentrated in the falcon's prey. Their accumulation in the peregrines' bodies interfered with the deposition of calcium in eggshells. As a result, most of the falcons' eggs broke before they hatched.

Much of the eastern United States became suitable habitat for peregrines again after the use of DDT in the United States was banned by federal law. Captive breeding of peregrines began at Cornell University in 1970, and by the end of 1986, more than 850 birds reared in captivity had been released in 13 eastern states, with spectacular success (Figure 58.17). Peregrines probably would have recolonized the East by themselves, but they would have done so much more slowly without human assistance.

the California condor. With its 9-foot wing span, the California condor is North America's largest bird. Two hundred years ago, condors ranged from southern British Columbia to northern Mexico, but by 1978, the wild population was plunging toward extinction—only 25 to 30 birds remained in southern California. To save the condor from extinction, biologists initiated a captive propagation program in 1983.

The first chick conceived in captivity hatched in 1988. By 1993, nine captive pairs were producing chicks, and the captive population had increased to more than 60 birds. The captive population was large enough that six captive-bred birds could be released in the mountains north of Los Angeles in 1992. These birds are provided with contaminant-free food in remote areas, and they are using the same roosting sites, bathing pools, and mountain ridges as did their predecessors. Captive-reared birds also were released late in 1996 in northern Arizona. It is still too early to pronounce the program a success, but without captive propagation, the California condor would probably be extinct today

The cost of captive propagation is comparatively low

The California condor rehabilitation program costs about 1 million dollars a year. The Peregrine Fund at Cornell Uni-

1984 Year

1986 1988

1990

Pairs producing

offspring versify spent about 3 mil-

lion dollars over the past 30 years; the expenses of other cooperating agencies add at least another half million to the total. These amounts may seem large, but they are small compared with the costs of other human activities; for example, even a minor Hollywood film costs more than this to produce, and such films often lose money.

Establishing Priorities for Conservation Efforts

Many species and ecosystems are threatened, but the financial and human resources that can be allocated to preservation efforts are limited. How should those resources be spent to achieve the most conservation benefits? Because many species can survive only in the ecological communities in which they evolved, preserving the full array of ecological communities and habitats is vital.

Where should parks be established?

Parks, sanctuaries, and reserves function to maintain species and ecosystems relatively free of human disturbance. Parks are being created in many countries, but where should they be established to achieve the greatest conservation benefits?

High value sites for parks and reserves are those that

- Are home to unusually large numbers of different species.
- Have many endemic species—species that originated in that region and usually are found nowhere else.

Areas of high endemism should receive high conservation priority because if the endemic species are lost there, they often become globally extinct. Madagascar is a good example of such center of endemism: Nearly all the vascular plants and vertebrates of Madagascar are found only on that island (Figure 58.18). Therefore, if the small fragments of tropical and subtropical forests remaining on Madagascar were destroyed, many species would be exterminated.

CONSERVATION BIOLOGY

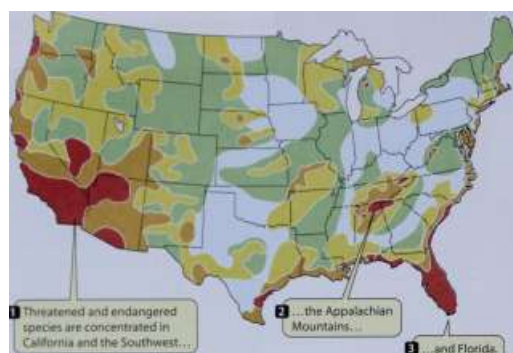

Eulemur fulvus (brown lemur)

58.18 Madagascar Abounds with Endemic Species

The majority of plant and animal species found on the island of Madagascar, off the eastern coast of Africa, are found nowhere else on Earth.

1042 CHAPTER FIFTY-EIGHT

| Threatened and endangered species are concentrated in California and the Southwest...

None <40 40-80 80-95 >90

Centers of endemism are not the same for all groups of organisms. Nevertheless, some areas have high concentrations of endangered species in many taxa. In the United States, species listed as threatened and endangered under the Endangered Species Act are concentrated in California, the Southwest, Florida, Hawaii, and the Appalachian Mountains (Figure 58.19).

Some economic land uses are compatible with conservation

In most countries, new parks and reserves must be established in already settled areas because few pristine areas remain. The people living there cannot be evicted, nor is it appropriate, in most cases, to prevent hungry people from settling in or hunting in parks. The high rates of human population growth in most tropical countries guarantee that pressures on parks from agricultural settlers will increase rather than decrease.

For these reasons, lands that are exploited for food, medicines, and fiber must play an important role in conservation. These lands are far more extensive than parks and reserves, and they include ecosystems not represented in parks. Fortunately, many species can be preserved on lands that are being used for economic purposes. Only a few species, such as predators on humans and domestic animals or large, destructive herbivores, are incompatible with most human uses of land.

Forest reserves in which economically valuable products are harvested can support both species preservation and economic development. In Belize, people known as hier-bateros collect medicinal plants in the forests and sell them to the curanderos (healers) who provide 75 percent of health care in the country. A botanist and an economist determined that two 1-hectare plots in the second-growth tropi-

58.19 Geographic Distribution of Threatened and Endangered Species in the United States

Threatened and endangered species are concentrated in just a few locations in the continental United States. These areas are obvious priorities for conservation efforts.

cal forest of Belize yielded gross annual revenues of \$865 and \$4,017, which are greater than the incomes that would result from cultivating squash and corn on those plots.

Conservation requires large-scale planning

Scientists at the World Wildlife Fund have developed a large-scale approach called Ecoregion-Based Conservation (ERBC). An ecoregion is an area that has a relatively uniform climate and a biota dominated by a group of widely distributed species. Using all available information on species' distributions and ecological requirements, scientists can identify sites of highest conservation priority within the ecoregion. This information is then used to develop a vision of what successful conservation would look like in 50 years.

An ecoregional conservation project, known as the Yellowstone to Yukon Initiative (Y2Y), is under way in Canada and the northern United States. Y2Y is a binational effort to restore and maintain biological diversity and landscape continuity in an area encompassing 1.2 million square kilometers along the spine of the Rocky Mountains. Information on the distributions of species, human cultures, and soil types in the region is being used to identify the most important areas for maintaining biological diversity. Investigators have also identified threats to biodiversity resulting from mining and its associated toxic waste pollution, unsustainable logging, and conversion of large ranches to suburban developments and sites for summer homes.

An important product of the Y2Y Initiative has been identification of areas that must be preserved or restored as key corridors for the movement of large mammals, such as grizzly bears, wolves, and elk, within the ecosystem. Efforts are now under way to build the base of political and financial support that will be necessary to make the vision a reality.

Restoring Degraded Ecosystems

Many areas that could be incorporated into reserves have been highly altered by human activities. Some of these areas can play their intended roles in biodiversity conservation only if they are restored to their original state. To accomplish this task, a subdiscipline of conservation biology, known as restoration ecology, is growing rapidly. Research on methods of restoring populations, communities, and

CONSERVATION BIOLOGY 1043

ecosystems is needed because many ecological communities will not recover, or will do so only very slowly, without creative intervention in the recovery process.

The world's largest restoration project is under way in Guanacaste National Park in northwestern Costa Rica. Its goal is to restore a large area of tropical deciduous forest—the most threatened ecosystem in Central America—from small fragments that remain in an area converted mostly to pastures.

The single most important threat to Guanacaste National Park is fires, most of which are started by people. These fires burn the introduced pasture grasses and spread far into surrounding forests. Grazing by domestic livestock lowers the densities of these grasses, and the animals also disperse the seeds of native trees that can invade pastures. Therefore, the restoration program encourages some initial grazing by domestic livestock in the park. When plant succession has progressed to the point where grass no longer poses serious competition to the woody species and is no longer sufficiently dense to carry hot fires, grazing is terminated.

Restoring damaged and degraded habitats is an important activity, but ecologists still have limited ability to restore natural ecosystems. In the United States, the self-serving but false belief that comparable ecosystems can be created somewhere else has made it easy to get building permits for developments that destroy habitats. Developers need only state that they will create substitutes for the ecosystems they are destroying, but promising to do this is much easier than doing so.

Even the most experienced wetland ecologists are having great difficulty creating new wetlands that mimic those being

destroyed. Such a "restored" wetland was conceived as part of a compensation agreement that allowed the California Department of Transportation to widen Interstate Highway 5 near San Diego. Despite stringent, court-imposed standards and the involvement of wetland experts, local endangered birds were still not breeding in the "restored" marsh 12 years after it was created. Therefore, as noted by a recent National Research Council committee on wetland restoration: "Wetland restoration should not be used to mitigate avoidable destruction of other wetlands until it can be scientifically demonstrated that the replacement ecosystems are of equal or better functioning."

Markets and Conservation

Most species are common property resources that are "owned" by everyone. Because no individual or group of individuals has strong incentives to use common property resources in a sustainable manner, their preservation usually depends on central governments. Unfortunately, governments generally lack sufficient resources to do the job. Also, governmental actions often are not well attuned to local situations. For these reasons, allowing local people to receive the economic benefits from managing biological resources on their lands can, under proper conditions, assist conservation efforts.

Preserving genes, species, and habitats provides many economic benefits. However, many of these benefits will assist future generations, not the current one. We do not know how future generations will value these benefits or the biodiversity that generates them. We do not even know how the current generation values them. We also cannot predict which species will turn out to be sources of valuable foods, medicines, or drugs.

Between 1951 and 1981, the National Cancer Institute screened extracts from 35,000 different species. To date, only one compound—taxol, derived from the Pacific yew tree—has received regulatory approval as a drug component. That drug is very valuable, but many species had to be searched to find it.

Although it is unlikely that any given species will have market value, extinction is forever. If we purposely or inadvertently exterminate a species, we have irreversibly destroyed a resource of unknown value. Therefore, loss of biodiversity is an especially urgent public issue.

How much should societies invest to preserve biodiversity? This question does not have a scientific answer. Economists and evolutionary biologists can contribute valuable information to the public debate, but the final decision is an ethical and political one that will depend on our beliefs about our responsibilities to the other organisms that share Earth with us.

The preservation of biological diversity and ecosystem services is one of the greatest challenges facing humankind. Many of the scientific tools needed for the task are already available, but appropriate use of these tools requires major changes in people's attitudes toward other species. If species are valued only because they are economically useful, increased losses of species are inevitable. Only when we value biological diversity and ecosystem functioning as the heritage of all humankind, a heritage to be passed on to our descendants as completely as possible, will we begin to reduce the current alarming rates of ecosystem destruction and species extinction.

©Chapter Summary Estimating Current Rates of Extinction

- ▶ Estimates of current rates of extinction worldwide are based primarily on species-area relationships and rates of tropical deforestation. Review Figure 58.1
- ▶ Rates of extinction are much higher on islands than on the mainland. Review Figure 58.2
- ▶ Demographic and genetic information is used to estimate risks of extinction. Review Figure 58.3

Why Do We Care about Species Extinctions?

- ▶ Diverse species provide the food, fiber, medicines, and aesthetic benefits upon which human life depends.
- ▶ Ecosystems provide services that can be replaced only by expensive and continuing human effort. Review Figure 58.5

Determining Causes of Endangerment and Extinction

- ▶ Rare species are the most vulnerable to extinction, but common species can also become extinct.

1044 CHAPTER FIFTY-EIGHT

- ▶ Habitat destruction is the most important cause of species extinction today, but overexploitation, which historically resulted in most human-caused extinctions, is still an important cause of extinctions. Review Figure 58.7

- ▶ [The fragmentation of habitats into patches that are too small to support populations is a major cause of extinction.

- ▶ [The proportion of a habitat patch subject to detrimental

effects increases as patch size decreases. Review Figure 58.9

- ▶ Exotic predators, competitors, and diseases introduced by humans are major causes of extinction. Review Figure 58.13

- ▶ In the future, global warming may be an important cause of extinction. Review Figure 58.15

Preventing Species Extinctions

► To ensure the recovery of endangered species, human manipulation of their environments and the other species that inhabit them is sometimes needed. Review Figure 58.16

► Captive propagation plays a useful role in conservation. Review Figure 58.17

Establishing Priorities for Conservation Efforts

► The best way to maintain populations is to set aside areas in which species and their habitats are protected. High-priority areas for establishing parks and reserves are regions of unusually high species richness and endemism. Review Figure 58.19

► In most countries, new parks must be created in already settled areas. Management of lands that are exploited for food, medicines, and fiber, must play an important role in conservation.

Restoring Degraded Ecosystems

► Restoration is an important component of recovery plans, but restoration of some types of environments, especially aquatic ones, is difficult.

Markets and Conservation

► Properly employed, markets can help preserve biodiversity.

► The conservation of biodiversity is not just a scientific or economic issue. It raises serious moral and ethical concerns that define what it means to be a human being on Earth.

For Discussion

1. Most species driven to extinction by people in the past were large vertebrates. Do you expect this pattern to persist into the future? If so, why? If not, why not?
2. Species endangered as a result of global warming might be preserved if we could move individuals from areas that are becoming unsuitable for them to those likely to be better for them in the future. What are the major difficulties associated with such interventions? For what types of species might they work well? Poorly? Make no difference?
3. Conservation biologists have debated extensively which is better: many small reserves or a few large ones. What ecological processes should be evaluated in making judgments about size and location of reserves? To what extent should we be concerned with preserving the largest number of species rather than those species judged to be of unusual importance for scientific, aesthetic, or commercial reasons?
4. During World War I, French doctors adopted a "triage" system of dealing with wounded soldiers. The wounded were divided into three categories: those almost certain to die no matter what was done to help them, those likely to recover even if not assisted, and those whose probability of survival was greatly increased if they were given medical attention. The limited resources available to the doctors were directed primarily at the third category. What would be the implications of adopting a similar attitude toward species preservation?
5. Economic arguments dominate discussions about the importance of preserving the biological richness of the planet. In your opinion, what role should moral arguments play?

Appendix:

Some Measurements Used in Biology

Glossary

Abdomen (ab' dun mun) [L.: belly] • In arthropods, the posterior portion of the body; in mammals, the part of the body containing the intestines and most other internal organs, posterior to the thorax.

Abscisic acid (ab sighs' ik) [L. abscissio: breaking off] • A plant growth substance having growth-inhibiting action. Causes stomata to close.

Abscission (ab sizh' un) [L. abscissio: breaking off] • The process by which leaves, petals, and fruits separate from a plant.

Absolute temperature scale • Also known as the Kelvin scale. A temperature scale in which zero is the state of no molecular motion. This "absolute zero" is -273° on the Celsius scale.

Absorption • (1) Of light: complete retention, without reflection or transmission. (2) Of liquids: soaking up (taking in through pores or cracks).

Absorption spectrum • A graph of light absorption versus wavelength of light; shows how much light is absorbed at each wavelength.

Abyssal zone (uh biss' ul) [Gr. abyssos: bottomless] • That portion of the deep ocean floor where no light penetrates.

Accessory pigments • Pigments that absorb light and transfer energy to chlorophylls for photosynthesis.

Acetylcholine • A neurotransmitter substance that carries information across vertebrate neuromuscular junctions and some other synapses. Acetylcholinesterase is an enzyme that breaks down acetylcholine.

Acetyl CoA (acetyl coenzyme A) •

Compound that reacts with oxaloacetate to produce citrate at the beginning of the citric acid cycle; a key metabolic intermediate in the formation of many compounds.

Acid [L. acidus: sharp, sour] • A substance that can release a proton in solution. (Contrast with base.)

Acid precipitation • Precipitation that has a lower pH than normal as a result of acid-forming precursors introduced into the atmosphere by human activities.

Acidic • Having a pH of less than 7.0 (a hydrogen ion concentration greater than 10^{-7} molar).

Acoelomate • Lacking a coelom.

Acquired Immune Deficiency Syndrome •

See AIDS.

Acrosome (a' krow soam) [Gr. akros: highest or outermost + soma: body] • The structure at the forward tip of an animal sperm which is the first to fuse with the egg membrane and enter the egg cell.

ACTH (adrenocorticotropin) • A pituitary hormone that stimulates the adrenal cortex.

Actin [Gr. aktis: a ray] • One of the two major proteins of muscle; it makes up the thin filaments. Forms the microfilaments found in most eukaryotic cells.

Action potential • An impulse in a neuron taking the form of a wave of depolarization or hyperpolarization imposed on a polarized cell surface.

Activating enzymes (also called aminoacyl-tRNA synthetases) • These enzymes catalyze the addition of amino acids to their appropriate tRNAs.

Activation energy (E_a) • The energy barrier that blocks the tendency for a set of chemical substances to react.

Active site • The region on the surface of an enzyme where the substrate binds, and where catalysis occurs.

Active transport • The transport of a substance across a biological membrane against a concentration gradient—that is, from a region of low concentration (of that substance) to a region of high concentration. Active transport requires the expenditure of energy and is a saturable process. (Contrast with facilitated diffusion, free diffusion; see primary active transport, secondary active transport.)

Adaptation (a dap tay' shun) • In evolutionary biology, a particular structure, physiological process, or behavior that makes an organism better able to survive and reproduce. Also, the evolutionary process that leads to the development or persistence of such a trait.

Adenine (a' den een) • A nitrogen-containing base found in nucleic acids, ATP, NAD, etc.

Adenosine triphosphate • See ATP.

Adenylate cyclase • Enzyme catalyzing the formation of cyclic AMP from ATP.

Adrenal (a dree' nal) [L. ad-: toward + renes: kidneys] • An endocrine gland located near the kidneys of vertebrates, consisting of two glandular parts, the cortex and medulla.

Adrenaline • See epinephrine.

Adrenocorticotropin • See ACTH.

Adsorption • Binding of a gas or a solute to the surface of a solid.

Aerobic (air oh' bic) [Gr. aer: air + bios: life] • In the presence of oxygen, or requiring oxygen.

Afferent (af ur unt) [L. ad: to + ferre: to bear] • To or toward, as in a neuron that carries impulses to the central nervous system, or a blood vessel that carries blood to a structure. (Contrast with efferents.)

AIDS (acquired immune deficiency syndrome) • Condition caused by a virus (HIV) in which the body's helper T lymphocytes are reduced, leaving the victim subject to opportunistic diseases.

Aldehyde (al' duh hide) • A compound with a -CHO functional group. Many sugars are aldehydes. (Contrast with ketone.)

Aldosterone (al dahs' ter own) • A steroid hormone produced in the adrenal cortex of mammals. Promotes secretion of potassium and reabsorption of sodium in the kidney.

Alga (al' gah) (plural: algae) [L.: seaweed] • Any one of a wide diversity of protists belonging to the phyla Pyrrophyta, Chrysophyta, Phaeophyta, Pdiophyta, and Chlorophyta.

Allele (a leel') [Gr. alios: other] • The alternate forms of a genetic character found at a given locus on a chromosome.

Allele frequency • The relative proportion of a particular allele in a specific population.

Allergy [Ger. allergie: altered reaction] • An overreaction to an antigen in amounts that do not affect most people; often involves IgE antibodies.

Allometric growth • A pattern of growth in which some parts of the body of an organism grow faster than others, resulting in a change in body proportions as the organism grows.

Allopatric speciation (al' lo pat' rick) [Gr. alios: other + patria: fatherland] • Also called geographical speciation, this is the formation of two species from one when reproductive isolation occurs because of the the interposition of (or crossing of) a physical geographic barrier such as a river. (Contrast with parapatric speciation, sympatric speciation.)

GLOSS \ ^

Allopolyploid • A polyploid in which the chromosome sets are derived from more than one species.

Allosteric regulation (al' lo steer' \) [Gr. alios: other + stereos: structure] • Regulation of the activity of a protein by the binding of an effector molecule at a site other than the active site.

Alpha helix • I\ pe of protein secondary

structure; a right-handed spiral.

Alternation of generations • The succession of haploid and diploid phases in some sexually reproducing organisms, notably plants.

Altruism • A behavior whose performance harms the actor but benefits other individuals.

Alveolus (al ve' o lus) (plural: alveoli) [L. alveus: cavity] • A small, baglike cavity, especially the blind sacs of the lung.

Amensalism (a men' sul ism) • Interaction in which one animal is harmed and the other is unaffected. (Contrast with commensalism, mutualism.)

Amine • An organic compound with an amino group (see Amino acid).

Amino acid • An organic compound of the general formula $H_2N-CH(R)-COOH$, where R can be one of 20 or more different side groups. An amino acid is so named because it has both a basic amine group, $-NH_2$, and an acidic carboxyl group, $-COOH$. Proteins are polymers of amino acids.

Ammonotelic (am moan' o teel' ic) [Gr. telos: end] • Describes an organism in which the final product of breakdown of nitrogen-containing compounds (primarily proteins) is ammonia. (Contrast with ureotelic, uricotelic.)

Amniocentesis • A medical procedure in which cells from the fetus are obtained from the amniotic fluid. The genetic material of the cells is then examined. (Contrast with chorionic villus sampling.)

Amniote • An organism that lays eggs that can be incubated in air (externally) because the embryo is enclosed by a fluid-filled sac. Birds and reptiles are amniotes.

Amphipathic (am' fi path' ic) [Gr. amphi: both + pathos: emotion] • Of a molecule, having both hydrophilic and hydrophobic regions.

Amylase (am' ill ase) • Any of a group of enzymes that digest starch.

Anabolism (an ab' uh liz' em) [Gr. ana: up, throughout + ballein: to throw] • Synthetic reactions of metabolism, in which complex molecules are formed from simpler ones. (Contrast with catabolism.)

Anaerobic (an ur row' bie) [Gr. an: not + aer: air + bios: life] • Occurring without the use of molecular oxygen, O_2 .

Anagenesis • Evolutionary change in a single lineage over time.

Analogy (a nal' o jee) [Gr. analogia: resembling] • A resemblance in function, and often appearance as well, between two structures which is due to convergence in evolution rather than to common ancestry. (Contrast with homology.)

Anaphase (an' a phase) [Gr. ana: indicating upward progress] • The stage in nuclear division at which the first separation of sister chromatids (or, in the first meiotic division, of paired homologues) occurs. Anaphase lasts from the moment of first separation to the time at which the moving chromosomes converge at the poles of the spindle.

Anaphylactic shock • A precipitous drop in blood pressure caused by loss of fluid from capillaries because of an increase in their permeability stimulated by an allergic reaction.

Ancestral trait • Trait shared by a group of organisms as a result of descent from a common ancestor.

Androgens (an' dro jens) • The male sex steroids.

Aneuploidy (an' you ploy dee) • A condition in which one or more chromosomes or pieces of chromosomes are either lacking or present in excess.

Angiosperm (an' jee oh spurm) [Gr. angion: vessel + sperma: seed] • One of the flowering plants; literally, one whose seed is carried in a "vessel," which is the fruit. (See fruit.)

Angiotensin (an' jee oh ten' sin) • A peptide hormone that raises blood pressure by causing peripheral vessels to constrict; maintains glomerular filtration by constricting efferent glomerular vessels; stimulates thirst; and stimulates the release of aldosterone.

Animal [L. animus: breath, soul] • A member of the kingdom Animalia. In general, a multicellular eukaryote that obtains its food by ingestion.

Animal hemisphere • The metabolically active upper portion of some animal eggs, zygotes, and embryos, which does not contain the dense nutrient yolk. The animal pole refers to the very top of the egg or embryo. (Contrast with vegetal hemisphere.)

Anion (an' eye one) • An ion with one or more negative charges. (Contrast with cation.)

Anisogamy (an' eye sog' a mee) [Gr. aniso: unequal + gamos: marriage] • The existence of two dissimilar gametes (egg and sperm).

Annual • Referring to a plant whose life cycle is completed in one growing season. (Contrast with biennial, perennial.)

Anterior pituitary • The portion of the vertebrate pituitary gland that derives from gut epithelium and produces tropic hormones.

Anther (an' thur) [Gr. anthos: flower] • A pollen-bearing portion of the stamen of a flower.

Antheridium (an' thur id' ee um) (plural: antheridia) [Gr. anthems: blooming] • The multicellular structure that produces the sperm in bryophytes and ferns.

Antibody • One of millions of proteins, produced by the immune system, that specifically recognizes a foreign substance and initiates its removal from the body.

Anticodon • A "triplet" of three nucleotides in transfer RNA that is able to pair with a complementary triplet (a codon) in messenger RNA, thus aligning the transfer RNA on the proper place on the messenger. The codon (and, reciprocally, the anticodon) codes for a specific amino acid.

Antidiuretic hormone • A hormone that controls water reabsorption in the mammalian kidney. Also called vasopressin.

Antigen (an' ti jun) • Any substance that stimulates the production of an antibody or antibodies in the body of a vertebrate.

Antigen processing • The breakdown of antigenic proteins into smaller fragments, which are then presented on the cell surface, along with MHC proteins, to T cells.

Antigenic determinant • A specific region of an antigen, which is recognized by and binds to a specific antibody.

Antiport • A membrane transport process that carries one substance in one direction and another in the opposite direction. (Contrast with symport.)

Antisense nucleic acid • A single-stranded RNA or DNA complementary to and thus targeted against the mRNA transcribed from a harmful gene such as an oncogene.

Anus (a' nus) • Opening through which digestive wastes are expelled, located at the posterior end of the gut.

Aorta (a or' tuh) [Gr. aorte: aorta] • The main trunk of the arteries leading to the systemic (as opposed to the pulmonary) circulation.

Apex (a' pecks) • The tip or highest point of a structure, as the apex of a growing stem or root.

Apical (a' pi kul) • Pertaining to the apex, or tip, usually in reference to plants.

Apical dominance • Inhibition by the apical bud of the growth of axillary buds.

Apical meristem • The meristem at the tip of a shoot or root; responsible for the plant's primary growth.

Apomixis (ap oh mix' is) [Gr. apo: away from + mixis: sexual intercourse] • The asexual production of seeds.

Apoplast (ap' oh plast) • In plants, the continuous meshwork of cell walls and extracellular spaces through which material can pass without crossing a plasma membrane. (Contrast with symplast.)

Apoptosis (ay' pu toh sis) • A series of genetically programmed events leading to cell death.

Aquaporin • A transport protein in plant and animals cells through which water passes in osmosis.

Archegonium (ar' ke go' nee um) [Gr. archegonos: first of a kind] • The multicellular structure that produces eggs in bryophytes, ferns, and gymnosperms.

Archenteron (ark en' ter on) [Gr. archos: beginning + enteron: bowel] • The earliest primordial animal digestive tract.

Arteriosclerosis • See atherosclerosis.

GLOSSARY

Artery • A muscular blood vessel carrying oxygenated blood away from the heart to other parts of the body. (Contrast with vein.)

Ascus (ass' cuss) [Gr. askos: bladder] • In fungi belonging to the phylum Ascomycota (the sac fungi), the club-shaped sporangium within which spores (ascospores) are produced by meiosis.

Asexual • Without sex.

Assortative mating • A breeding system in which mates are selected on the basis of a particular trait or group of traits.

Atherosclerosis (ath' er oh sklair oh' sis) • A disease of the lining of the arteries characterized by fatty, cholesterol-rich deposits in the walls of the arteries. When fibroblasts infiltrate these deposits and calcium precipitates in them, the disease become arteriosclerosis, or "hardening of the arteries."

Atmosphere • The gaseous mass surrounding our planet. Also: a unit of pressure, equal to the normal pressure of air at sea level.

Atom [Gr. atomos: indivisible] • The smallest unit of a chemical element. Consists of a nucleus and one or more electrons.

Atomic mass (also called atomic weight) • The average mass of an atom of an element on the amu scale. (The average depends upon the relative amounts of different isotopes of an element on Earth.)

Atomic number • The number of protons in the nucleus of an atom, also equal to the number of electrons around the neutral atom. Determines the chemical properties of the atom.

ATP (adenosine triphosphate) • A compound containing adenine, ribose, and three phosphate groups. When it is formed, useful energy is stored; when it is broken down (to ADP or AMP), energy is released to drive endergonic reactions. ATP is an energy storage compound.

ATP synthase • An integral membrane protein that couples the transport of protons with the formation of ATP.

Atrium (a' tree um) • A body cavity, as in the hearts of vertebrates. The thin-walled chamber(s) entered by blood on its way to the ventricle(s). Also, the outer ear.

Autoimmune disease • A disorder in which the immune system attacks the animal's own antigens.

Autonomic nervous system • The system (which in vertebrates comprises sympathetic and parasympathetic subsystems) that controls such involuntary functions as those of guts and glands.

Autosome • Any chromosome (in a eukary-ote) other than a sex chromosome.

Autotroph (au' tow trow' fik) [Gr. antos: self + trophic: food] • An organism that is capable of living exclusively on inorganic materials, water, and some energy source such as sunlight or chemically reduced matter. (Contrast with heterotroph.)

Auxin (awk' sin) [Gr. auxein: increase] • In plants, a substance (indoleacetic acid) that regulates growth and various aspects of development.

Auxotroph (awks' o trofe) [Gr. auxanein: to grow + trophe: food] • A mutant form of an organism that requires a nutrient or nutrients not required by the wild type, or reference, form of the organism. (Contrast with prototroph.)

Axon [Gr.: axle] • Fiber of a neuron which can carry action potentials. Carries impulses away from the cell body of the neuron; releases a neurotransmitter substance.

Axon hillock • The junction between an axon and its cell body; where action potentials are generated.

Axon terminals • The endings of an axon; they form synapses and release neurotransmitter.

Axoneme (ax' oh neem) • The complex of microtubules and their crossbridges that forms the motile apparatus of a cilium.

Bacillus (buh sil' us) [L.: little rod] • Any of various rod-shaped bacteria.

Bacteriophage (bak teer' ee o fayj) [Gr. bak-terion: little rod + phagein: to eat] • One of a group of viruses that infect bacteria

and ultimately cause their disintegration.

Bacteria (bak teer' ee ah) (singular: bacterium) [Gr. bakterion: little rod] • Prokaryote in the Domain Bacteria. The chromosomes of bacteria are not contained in nuclear envelopes.

Balanced polymorphism [Gr. pohjmorphos: having many forms] • The maintenance of more than one form, or the maintenance at a given locus of more than one allele, at frequencies of greater than one percent in a population. Often results when heterozygotes are superior to both homozygotes.

Bark • All tissues outside the vascular cambium of a plant.

Baroreceptor [Gr. baros: weight] • A pressure-sensing cell or organ.

Barr body • In mammals, an inactivated X chromosome.

Basal body • Centriole found at the base of a eukaryotic flagellum or cilium.

Basal metabolic rate • The minimum rate of energy turnover in an awake (but resting) bird or mammal that is not expending energy for thermoregulation.

Base • (1) A substance which can accept a proton (hydrogen ion; H^+) in solution. (Contrast with acid.) (2) In nucleic acids, a nitrogen-containing molecule that is attached to each sugar in the backbone. (See purine; pyrimidine.)

Base pairing • See complementary base pairing.

Basic • having a pH greater than 7.0 (having a hydrogen ion concentration lower than 10^{-7} molar).

Basidium (bass id' ee yum) • In fungi of the class Basidiomycetes, the characteristic sporangium in which four spores are formed by meiosis and then borne externally before being shed.

Batesian mimicry • Mimicry by a relatively harmless kind of organism of a more dangerous one, by which the mimic enjoys protection from predators that mistake it for

the dangerous model. (Contrast with Mullerian mimicry.)

B cell • A type of lymphocyte involved in the humoral immune response of vertebrates. Upon recognizing an antigenic determinant, a B cell develops into a plasma cell, which secretes an antibody. (Contrast with a T cell.)

Benefit • An improvement in survival and reproductive success resulting from a behavior. (Contrast with cost.)

Benign (be nine') • A tumor that grows to a certain size and then stops, usually with a fibrous capsule surrounding the mass of cells. Benign tumors do not spread (metastasize) to other organs.

Benthic zone [Gr. benthos: bottom of the sea] • The bottom of the ocean. (Contrast with pelagic zone.)

Beta-pleated sheet • Type of protein secondary structure; results from hydrogen bonding between polypeptide regions running antiparallel to each other.

Biennial • Referring to a plant whose life cycle includes vegetative growth in the first year and flowering and senescence in the second year. (Contrast with annual, perennial.)

Bilateral symmetry • The condition in which only the right and left sides of an organism, divided exactly down the back, are mirror images of each other. (Contrast with biradial symmetry)

Bile • A secretion of the liver delivered to the small intestine via the common bile duct. In the intestine, bile emulsifies fats.

Binocular cells • Neurons in the visual cortex that respond to input from both retinas; involved in depth perception.

Binomial (bye nome' ee al) • Consisting of two names; for example, the binomial nomenclature of biology which gives the name of the genus followed by the name of the species.

Biodiversity crisis • The current high rate of loss of species, caused primarily by human activities.

Biogeochemical cycles • Movement of elements through living organisms and the physical environment.

Biogeography • The scientific study of the geographic distribution of organisms.

Biogeographic region • A continental-scale part of Earth that has a biota distinct from that of other such regions.

Biological species concept • The view that a species is most usefully defined as a population or series of populations within which there is a significant amount of gene flow under natural conditions, but which is genetically isolated from other populations.

Bioluminescence • The production of light by biochemical processes in an organism.

Biomass • The total weight of all the living organisms, or some designated group of living organisms, in a given area.

Biome (bye' ome) • A major division of the ecological communities of Earth; characterized by distinctive vegetation.

SSAItt

Biota (bye oh' tah) • All of the organisms including animals, plants, fungi, and microorganisms, found in a given area.

Biotechnology • The use of cells to make medicines, foods and other products useful to humans.

Radial symmetry • Radial symmetry modified so that only two planes can divide the animal into similar halves.

Blastocoel (blass' toe seal) [Br. blastos: sprout + koilos: hollow] • The central, hollow center of a blastula.

Blastodisc (blass' toe disk) • A disk of cells forming on the surface of a large yolk mass, comparable to a blastula, but occurring in animals such as birds and reptiles, in which the mass of yolk restricts cleavage to one side of the egg only.

Blastomere • A cell produced by the division of a fertilized egg.

Blastopore • The opening from the archenteron to the exterior of a gastrula.

Blastula (blass' chu luh) [Gr. blastos: sprout] • An early stage in animal embryology; in many species, a hollow sphere of cells surrounding a central cavity, the blastocoel. (Contrast with blastodisc.)

Blood-brain barrier • A property of the blood vessels of the brain that prevents most chemicals from diffusing from the blood into the brain.

Body plan • A basic structural design that includes an entire animal, its organ systems, and the integrated functioning of its parts. Phylogenetic groups of organisms are classified in part on the basis of a shared body plan.

Bowman's capsule • An elaboration of kidney tubule cells that surrounds a network of capillaries (the glomerulus). Blood is filtered across the walls of these capillaries and the filtrate is collected into Bowman's capsule.

Brain stem • The portion of the vertebrate brain between the spinal cord and the fore-brain.

Brassinosteroids • Plant steroid hormones that promote the elongation of stems and pollen tubes.

Bronchus (plural: bronchi) • The major air-way(s) branching off the trachea into the vertebrate lung.

Brown fat • Fat tissue in mammals that is specialized to produce heat. It has many mitochondria and capillaries, and a protein that uncouples oxidative phosphorylation.

Browser • An animal that feeds on the tissues of woody plants.

Bryophyte (bri' uh fite') [Gr. bruon: moss + phyton: plant] • A moss. Formerly was often used to refer to all the nontracheophyte plants.

Budding • Asexual reproduction in which a more or less complete new organism simply grows from the body of the parent organism and eventually detaches itself.

Buffering • A process by which a system resists change—particularly in pH, in which case added acid or base is partially converted to another form.

C₃ photosynthesis • The form of photosynthesis in which 3-phosphoglycerate is the first stable product, and ribulose biphosphate is the CO₂ receptor.

C₄ photosynthesis • The form of photosynthesis in which oxaloacetate is the first stable product, and phosphoenolpyruvate is the CO₂ acceptor. C₄ plants also perform the reactions of C₃ photosynthesis.

Calcitonin • A hormone produced by the thyroid gland; it lowers blood calcium and promotes bone formation. (Contrast with parathormone.)

Calmodulin (cal mod' joo lin) • A calcium-binding protein found in all animal and plant cells; mediates many calcium-regulated processes.

calorie [L. calor. heat] • The amount of heat required to raise the temperature of one gram of water by one degree Celsius (1°C) from 14.5°C to 15.5°C. In nutrition studies, "Calorie" (spelled with a capital C) refers to the kilocalorie (1 kcal = 1,000 cal).

Calvin-Benson cycle • The stage of photosynthesis in which CO₂ reacts with RuBP to form 3PG, 3PG is reduced to a sugar, and RuBP is regenerated, while other products are released to the rest of the plant.

Calyx (kay' licks) [Gr. kalyx: cup] • All of the sepals of a flower, collectively.

CAM • See crassulacean acid metabolism.

Cambium (kam' bee um) [L. cambiare: to exchange] • A meristem that gives rise to radial rows of cells in stem and root,

increasing them in girth; commonly applied to the vascular cambium which produces wood and phloem, and the cork cambium, which produces bark.

cAMP (cyclic AMP) • A compound, formed from ATP, that mediates the effects of numerous animal hormones. Also needed for the transcription of catabolite-repressible operons in bacteria. Used for communication by cellular slime molds.

Canopy • The leaf-bearing part of a tree. Collectively the aggregate of the leaves and branches of the larger woody plants of an ecological community.

Capillaries [L. capillaris: hair] • Very small tubes, especially the smallest blood-carrying vessels of animals between the termination of the arteries and the beginnings of the veins.

Capsid • The protein coat of a virus.

Carbohydrates • Organic compounds with the general formula $C_n(H_2O)_m$. Common examples are sugars, starch, and cellulose.

Carboxylic acid (kar box sill' ik) • An organic acid containing the carboxyl group, $-COOH$, which dissociates to the carboxylate ion, $-COO^-$.

Carcinogen (car sin' oh jen) • A substance that causes cancer.

Cardiac (kar' dee ak) [Gr. kardia: heart] • Pertaining to the heart and its functions.

Carnivore [L. earn: flesh + vorare: to devour] • An organism that feeds on animal tissue. (Contrast with detritivore, herbivore, omni-vore.)

Carotenoid (ka rah' tuh noid) [L. carota: carrot] • A yellow, orange, or red lipid pigment commonly found as an accessory pigment in photosynthesis; also found in fungi.

Carpel (kar' pel) [Gr. karpos: fruit] • The organ of the flower that contains one or more ovules.

Carrier • (1) In facilitated diffusion, a membrane protein that binds a specific molecule and transports it through the membrane. (2) In respiratory and photosynthetic electron transport, a participating substance such as NAD that exists in both oxidized and reduced forms. (3) In genetics, a person heterozygous for a recessive trait.

Carrying capacity • In ecology, the largest number of organisms of a particular species that can be maintained indefinitely in a given part of the environment.

Cartilage • In vertebrates, a tough connective tissue found in joints, the outer ear, and elsewhere. Forms the entire skeleton in some animal groups.

Casparian strip • A band of cell wall containing suberin and lignin, found in the endodermis. Restricts the movement of water across the endodermis.

Catabolism [Ge. kata: down + ballein: to throw] • Degradational reactions of metabolism, in which complex molecules are broken down. (Contrast with anabolism.)

Catalyst (cat' a list) [Gr. kata-, implying the breaking down of a compound] • A chemical substance that accelerates a reaction without itself being consumed in the overall course of the reaction. Catalysts lower the activation energy of a reaction. Enzymes are biological catalysts.

Cation (cat' eye on) • An ion with one or more positive charges. (Contrast with anion.)

Caudal [L. cauda: tail] • Pertaining to the tail, or to the posterior part of the body.

cDNA • See complementary DNA.

Cecum (see' cum) [L. caecus: blind] • A blind branch off the large intestine. In many nonruminant mammals, the cecum contains a colony of microorganisms that contribute to the digestion of food.

Cell adhesion molecules • Molecules on animal cell surfaces that affect the selective association of cells during development of the embryo.

Cell cycle • The stages through which a cell passes between one division and the next. Includes all stages of interphase and mitosis.

Cell division • The reproduction of a cell to produce two new cells. In eukaryotes, this process involves nuclear division (mitosis) and cytoplasmic division (cytokinesis).

Cell theory • The theory, well established, that organisms consist of cells, and that all cells come from preexisting cells.

Cell wall • A relatively rigid structure that encloses cells of plants, fungi, many protists, and most bacteria. The cell wall gives these cells their shape and limits their expansion in hypotonic media.

GLOSSARY

Cellular immune system • That part of the immune system that is based on the activities of T cells. Directed against parasites, fungi, intracellular viruses, and foreign tissues (grafts). (Contrast with humoral immune system.)

Cellular respiration • See respiration.

Cellulose (sell' you lowss) • A straight-chain polymer of glucose molecules, used by plants as a structural supporting material.

Central dogma • The statement that information flows from DNA to RNA to polypeptide (in retroviruses, there is also information flow from RNA to cDNA).

Central nervous system • That part of the nervous system which is condensed and centrally located, e.g., the brain and spinal cord of vertebrates; the chain of cerebral, thoracic and abdominal ganglia of arthropods.

Centrifuge [L.figere: to flee] • A device in which a sample can be spun around a central axis at high speed, creating a centrifugal force that mimics a very strong gravitational force. Used to separate mixtures of suspended materials.

Centriole (sen' tree ole) • A paired organelle that helps organize the microtubules in animal and protist cells during nuclear division.

Centromere (sen' tro meer) [Gr. centron: center + mews: part] • The region where sister chromatids join.

Centrosome (sen' tro soam) • The major microtubule organizing center of an cell.

Cephalization (sef uh luh zay' shun) [Gr. kephale: head] • The evolutionary trend toward increasing concentration of brain and sensory organs at the anterior end of the animal.

Cerebellum (sair' uh bell' um) [L.: diminutive of cerebrum: brain] • The brain region that controls muscular coordination; located at the anterior end of the hindbrain.

Cerebral cortex • The thin layer of gray matter (neuronal cell bodies) that overlays the cerebrum.

Cerebrum (su ree' brum) [L.: brain] • The dorsal anterior portion of the forebrain, making up the largest part of the brain of mammals. In mammals, the chief coordination center of the nervous system; consists of two cerebral hemispheres.

Cervix (sir' vix) [L.: neck] • The opening of the uterus into the vagina.

cGMP (cyclic guanosine monophosphate)

• An intracellular messenger that is part of signal transmission pathways involving G proteins. (See G protein.)

Channel • A membrane protein that forms an aqueous passageway through which specific solutes may pass by simple diffusion; some channels are gated: they open and close in response to binding of specific molecules.

Chaperone protein • A protein that assists a newly forming protein in adopting its appropriate tertiary structure.

animal

Chemical bond • An attractive force stably linking two atoms.

Chemiosmotic mechanism • The formation of ATP in mitochondria and chloroplasts, resulting from a pumping of protons across a membrane (against a gradient of electrical charge and of pH), followed by the return of the protons through a protein channel with ATPase activity.

Chemoautotroph • An organism that uses carbon dioxide as a carbon source and obtains energy by oxidizing inorganic substances from its environment. (Contrast with chemoheterotroph, photoautotroph, photoheterotroph.)

Chemoheterotroph • An organism that must obtain both carbon and energy from organic substances. (Contrast with chemoautotroph, photoautotroph, photoheterotroph.)

Chemoreceptor • A cell or tissue that senses specific substances in its environment.

Chemosynthesis • Synthesis of food substances, using the oxidation of reduced materials from the environment as a source of energy.

Chiasma (kie az' muh) (plural: chiasmata) [Gr.: cross] • An X-shaped connection between paired homologous chromosomes in prophase I of meiosis. A chiasma is the visible manifestation of crossing over between homologous chromosomes.

Chitin (kye' tin) [Gr. kiton: tunic] • The characteristic tough but flexible organic component of the exoskeleton of arthropods, consisting of a complex, nitrogen-containing polysaccharide. Also found in cell walls of fungi.

Chlorophyll (klor' o fill) [Gr. kloros: green + phyllon: leaf] • Any of a few green pigments associated with chloroplasts or with certain bacterial membranes; responsible for trapping light energy for photosynthesis.

Chloroplast [Gr. kloros: green + plast: a particle] • An organelle bounded by a double membrane containing the enzymes and pigments that perform photosynthesis. Chloroplasts occur only in eukaryotes.

Choanocyte (cho' an oh cite) • The collared, flagellated feeding cells of sponges.

Cholecystokinin (ko' lee sis to kai nin) • A hormone produced and released by the lining of the duodenum when it is stimulated by undigested fats and proteins. It stimulates the gallbladder to release bile and slows stomach activity.

Chorion (kor' ee on) [Gr. kliorkm: afterbirth] • The outermost of the membranes protecting mammal, bird, and reptile embryos; in mammals it forms part of the placenta.

Chorionic villus sampling • A medical procedure that extracts a portion of the chorion from a pregnant woman to enable genetic and biochemical analysis of the embryo. (Contrast with amniocentesis.)

Chromatid (kro' ma tid) • Each of a pair of new sister chromosomes from the time at which the molecular duplication occurs until the time at which the centromeres separate at the anaphase of nuclear division.

Chromatin • The nucleic acid-protein complex found in eukaryotic chromosomes.

Chromatophore (krow mat' o for) [Gr. kroma: color + phoreus: carrier] • A pigment-bearing cell that expands or contracts to change the color of the organism.

Chromosome (krome' o sowm) [Gr. kroma: color + soma: body] • In bacteria and viruses, the DNA molecule that contains most or all of the genetic information of the cell or virus. In eukaryotes, a structure composed of DNA and proteins that bears part of the genetic information of the cell.

Chylomicron (ky low my' cron) • Particles of lipid coated with protein, produced in the gut from dietary fats and secreted into the extracellular fluids.

Chyme (kime) [Gr. kymus, juice] • Created in the stomach; a mixture of ingested food with the digestive juices secreted by the salivary glands and the stomach lining.

Cilium (sil' ee um) (plural: cilia) [L. cilium: eyelash] • Hairlike organelle used for locomotion by many unicellular organisms and for moving water and mucus by many multicellular organisms. Generally shorter than a flagellum.

Circadian rhythm (sir kade' ee an) [L. circa:

approximately + dies: day] • A rhythm in behavior, growth, or some other activity that recurs about every 24 hours under constant conditions.

Circannual rhythm (sir can' you al) [L. circa: approximately + annus: year] • A rhythm of behavior, growth, or some other activity that recurs on a yearly basis.

Citric acid cycle • A set of chemical reactions in cellular respiration, in which acetyl CoA reacts with oxaloacetate to form citric acid, and oxaloacetate is regenerated. Acetyl CoA is oxidized to carbon dioxide, and hydrogen atoms are stored as NADH and FADH₂. Also called the Krebs cycle.

Class • In taxonomy, the category below the phylum and above the order; a group of related, similar orders.

Class I MHC molecules • These cell surface proteins participate in the cellular immune response directed against virus-infected cells.

Class II MHC molecules • These cell surface proteins participate in the cell-cell interactions (of helper T cells, macrophages, and B cells) of the humoral immune response.

Class switching • The process whereby a plasma cell changes the class of immunoglobulin that it synthesizes. This results from the deletion of part of the constant region of DNA, bringing in a new C segment. The variable region is the same as before, so that the new immunoglobulin has the same antigenic specificity.

Clathrin • A fibrous protein on the inner surfaces of animal cell membranes that strengthens coated vesicles and thus participates in receptor-mediated endocytosis.

Clay • A soil constituent comprising particles smaller than 2 micrometers in diameter.

Cleavages • First divisions of the fertilized egg of an animal.

GLOSSAL

Cline • A gradual change in the traits of a species over a geographical gradient.

Cloaca (klo a\ kuh) [L. cloaca: sewer] • In some invertebrates, the posterior part of the gut; in many vertebrates, an opening receiving

material from the digestive reproductive, muscular, excretory systems.

Clonal anergy • When a naive T cell encounters a self-antigen, the T cell may

bind to the antigen but does not receive signals from an antigen-presenting cell. Instead of being activated, the T cell dies (becomes anergic). In this way, we avoid reacting to our own tissue-specific antigens.

Clonal deletion • In immunology, the inactivation or destruction of lymphocyte clones that would produce immune reactions against the animal's own body.

Clonal selection • The mechanism by which exposure to antigen results in the activation of selected T- or B-cell clones, resulting in an immune response.

Clone [Gr. klon: twig, shoot] • Genetically identical cells or organisms produced from a common ancestor by asexual means.

Cnidocytes • The feeding cells of cnidarians, within which nematocysts are housed.

Coacervate (ko as' er vate) [L. coacervare: to heap up] • An aggregate of colloidal particles in suspension.

Coacervate drop • Drops formed when a mixture of large proteins and polysaccharides is shaken in water. The interiors of these drops, which are often very stable, contain most of the proteins and polysaccharides.

Coated vesicle • Vesicle, sometimes formed from a coated pit, with characteristic "bristly" surface; its membrane contains distinctive proteins, including clathrin.

Coccus (kock' us) [Gr. kokkos: berry, pit] • Any of various spherical or spheroidal bacteria.

Cochlea (kock' lee uh) [Gr. kokhlos: a land snail] • A spiral tube in the inner ear of vertebrates; it contains the sensory cells involved in hearing.

Codominance • A condition in which two alleles at a locus produce different phenotypic effects and both effects appear in heterozygotes.

Codon • A "triplet" of three nucleotides in messenger RNA that directs the placement of a particular amino acid into a polypeptide chain. (Contrast with anticodon.)

Coefficient of relatedness • The probability that an allele in one individual is an identical copy, by descent, of an allele in another individual.

Coelom (see' lum) [Gr. koiloma: cavity] • The body cavity of certain animals, which is lined with cells of mesodermal origin.

Coelomate • Having a coelom.

Coenocyte (seen' a sight) [Gr.: common cell] • A "cell" bounded by a single plasma membrane, but containing many nuclei.

Coenzyme • A nonprotein molecule that plays a role in catalysis by an enzyme. The coenzyme may be part of the enzyme molecule or free in solution. Some coenzymes are oxidizing or reducing agents.

Coevolution • Concurrent evolution of two or more species that are mutually affecting each other's evolution.

Cohort (co' hort) [L. cohors: company of soldiers] • A group of similar-age organisms, considered as it passes through time.

Collagen [Gr. kolla: glue] • A fibrous protein found extensively in bone and connective tissue.

Collecting duct • In vertebrates, a tubule that receives urine produced in the nephrons of the kidney and delivers that fluid to the ureter for excretion.

Collenchyma (cull eng' kyma) [Gr. kolla: glue + enchyma: infusion] • A type of plant cell, living at functional maturity, which lends flexible support by virtue of primary cell walls thickened at the corners. (Contrast with parenchyma, sclerenchyma.)

Colon [Gr. kolon: large intestine] • The large intestine.

Commensalism • The form of symbiosis in which one species benefits from the association, while the other is neither harmed nor benefited.

Common bile duct • A single duct that delivers bile from the gallbladder and secretions from the pancreas into the small intestine.

Communication • A signal from one organism (or cell) that alters the pattern of behavior in another organism (or cell) in an adaptive fashion.

Community • Any ecologically integrated group of species of microorganisms, plants, and animals inhabiting a given area.

Companion cell • Specialized cell found adjacent to a sieve tube member in flowering plants.

Comparative analysis • An approach to studying evolution in which hypotheses are tested by measuring the distribution of

states among a large number of species.

Comparative genomics • Computer-aided comparison of DNA sequences between different organisms to reveal genes with related functions.

Compensation point • The light intensity at which the rates of photosynthesis and of cellular respiration are equal.

Competitive inhibitor • A substance, similar in structure to an enzyme's substrate, that binds the active site and thus inhibits a reaction.

Competition • In ecology, use of the same resource by two or more species, when the resource is present in insufficient supply for the combined needs of the species.

Competitive exclusion • A result of competition between species for a limiting resource in which one species completely eliminates the other.

Competitive inhibitor • A substance, similar in structure to an enzyme's substrate, that binds the active site and inhibits a reaction.

Complement system • A group of eleven proteins that play a role in some reactions of the immune system. The complement proteins are not immunoglobulins.

Complementary base pairing • The A-T

(or A-U), T-A (or U-A), C-G and G-C pairing of bases in double-stranded DNA, in transcription, and between tRNA and mRNA.

Complementary DNA (cDNA) • DNA

formed by reverse transcriptase acting with an RNA template; essential intermediate in the reproduction of retroviruses; used as a tool in recombinant DNA technology; lacks introns.

Complete metamorphosis • A change of state during the life cycle of an organism in which the body is almost completely rebuilt to produce an individual with a very different body form. Characteristic of insects such as butterflies, moths, beetles, ants, wasps, and flies.

Compound • (1) A substance made up of atoms of more than one element. (2) Made up of many units, as the compound eyes of arthropods (as opposed to the simple eyes of the same group of organisms).

Condensation reaction • A reaction in which two molecules become connected by a covalent bond and a molecule of water is released. ($AH + BOH \rightarrow AB + H_2O$.)

Cones • (1) In the vertebrate retina: photoreceptors responsible for color vision. (2) In gymnosperms: reproductive structures consisting of many sporophylls packed relatively tightly.

Conidium (ko nid' ee um) [Gr. konis: dust] • An asexual fungus spore borne singly or in chains either apically or laterally on a hypha.

Conifer (kahn' e fer) [Gr. konos: cone + phew: carry] • One of the cone-bearing gymnosperms, mostly trees, such as pines and firs.

Conjugation (kahn' jew gay' shun) [L. con-jugare: yoke together] • The close approximation of two cells during which they exchange genetic material, as in Paramecium and other ciliates, or during which DNA passes from one to the other through a tube, as in bacteria.

Connective tissue • An animal tissue that connects or surrounds other tissues; its cells are embedded in a collagen-containing matrix.

Connexon • In a gap junction, a protein channel linking adjacent animal cells.

Consensus sequences • Short stretches of DNA that appear, with little variation, in many different genes.

Constant region • The constant region in an immunoglobulin is encoded by a single exon and determines the function, but not the specificity, of the molecule. The constant region of the T cell receptor anchors the protein to the plasma membrane.

Constitutive enzyme • An enzyme that is present in approximately constant amounts in a system, whether its substrates are present or absent. (Contrast with inducible enzyme.)

GLOSSARY

Consumer • An organism that eats the tissues of some other organism.

Continental drift • The gradual drifting apart of the world's continents that has occurred over a period of billions of years.

Convergent evolution • The evolution of

similar features independently in unrelated taxa from different ancestral structures.

Cooperative act • Behavior in which two or more individuals interact to their mutual benefit. No conscious awareness by the actors of the effects of their behavior is implied.

Cooption • The act of capturing something for a particular use. In ecology refers to the diversion of ecological production for human use. Such production is said to be coopted.

Copulation • Reproductive behavior that results in a male depositing sperm in the reproductive tract of a female.

Corepressor • A low molecular weight compound that unites with a protein (the repressor) to prevent transcription in a repressible operon.

Cork • A waterproofing tissue in plants, with suberin-containing cell walls. Produced by a cork cambium.

Corolla (ko role' lah) [L.: diminutive of corona: wreath, crown] • All of the petals of a flower, collectively.

Coronary (kor' oh nair ee) • Referring to the blood vessels of the heart.

Corpus luteum (kor' pus loo' tee um) [L. corpus: body + luteum: yellow] A structure formed from a follicle after ovulation; it produces hormones important to the maintenance of pregnancy.

Cortex [L.: bark or rind] • (1) In plants, the tissue between the epidermis and the vascular tissue of a stem or root. (2) In animals, the outer tissue of certain organs, such as the adrenal cortex and cerebral cortex.

Corticosteroids • Steroid hormones produced and released by the cortex of the adrenal gland.

Cost • See energetic cost, opportunity cost, risk cost.

Cotyledon (kot' ul lee' dun) [Gr. kotyledon: a hollow space] • A "seed leaf." An embryonic organ which stores and digests reserve materials; may expand when seed germinates.

Countercurrent exchange • An adaptation that promotes maximum exchange of heat or any diffusible substance between two fluids by the fluids flow in opposite directions through parallel tubes in close approximation to each other. An example is counter-current heat exchange between arterioles and venules in the extremities of some animals.

Covalent bond • A chemical bond that arises from the sharing of electrons between two atoms. Usually a strong bond.

Crassulacean acid metabolism (CAM) • A metabolic pathway enabling the plants that possess it to store carbon dioxide at night and then perform photosynthesis during the day with stomata closed.

Crista (plural; cristae) • A small, shelflike projection of the inner membrane of a mitochondrion; the site of oxidative phosphorylation.

Critical night length • In the photoperiodic flowering response of short-day plants, the length of night above which flowering occurs and below which the plant remains vegetative. (The reverse applies in the case of long-day plants.)

Critical period • The age during which some particular type of learning must take place or during which it occurs much more easily than at other times. Typical of song learning among birds.

Cross section (also called a transverse section) • A section taken perpendicular to the longest axis of a structure.

Crossing over • The mechanism by which linked markers undergo recombination. In general, the term refers to the reciprocal exchange of corresponding segments between two homologous chromatids.

CRP • The cAMP receptor protein that interacts with the promoter to enhance transcription; a lowered cAMP concentration results in catabolite repression.

Crustacean (crus tay' see an) • A member of the phylum Crustacea, such as a crab, shrimp, or sowbug.

Cryptic appearance [Gr. kryptos: hidden] • The resemblance of an animal to some part of its environment, which helps it to escape detection by predators.

Cryptochromes [Gr. kryptos: hidden + kroma: color] • Photoreceptors mediating some blue-light effects in plants and animals.

Culture • (1) A laboratory association of organisms under controlled conditions. (2) The collection of knowledge, tools, values, and rules that characterize a human society.

Cuticle • A waxy layer on the outer surface of a plant or an insect, tending to retard water loss.

Cyanobacteria (sigh an' o bacteria) [Gr. kuanos: the color blue] • A division of photo-synthetic bacteria, formerly referred to as blue-green algae; they lack sexual reproduction, and they use chlorophyll a in their photosynthesis.

Cyclic AMP • See cAMP

Cyclins • Proteins that activate cyclin-dependent kinases, bringing about transitions in the cell cycle.

Cyclin-dependent kinase (cdk) • A kinase is an enzyme that catalyzes the addition of phosphate groups from ATP to target molecules. Cdk's target proteins involved in transitions in the cell cycle and are active only when complexed to additional protein subunits, cyclins.

Cyst (sist) [Gr. kystis: pouch] • (1) A resistant, thick-walled cell formed by some protozoists and other organisms. (2) An abnormal sac, containing a liquid or semisolid substance, produced in response to injury or illness.

Cytochromes (sy' toe chromes) [Gr. kytos: container + chroma: color] • Iron-containing red proteins, components of the electron-

transfer chains in photophosphorylation and respiration.

Cytokinesis (sy' toe kine ee' sis) [Gr. kytos: container + kinein: to move] • The division of the cytoplasm of a dividing cell. (Contrast with mitosis.)

Cytokinin (sy' toe kine' in) [Gr. kytos: container + kinein: to move] • A member of a class of plant growth substances playing roles in senescence, cell division, and other phenomena.

Cytoplasm • The contents of the cell, excluding the nucleus.

Cytoplasmic determinants • In animal development, gene products whose spatial distribution may determine such things as embryonic axes.

Cytosine (site' oh seen) • A nitrogen-containing base found in DNA and RNA.

Cytoskeleton • The network of microtubules and microfilaments that gives a eukaryotic cell its shape and its capacity to arrange its organelles and to move.

Cytosol • The fluid portion of the cytoplasm, excluding organelles and other solids.

Cytotoxic T cells • Cells of the cellular immune system that recognize and directly eliminate virus-infected cells. (Contrast with helper T cells, suppressor T cells.)

Decomposer • See detritivore.

Degeneracy • The situation in which a single amino acid may be represented by any of two or more different codons in messenger RNA. Most of the amino acids can be represented by more than one codon.

Degradative succession • Ecological succession occurring on the dead remains of the bodies of plants and animals, as when leaves or animal bodies rot.

Deletion (genetic) • A mutation resulting from the loss of a continuous segment of a gene or chromosome. Such mutations never revert to wild type. (Contrast with duplication, point mutation.)

Deme (deem) [Gr. demos: common people] • Any local population of individuals belonging to the same species that interbreed with one another.

Demographic processes • The events—such as births, deaths, immigration, and emigration—that determine the number of individuals in a population.

Demographic stochasticity • Random variations in the factors influencing the size, density, and distribution of a population.

Demography • The study of dynamical changes in the sizes, densities, and distributions of populations.

Denaturation • Loss of activity of an enzyme or nucleic acid molecule as a result of structural changes induced by heat or other means.

Dendrite [Gr. dendron: a tree] • A fiber of a neuron which often cannot carry action potentials. Usually much branched and relatively short compared with the axon, and commonly carries information to the cell body of the neuron.

SSAR\

Denitrification • Metabolic activity by which inorganic nitrogen-containing ions are reduced to form nitrogen gas and other products; carried on in certain soil bacteria.

Density dependence • Change in the severity

of action of agents affecting birth and death rate within populations that are directly or inversely related to population density.

Density independence • The state where the severity of action of agents affecting birth and death rates within a population does not change with the density of the population.

Deoxyribonucleic acid • See DNA.

Depolarization • A change in the electric potential across a membrane from a condition in which the inside of the cell is more negative than the outside to a condition in which the inside is less negative, or even positive, with reference to the outside of the cell. (Contrast with hyperpolarization.)

Derived trait • A trait found among members of a lineage that was not present in the ancestors of that lineage.

Dermal tissue system • The outer covering of a plant, consisting of epidermis in the young plant and periderm in a plant with extensive secondary growth. (Contrast with ground tissue system and vascular tissue SJ stem.)

Desmosome (dez' mo sovvm) [Gr. desmos: bond + soma: body] • An adhering junction between animal cells.

Determination • Process whereby an embryonic cell or group of cells becomes fixed into a predictable developmental pathway.

Detritivore (di try' ti vore) [L. detritus: worn away + vorare: to devour] • An organism that obtains its energy from the dead bodies and/or waste products of other organisms.

Deuterostome • A major evolutionary lineage in animals, characterized by radial cleavage, enterocoelous development, and other traits. (Compare with protostome.)

Development • Progressive change, as in structure or metabolism; in most kinds of organisms, development continues throughout the life of the organism.

Diaphragm (dye' uh fram) [Gr. diaphrassein, to barricade] • (1) A sheet of muscle that separates the thoracic and abdominal cavities in mammals; responsible for the action of breathing. (2) A method of birth control in which a sheet of rubber is fitted over the woman's cervix, blocking the entry of sperm.

Diastole (dye ahs' toll ee) [Gr.: dilation] • The portion of the cardiac cycle when the heart muscle relaxes. (Contrast with systole.)

Dicot (short for dicotyledon) [Gr. di: two + kotyledon: a hollow space] • This term, not used in this book, formerly referred to all angiosperms other than the monocots. (See eudicot, monocot.)

Differentiation • Process whereby original-Is- similar cells follow different developmental pathways. The actual expression of determination.

Diffusion • Random movement of molecules or other particles, resulting in even distribution of the particles when no barriers are present.

Digestibility-reducing chemicals •

Defensive chemicals produced by plants that make the plant's tissues difficult to digest.

Digestion • Enzyme-catalyzed process by which large, usually insoluble, molecules (foods) are hydrolyzed to form smaller molecules of soluble substances.

Dihybrid cross • A mating in which the parents differ with respect to the alleles of two loci of interest.

Dikaryon (di care' ee ahn) [Gr. dis: two + karyon: kernel] • A cell or organism carrying two genetically distinguishable nuclei. Common in fungi.

Dioecious (die eesh' us) [Gr.: two houses] • Organisms in which the two sexes are "housed" in two different individuals, so that eggs and sperm are not produced in the same individuals. Examples: humans, fruit flies, oak trees, date palms. (Contrast with monoecious.)

Diploblastic • Having two cell layers. (Contrast with triploblastic.)

Diploid (dip' loid) [Gr. diploos: double] • Having a chromosome complement consisting of two copies (homologues) of each chromosome. A diploid individual (or cell) usually arises as a result of the fusion of two gametes, each with just one copy of each chromosome. Thus, the two homologues in each chromosome pair in a diploid cell are of separate origin, one derived from the female parent and one from the male parent.

Directional selection • Selection in which phenotypes at one extreme of the population distribution are favored. (Contrast with disruptive selection; stabilizing selection.)

Disaccharide • A carbohydrate made up of two monosaccharides (simple sugars).

Dispersal stage • Stage in its life history at which an organism moves from its birthplace to where it will live as an adult.

Displacement activity • Apparently irrelevant behavior performed by an animal under conflict situations, especially when tendencies to attack and escape are closely balanced.

Display • A behavior that has evolved to influence the actions of other individuals.

Disruptive selection • Selection in which phenotypes at both extremes of the population distribution are favored. (Contrast with directional selection; stabilizing selection.)

Distal • Away from the point of attachment or other reference point. (Contrast with proximal.)

Disturbance • A short-term event that disrupts populations, communities, or ecosystems by changing the environment.

Diverticulum (di ver tic' u lum) [L. divertere: turn away] • A small cavity or tube that connects to a major cavity or tube.

Division • A term used by some microbiologists and formerly by botanists, corresponding to the term phylum.

DNA (deoxyribonucleic acid) • The fundamental hereditary material of all living organisms. In eukaryotes, stored primarily in the cell nucleus. A nucleic acid using deoxyribose rather than ribose.

DNA chip • A small glass or plastic square onto which thousands of single-stranded DNA sequences are fixed. Hybridization of cell-derived RNA or DNA to the target sequences can be performed. (See DNA hybridization.)

DNA hybridization • A process by which DNAs from two species are mixed and heated so that interspecific double helices are formed.

DNA ligase • Enzyme that unites Okazaki fragments of the lagging strand during DNA replication; also mends breaks in DNA strands. It connects pieces of a DNA strand and is used in recombinant DNA technology.

DNA methylation • Addition of methyl groups to DNA; plays role in regulation of gene expression; protects a bacterium's DNA against its restriction endonucleases.

DNA polymerase • Any of a group of enzymes that catalyze the formation of DNA strands from a DNA template.

Domain • The largest unit in the current taxonomic nomenclature. Members of the three domains (Bacteria, Archaea, and Eukarya) are believed to have been evolving independently of each other for at least a billion years.

Dominance • In genetic terminology, the ability of one allelic form of a gene to determine the phenotype of a heterozygous individual, in which the homologous chromosome carries both it and a different allele. For example, if A and a are two allelic forms of a gene, A is said to be dominant to a if AA diploids and Aa diploids are phenotypically identical and are distinguishable from aa diploids. The a allele is said to be recessive.

Dominance hierarchy • In animal behavior, the set of relationships within a group of animals, usually established and maintained by aggression, in which one individual has precedence over all others in eating, mating, and other activities.

Dormancy • A condition in which normal activity is suspended, as in some seeds and buds.

Dorsal [L. dorsum: back] • Pertaining to the back or upper surface. (Contrast with ventral.)

Double fertilization • Process virtually unique to angiosperms in which one sperm nucleus combines with the egg to produce a zygote, and the other sperm nucleus combines with the two polar nuclei to produce the first cell of the triploid endosperm.

Double helix • Of DNA: molecular structure in which two complementary polynucleotide strands, antiparallel to each other, form a right-handed spiral.

Duodenum (doo' uh dee' num.) • The beginning portion of the vertebrate small intestine. (Contrast with ileum, jejunum.)

Duplication (genetic) • A mutation resulting from the introduction into the genome

GLOSSARY

of an extra copy of a segment of a gene or chromosome. (Contrast with deletion, point mutation.)

Dynein [Gr. dunamis: power] • A protein that undergoes conformational changes and thus plays a part in the movement of eukaryotic flagella and cilia.

Ecdysone (eck die' sone) [Gr. ek: out of + dyo: to clothe] • In insects, a hormone that induces molting.

Ecological biogeography • The study of the distributions of organisms from an ecological perspective, usually concentrating on migration, dispersal, and species interactions.

Ecological community • The species living together at a particular site.

Ecological niche (nitch) [L. nidus: nest] • The functioning of a species in relation to other species and its physical environment.

Ecological succession • The sequential replacement of one population assemblage by another in a habitat following some disturbance. Succession sometimes ends in a relatively stable ecosystem.

Ecology [Gr. oikos: house + logos: discourse, study] • The scientific study of the interaction of organisms with their environment, including both the physical environment and the other organisms that live in it.

Ecoregion • A large geographic unit characterized by a typical climate and a widespread assemblage of similar species.

Ecosystem (eek' oh sis turn) • The organisms of a particular habitat, such as a pond or forest, together with the physical environment in which they live.

Ecto- (eck' toh) [Gr.: outer, outside] • A prefix used to designate a structure on the outer surface of the body. For example, ectoderm. (Contrast with endo- and meso-.)

Ectoderm [Gr. ektos: outside + derma: skin] • The outermost of the three embryonic tissue layers first delineated during gastrulation. Gives rise to the skin, sense organs, nervous system, etc.

Ectotherm [Gr. ektos: outside + thermos: heat] • An animal unable to control its body temperature. (Contrast with endotherm.)

Edema (i dee' mah) [Gr. oidema: swelling] • Tissue swelling caused by the accumulation of fluid.

Edge effect • The changes in ecological processes in a community caused by physical and biological factors originating in an adjacent community.

Effector • Any organ, cell, or organelle that moves the organism through the environment or else alters the environment to the organism's advantage. Examples include muscle, bone, and a wide variety of exocrine glands.

Effector cell • A lymphocyte that performs a role in the immune system without further differentiation.

Effector phase • In this phase of the immune response, effector T cells called cytotoxic T cells attack virus-infected cells, and effector helper T cells assist B cells to

differentiate into plasma cells, which release antibodies.

Efferent [L. ex: out + fare: to bear] • Away from, as in neurons that conduct action potentials out from the central nervous system, or arterioles that conduct blood away from a structure. (Contrast with afferent.)

Egg • In all sexually reproducing organisms, the female gamete; in birds, reptiles, and some other vertebrates, a structure within which early embryonic development occurs.

Elasticity • The property of returning quickly to a former state after a disturbance.

Electrocardiogram (EKG) • A graphic recording of electrical potentials from the heart.

Electroencephalogram (EEG) • A graphic recording of electrical potentials from the brain.

Electromyogram (EMG) • A graphic recording of electrical potentials from muscle.

Electron (e lek' tron) [L. electrum: amber (associated with static electricity), from Gr. slektor: bright sun (color of amber)] • One of the three most important fundamental particles of matter, with mass approximately 0.00055 amu and charge -1.

Electronegativity • The tendency of an atom to attract electrons when it occurs as part of a compound.

Electrophoresis (e lek' tro fo ree' sis) [L. electrum: amber + Gr. phorein: to bear] • A separation technique in which substances are separated from one another on the basis of their electric charges and molecular weights.

Electrotonic potential • In neurons, a hyperpolarization or small depolarization of the membrane potential induced by the application of a small electric current. (Contrast with action potential, resting potential.)

Elemental substance • A substance composed of only one type of atom.

Embolus (em' buh lus) [Gr. embolos: inserted object; stopper] • A circulating blood clot. Blockage of a blood vessel by an embolus or by a bubble of gas is referred to as an embolism. (Contrast with thrombus.)

Embryo [Gr. en-: in + bryein: to grow] • A young animal, or young plant sporophyte, while it is still contained within a protective structure such as a seed, egg, or uterus.

Embryo sac • In angiosperms, the female gametophyte. Found within the ovule, it consists of eight or fewer cells, membrane bounded, but without cellulose walls between them.

Emergent property • A property of a complex system that is not exhibited by its individual component parts.

Emigration • The deliberate and usually oriented departure of an organism from the habitat in which it has been living.

3' End (3-prime) • The end of a DNA or RNA strand that has a free hydroxyl group at the 3'-carbon of the sugar (deoxyribose or ribose).

5' End (5-prime) • The end of a DNA or RNA strand that has a free phosphate group at the 5'-carbon of the sugar (deoxyribose or ribose).

Endemic (en dem' ik) [Gr. endemos: dwelling in a place] • Confined to a particular region, thus often having a comparatively restricted distribution. •

Endergonic reaction • One for which energy must be supplied. (Contrast with exergonic reaction.)

Endo- [Gr.: within, inside] • A prefix used to designate an innermost structure. For example, endoderm, endocrine. (Contrast with ecto-, meso-.)

Endocrine gland (en' doh krin) [Gr. eudon: inside + krincin: to separate] • Any gland, such as the adrenal or pituitary gland of vertebrates, that secretes certain substances, especially hormones, into the body through the blood.

Endocrinology • The study of hormones and their actions.

Endocytosis • A process by which liquids or solid particles are taken up by a cell through invagination of the plasma membrane. (Contrast with exocytosis.)

Endoderm [Gr. endow, within + derma: skin] • The innermost of the three embryonic tissue layers first delineated during gastrulation. Gives rise to the digestive and respiratory tracts and structures associated with them.

Endodermis [Gr. eudon: within + derma: skin] • In plants, a specialized cell layer marking the inside of the cortex in roots and some stems. Frequently a barrier to free diffusion of solutes.

Endomembrane system • Endoplasmic reticulum plus Golgi apparatus plus, when present, lysosomes; thus, a system of membranes that exchange material with one another.

Endoplasmic reticulum [Gr. endon: within + L. plasma: form; L. reticulum: little net] • A system of membrane-bounded tubes and flattened sacs found in the cytoplasm of eukaryotes. Exists as rough ER, studded with ribosomes; and smooth ER, lacking ribosomes.

Endorphins • Naturally occurring, opiatelike substances in the mammalian brain.

Endoskeleton [Gr. endon: within + skleros: hard] • A skeleton covered by other, soft body tissues. (Contrast with exoskeleton.)

Endosperm [Gr. endon: within + spernia: seed] • A specialized triploid seed tissue found only in angiosperms; contains stored food for the developing embryo.

Endosymbiosis [Gr. endon: within + syn: together + bios: life] • The living together of two species, with one living inside the body (or even the cells) of the other.

Endosymbiotic theory • Theory that the eukaryotic cell evolved from a prokaryote that contained other, endosymbiotic prokaryotes.

Endotherm [Gr. endon: within + thermos: hot] • An animal that can control its body temperature by the expenditure of its own

SSAR\

metabolic energy. (Contrast with ectotherm.)

Endotoxins [Gr. endon: within + I. toxicum: poison] • Lipopolysaccharides released by the lysis of some Gram-negative bacteria that cause fever and vomiting in a host organism.

Energetic cost • [the difference between the energy an animal would have expended had it rested, and that expended in performing a behavior.]

Energy • The capacity to do work.

Enhancer • In eukaryotes, a DNA sequence, lying on either side of the gene it regulates, that stimulates a specific promoter.

Enterocoelous development • A pattern of development in which the coelum is formed by an outpocketing of the embryonic gut (enteron).

Enterokinase (ent uh row kine' ase) • An enzyme secreted by the mucosa of the duodenum. It activates the zymogen trypsinogen to create the active digestive enzyme trypsin.

Entrainment • With respect to circadian rhythms, the process whereby the period is adjusted to match the 24-hour environmental cycle.

Entropy (en' tro pee) [Gr. en: in + tropein: to change] • A measure of the degree of disorder in any system. A perfectly ordered system has zero entropy; increasing disorder is measured by positive entropy. Spontaneous reactions in a closed system are always accompanied by an increase in disorder and entropy.

Environment • An organism's surroundings, both living and nonliving; includes temperature, light intensity, and all other

species that influence the focal organism.

Environmental toxicology • The study of the distribution and effects of toxic compounds in the environment.

Enzyme (en' zime) [Gr. en: in + zyme: yeast] • A protein, on the surface of which are chemical groups so arranged as to make the enzyme a catalyst for a chemical reaction.

Epi- [Gr.: upon, over] • A prefix used to designate a structure located on top of another; for example: epidermis, epiphyte.

Epicotyl (epp' i kot' il) [Gr. epi: upon + kotyle: something hollow] • That part of a plant embryo or seedling that is above the cotyledons.

Epidermis [Gr. epi: upon + derma: skin] • In plants and animals, the outermost cell layers. (Only one cell layer thick in plants.)

Epididymis (epuh did' uh mus) [Gr. epi: upon + didymos: testicle] • Coiled tubules in the testes that store sperm and conduct sperm from the seminiferous tubules to the vas deferens.

Epinephrine (ep i nef rin) [Gr. epi: upon + nephros: a kidney] • The "fight or flight" hormone. Produced by the medulla of the adrenal gland, it also functions as a neurotransmitter. Also known as adrenaline.

Epiphyte (ep' e fyte) [Gr. epi: upon + phyton: plant] • A specialized plant that grows on

the surface of other plants but does not parasitize them.

Episome • A plasmid that may exist either free or integrated into a chromosome. (See plasmid.)

Epistasis • An interaction between genes, in which the presence of a particular allele of one gene determines whether another gene will be expressed.

Epithelium • In animals, a layer of cells covering or lining an external surface or a cavity.

Equilibrium • (1) In biochemistry, a state in which forward and reverse reactions are proceeding at counterbalancing rates, so there is no observable change in the concentrations of reactants and products. (2) In evolutionary genetics, a condition in which allele and genotype frequencies in a population are constant from generation to generation. .

Erythrocyte (ur rith' row sight) [Gr. erythros: red + kytos: hollow vessel] • A red blood cell.

Esophagus (i soff i gus) [Gr. oisophagos: gullet] • That part of the gut between the pharynx and the stomach.

Ester linkage • A condensation (water-releasing) reaction in which the carboxyl group of a fatty acid reacts with the hydroxyl group of an alcohol. Lipids are formed in this way.

Estivation (ess tuh vay' shun) [L. aestivalis: summer] • A state of dormancy and hypometabolism that occurs during the summer; usually a means of surviving drought and/or intense heat. Contrast with hibernation.

Estrogen • Any of several steroid sex hormones, produced chiefly by the ovaries in mammals.

Estrus (es' truss) [L. oestrus: frenzy] • The period of heat, or maximum sexual receptivity, in some female mammals. Ordinarily, the estrus is also the time of release of eggs in the female.

Ethylene • One of the plant hormones, the gas $H_2C=CH_2$.

Euchromatin • Chromatin that is diffuse and non-staining during interphase; may be transcribed. (Contrast with heterochromatin.)

Eudicots (yew di' kots) [Gr. eu: true + di: two + kotyledon: a cup-shaped hollow] • Members of the angiosperm class Eudicotyledones, flowering plants in which the embryo produces two cotyledons prior to germination. Leaves of most eudicots have major veins arranged in a branched or reticulate pattern.

Eukaryotes (yew car' ry otes) [Gr. eu: true + karyon: kernel or nucleus] • Organisms whose cells contain their genetic material inside a nucleus. Includes all life other than the viruses, Archaeobacteria, and Eubacteria.

Eusocial • Term applied to insects, such as termites, ants, and many bees and wasps, in which individuals cooperate in the care of offspring, there are sterile castes, and generations overlap.

Eutrophication (yoo trofe' ik ay' shun) [Gr. eu-: well + trephein: to flourish] • The addition of nutrient materials to a body of water, resulting in changes to species composition therein.

Evolution • Any gradual change. Organic evolution, often referred to as evolution, is any genetic and resulting phenotypic change in organisms from generation to generation.

Evolutionary agent • Any factor that influences the direction and rate of evolutionary changes.

Evolutionarily conservative • Traits of organisms that evolve very slowly.

Evolutionary innovations • Major changes in body plans of organisms; these have been very rare during evolutionary history.

Evolutionary radiation • The proliferation of species within a single evolutionary lineage.

Evolutionary reversal • The reappearance of the ancestral state of a trait in a lineage in which that trait had acquired a derived state.

Excision repair • The removal and damaged DNA and its replacement by the appropriate nucleotides.

Excitatory postsynaptic potential (EPSP) •

A change in the resting potential of a postsynaptic membrane in a positive (depolarizing) direction. (Contrast with inhibitory postsynaptic potential.)

Excretion • Release of metabolic wastes by an organism.

Exergonic reaction • A reaction in which free energy is released. (Contrast with endergonic reaction.)

Exo- (eks' oh) • Same as ecto-.

Exocrine gland (eks' oh krin) [Gr. exo: outside + krinein: to separate] • Any gland, such as a salivary gland, that secretes to the outside of the body or into the gut.

Exocytosis • A process by which a vesicle within a cell fuses with the plasma membrane and releases its contents to the outside. (Contrast with endocytosis.)

Exon • A portion of a DNA molecule, in eukaryotes, that codes for part of a polypeptide. (Contrast with intron.)

Exoskeleton (eks' oh skel' e ton) [Gr. exos: outside + skleros: hard] • A hard covering on the outside of the body to which muscles are attached. (Contrast with endoskeleton.)

Exotoxins • Highly toxic proteins released by living, multiplying bacteria.

Experiment • A scientific method in which particular factors are manipulated while other factors are held constant so that the potential influences of the manipulated factors can be determined.

Exponential growth • Growth, especially in the number of organisms in a population, which is a simple function of the size of the growing entity: the larger the entity, the faster it grows. (Contrast with logistic growth.)

Expression vector • A DNA vector, such as a plasmid, that carries a DNA sequence that

^

GLOSSARY

includes the adjacent sequences for its expression into mRNA and protein in a host cell.

Expressivity • The degree to which a genotype is expressed in the phenotype— may be affected by the environment.

Extensor • A muscle the extends an appendage.

Extinction • The termination of a lineage of organisms.

Extrinsic protein • A membrane protein found only on the surface of the membrane. (Contrast with intrinsic protein.)

F₁ generation • The immediate progeny of a parental (P) mating; the first filial generation.

F₂ generation • The immediate progeny of a mating between members of the F₁ generation.

Facilitated diffusion • Passive movement through a membrane involving a specific carrier protein; does not proceed against a concentration gradient. (Contrast with active transport, free diffusion.)

Family • In taxonomy, the category below the order and above the genus; a group of related, similar genera.

Fat • A triglyceride that is solid at room temperature. (Contrast with oil.)

Fatty acid • A molecule with a long hydrocarbon tail and a carboxyl group at the other end. Found in many lipids.

Fauna (faw' nah) • All of the animals found in a given area. (Contrast with flora.)

Feces [L. faeces: dregs] • Waste excreted from the digestive system.

Feedback control • Control of a particular step of a multistep process, induced by the presence or absence of a product of one of the later steps. A thermostat regulating the flow of heating oil to a furnace in a home is a negative feedback control device.

Fermentation (fur men tay' shun) [L. fcr-mentum: yeast] • The degradation of a substance such as glucose to smaller

molecules with the extraction of energy, without the use of oxygen (i.e., anaerobically). Involves the glycolytic pathway.

Fertilization • Union of gametes. Also known as syngamy

Fertilization membrane • A membrane surrounding an animal egg which becomes rapidly raised above the egg surface within seconds after fertilization, serving to prevent entry of a second sperm.

Fetus • The latter stages of an embryo that is still contained in an egg or uterus; in humans, the unborn young from the eighth week of pregnancy to the moment of birth.

Fiber • An elongated and tapering cell of flowering plants, usually with a thick cell wall. Serves a support function.

Fibrin • A protein that polymerizes to form long threads that provide structure to a blood clot.

Filter feeder • An organism that feeds upon much smaller organisms, that are suspended in water or air, by means of a straining device.

Filtration • In the excretory physiology of some animals, the process by which the initial urine is formed; water and most solutes are transferred into the excretory tract, while proteins are retained in the blood or hemolymph.

First law of thermodynamics • Energy can be neither created nor destroyed.

Fission • Reproduction of a prokaryote by division of a cell into two comparable progeny cells.

Fitness • The contribution of a genotype or phenotype to the composition of subsequent generations, relative to the contribution of other genotypes or phenotypes. (See inclusive fitness.)

Fixed action pattern • A behavior that is genetically programmed.

Flagellum (fla jell' um) (plural: flagella) [L. flagellum: whip] • Long, whiplike appendage that propels cells. Prokaryotic flagella differ sharply from those found in eukaryotes.

Flexor • A muscle that flexes an appendage.

Flora (flore' ah) • All of the plants found in a given area. (Contrast with fauna.)

Florigen • A plant hormone (not yet isolated) involved in the conversion of a vegetative shoot apex to a flower.

Flower • The total reproductive structure of an angiosperm; its basic parts include the calyx, corolla, stamens, and carpels.

Fluorescence • The emission of a photon of visible light by an excited atom or molecule.

Follicle [L.folliculiis: little bag] • In female mammals, an immature egg surrounded by nutritive cells.

Follicle-stimulating hormone • A

gonadotropic hormone produced by the anterior pituitary

Food chain • A portion of a food web, most commonly a simple sequence of prey species and the predators that consume them.

Food web • The complete set of food links between species in a community; a diagram indicating which ones are the eaters and which are consumed.

Forb • Any broad-leaved (dicotyledonous), herbaceous plant. Especially applied to such plants growing in grasslands.

Fossil • Any recognizable structure originating from an organism, or any impression from such a structure, that has been preserved over geological time.

Fossil fuel • A fuel (particularly petroleum products) composed of the remains of organisms that lived in the remote past.

Founder effect • Random changes in allele frequencies resulting from establishment of a population by a very small number of individuals.

Fovea [L. fovea; a small pit] • The area, in the vertebrate retina, of most distinct vision.

Frame-shift mutation • A mutation resulting from the addition or deletion of a single base pair in the DNA sequence of a gene. As

a result of this, mRNA transcribed from such a gene is translated normally until the ribosome reaches the point at which the mutation has occurred. From that point on, codons are read out of proper register and the amino acid sequence bears no resemblance to the normal sequence. (Contrast with missense mutation, nonsense mutation, synonymous mutation.)

Free energy • That energy which is available for doing useful work, after allowance has been made for the increase or decrease of disorder. Designated by the symbol G (for Gibbs free energy), and defined by: $G = H - TS$, where H = heat, S =

entropy, and T = absolute (Kelvin) temperature.

Frequency-dependent selection • Selection that changes in intensity with the proportion of individuals having the trait.

Fruit • In angiosperms, a ripened and mature ovary (or group of ovaries) containing the seeds. Sometimes applied to reproductive structures of other groups of plants, and includes any adjacent parts which may be fused with the reproductive structures.

Fruiting body • A structure that bears spores.

Fundamental niche • The range of condition under which an organism could survive if it were the only one in the environment. (Contrast with realized niche.)

Fungus (fung' gus) • A member of the kingdom Fungi, a (usually) multicellular eukaryote with absorptive nutrition.

G₁ phase • In the cell cycle, the gap between the end of mitosis and the onset of the S phase.

G₂ phase • In the cell cycle, the gap between the S (synthesis) phase and the onset of mitosis.

G protein • A membrane protein involved in signal transduction; characterized by binding guanyl nucleotides. The activation of certain receptors activates the G protein, which in turn activates adenylate cyclase. G protein activation involves binding a GTP molecule in place of a GDP molecule.

Gametangium (gam i tan' gee um) [Gr. gamos: marriage + angeion: vessel or reservoir] • Any plant or fungal structure within which a gamete is formed.

Gamete (gam' eet) [Gr. gamete: wife, gametes: husband] • The mature sexual reproductive cell: the egg or the sperm.

Gametocyte (ga meet' oh site) [Gr. gamete: wife, gametes: husband + kytos: cell] • The cell that gives rise to sex cells, either the eggs or the sperm. (See oocyte and spermatocyte.)

Gametogenesis (ga meet' oh jen' e sis) [Gr. gamete: wife, gametes: husband + genesis: source] • The specialized series of cellular divisions that leads to the production of sex cells (gametes). (Contrast with oogenesis and spermatogenesis.)

Gametophyte (ga meet' oh fyte) • In plants and photosynthetic protists with alternation of generations, the haploid phase that produces the gametes. (Contrast with sporo-phyte.)

^s \KN

Ganglion (gang* glee un) [Gr.: tumor] • \ group or concentration of neuron cell bodies.

Gap junction • A 2-7-nanometer gap between plasma membranes of two animal cells, spanned by protein channels. Gap junctions allow chemical substances or electrical signals to pass from cell to cell.

Gas exchange • In animals, the process of taking up oxygen from the environment and releasing carbon dioxide to the environment.

Gastrovascular cavity • Serving for both digestion (gastro) and circulation (vascular); in particular, the central cavity of the body of jellyfish and other cnidarians.

Gastrula (gas' true luh) [Gr. gaster. stomach]

• An embryo forming the characteristic three cell layers (ectoderm, endoderm, and mesoderm) which will give rise to all of the major tissue systems of the adult animal.

Gastrulation • Development of a blastula into a gastrula.

Gated channel • A channel (membrane protein) that opens and closes in response to binding of specific molecules or to changes in membrane potential.

Gel electrophoresis (jel ul lee tro for' eesis)

• A semisolid matrix suspended in a salty buffer in which molecules can be separated on the basis of their size and charge when current is passed through the gel.

Gene [Gr. gen: to produce] • A unit of heredity. Used here as the unit of genetic function which carries the information for a single polypeptide.

Gene amplification • Creation of multiple copies of a particular gene, allowing the production of large amounts of the RNA transcript (as in rRNA synthesis in oocytes).

Gene cloning • Formation of a clone of bacteria or yeast cells containing a particular foreign gene.

Gene family • A set of identical, or once-identical, genes, derived from a single parent gene; need not be on the same chromosomes; classic example is the globin family in vertebrates.

Gene flow • The exchange of genes between different species (an extreme case referred to as hybridization) or between different populations of the same species caused by migration following breeding.

Gene pool • All of the genes in a population.

Gene therapy • Treatment of a genetic disease by providing patients with cells containing wild type alleles for the genes that are nonfunctional in their bodies.

Generative nucleus • In a pollen tube, a haploid nucleus that undergoes mitosis to produce the two sperm nuclei that participate in double fertilization. (Contrast with tube nucleus.)

Genet • The genetic individual of a plant that is composed of a number of nearly identical but repeated units.

Genetic drift • Changes in gene frequencies from generation to generation in a small population as a result of random processes.

Genetic stochasticity • Variation in the frequencies of alleles and genotypes in a population over time.

Genetics • The study of heredity.

Genetic structure • The frequencies of alleles and genotypes in a population.

Genome (jee' nome) • The genes in a complete haploid set of chromosomes.

Genotype (jean' oh type) [Gr. gen: to produce + typos: impression] • An exact description of the genetic constitution of an individual, either with respect to a single trait or with respect to a larger set of traits. (Contrast with phenotype.)

Genus (jean' us) (plural: genera) [Gr. genos: stock, kind] • A group of related, similar species.

Geotropism • See gravitropism.

Germ cell • A reproductive cell or gamete of a multicellular organism.

Germination • The sprouting of a seed or spore.

Gestation (jes ray' shun) [L. gestare: to bear] • The period during which the embryo of a mammal develops within the uterus. Also known as pregnancy.

Gibberellin (jib er el' lin) [L. gibberella: hunchback (refers to shape of a reproductive structure of a fungus that produces gibberellins)] • One of a class of plant growth substances playing roles in stem elongation, seed germination, flowering of certain plants, etc. Named for the fungus *Gibberella*.

Gill • An organ for gas exchange in aquatic organisms.

Gill arch • A skeletal structure that supports gill filaments and the blood vessels that supply them.

Gizzard (giz' erd) [L. gigeria: cooked chicken parts] • A very muscular part of the stomach of birds that grinds up food, sometimes with the aid of fragments of stone.

Gland • An organ or group of cells that produces and secretes one or more substances.

Glans penis • Sexually sensitive tissue at the tip of the penis.

Glia (glee' uh) [Gr.: glue] • Cells, found only in the nervous system, which do not conduct action potentials.

Glomerulus (glo mare' yew lus) [L. glomus: ball] • Sites in the kidney where blood filtration takes place. Each glomerulus consists of a knot of capillaries served by afferent and efferent arterioles.

Glucocorticoids • Steroid hormones produced by the adrenal cortex. Secreted in response to ACTH, they inhibit glucose uptake by many tissues in addition to mediating other stress responses.

Glucagon • A hormone produced and released by cells in the islets of Langerhans of the pancreas. It stimulates the breakdown of glycogen in liver cells.

Gluconeogenesis • The biochemical synthesis of glucose from other substances, such as amino acids, lactate, and glycerol.

Glucose (glue' kose) [Gr. gleukos: sweet wine mash for fermentation] • The most common sugar, one of several monosaccharides with the formula $C_6H_{12}O_6$.

Glycerol (gliss' er ole) • A three-carbon alcohol with three hydroxyl groups, the linking component of phospholipids and triglycerides.

Glycogen (gly' ko jen) • A branched-chain polymer of glucose, similar to starch (which is less branched and may be of lower molecular weight). Exists mostly in liver and muscle; the principal storage carbohydrate of most animals and fungi.

Glycolysis (gly kol' li sis) [from glucose + Gr. lysis: loosening] • The enzymatic breakdown of glucose to pyruvic acid. One of the oldest energy-yielding mechanisms in living organisms.

Glycosidic linkage • The connection in an oligosaccharide or polysaccharide chain, formed by removal of water during the linking of monosaccharides by root pressure.

Glyoxysome (gly ox' ee soam) • An organelle found in plants, in which stored lipids are converted to carbohydrates.

Golgi apparatus (goal' jee) • A system of concentrically folded membranes found in the cytoplasm of eukaryotic cells. Plays a role in the production and release of secretory materials such as the digestive enzymes manufactured in the pancreas. First described by Camillo Golgi (1844-1926).

Gonad (go' nad) [Gr. gone: seed, that which produces seed] • An organ that produces sex cells in animals: either an ovary (female gonad) or testis (male gonad).

Gonadotropin • A hormone that stimulates the gonads.

Gondwana • The large southern land mass that existed from the Cambrian (540 mya) to the Jurassic (138 mya). Present-day South America, Africa, India, Australia, and Antarctica.

Gram stain • A differential stain useful in characterizing bacteria.

Granum • Within a chloroplast, a stack of thylakoids.

Gravitropism • A directed plant growth response to gravity.

Grazer • An animal that eats the vegetative tissues of herbaceous plants.

Green gland • An excretory organ of crustaceans.

Greenhouse effect • The heating of Earth's atmosphere by gases that are transparent to sunlight but opaque to radiated heat.

Gross primary production • The total energy captured by plants growing in a particular area.

Ground meristem • That part of an apical meristem that gives rise to the ground tissue system of the primary plant body

Ground tissue system • Those parts of the plant body not included in the dermal or vascular tissue systems. Ground tissues function in storage, photosynthesis, and support.

GLOSSARY

Group transfer • The exchange of atoms between molecules.

Growth • Irreversible increase in volume (probably the most accurate definition, but at best a dangerous oversimplification).

Growth factors • A group of proteins that circulate in the blood and trigger the normal growth of cells. Each growth factor acts only on certain target cells.

Guanine (gwan'een) • A nitrogen-containing base found in DNA, RNA and GTP.

Guard cells • In plants, paired epidermal cells which surround and control the opening of a stoma (pore).

Gut • An animal's digestive tract.

Guttation • The extrusion of liquid water through openings in leaves, caused by root pressure.

Gymnosperm (jim' no sperm) [Gr. gymnos: naked + sperma: seed] • A plant, such as a pine or other conifer, whose seeds do not develop within an ovary (hence, the seeds are "naked").

Gyrus (plural: gyri) • The raised or ridged portion of the convoluted surface of the brain. (Contrast to sulcus.)

Habit • The form or pattern of growth characteristic of an organism.

Habitat • The environment in which an organism lives.

Habituation (ha bich' oo ay shun) • The simplest form of learning, in which an animal presented with a stimulus without reward or punishment eventually ceases to respond.

Hair cell • A type of mechanoreceptor in animals.

Half-life • The time required for half of a sample of a radioactive isotope to decay to its stable, nonradioactive form.

Halophyte (hal' oh fyte) [Gr. Jmlos: salt + pin/ton: plant] • A plant that grows in a saline (salty) environment.

Haploid (hap' loid) [Gr. haploides: single] • Having a chromosome complement consisting of just one copy of each chromosome. This is the normal "ploidy" of gametes or of asexual spores produced by meiosis or of organisms (such as the

gametophyte generation of plants) that grow from such spores without fertilization.

Hardy-Weinberg equilibrium • The percentages of diploid combinations expected from a knowledge of the proportions of alleles in the population if no agents of evolution are acting on the population.

Haustorium (haw stor' ee um) [L. haustus: draw up] • A specialized hypha or other structure by which fungi and some parasitic plants draw food from a host plant.

Haversian systems • Units of organization in compact bone that reflect the action of intercommunicating osteoblasts.

Heat-shock proteins • Chaperone proteins expressed in cells exposed to high temperatures or other forms of environmental stress.

Helper T cells • T cells that participate in the activation of B cells and of other T cells; targets of the HIV-I virus, the agent of AIDS. (Contrast with cytotoxic T cells, suppressor T cells.)

Hematocrit (heme at o krit) [Gr. haima: blood + krites: judge] • The proportion of 100 cc of blood that consists of red blood cells.

Hemizygous (hem' ee zie' gus) [Gr. hemi: half + zygos: joined] • In a diploid organism, having only one allele for a given trait, typically the case for X-linked genes in male mammals and Z-linked genes in female birds. (Contrast with homozygous, heterozygous.)

Hemoglobin (hee' mo glow' bin) [Gr. haima: blood + L. globus: globe] • The colored protein of vertebrate blood (and blood of some invertebrates) which transports oxygen.

Hepatic (heh pat' ik) [Gr. liepar: liver] • Pertaining to the liver.

Hepatic duct • The duct that conveys bile from the liver to the gallbladder.

Herbicide (ur' bis ide) • A chemical substance that kills plants.

Herbivore [L. herba: plant + vorare: to devour] • An animal which eats the tissues of plants. (Contrast with carnivore, detritivore, omnivore.)

Heritable • Able to be inherited; in biology usually refers to genetically determined traits.

Hermaphroditism (her maf row dite' ism) [Gr. Iiermaphroditos: a person with both male and female traits] • The coexistence of both female and male sex organs in the same organism.

Hertz (abbreviated as Hz) • Cycles per second.

Hetero- [Gr.: other, different] • A prefix used in biology to mean that two or more different conditions are involved; for example, heterotroph, heterozygous.

Heterochromatin • Chromatin that retains its coiling during interphase; generally not transcribed. (Contrast with euchromatin.)

Heterocyst • A large, thick-walled cell in the filaments of certain cyanobacteria; performs nitrogen fixation.

Heterogeneous nuclear RNA (hnRNA) •

The product of transcription of a eukaryotic gene, including transcripts of introns.

Heteromorphic (hef er oh more' fik) [Gr. heteros: different + morphe: form] • having a different form or appearance, as two heteromorphic life stages of a plant. (Contrast with isomorphic.)

Heterosporous (het' er os' por us) • Producing two types of spores, one of which gives rise to a female megaspore and the other to a male microspore. Heterosporous plants produce distinct female and male gametophytes. (Contrast with homosporous.)

Heterotherm • An animal that regulates its body temperature at a constant level at some times but not others, such as a hibernator.

Heterotroph (het' er oh trof) [Gr. heteros: different + trophic: food] • An organism that requires preformed organic molecules as food. (Contrast with autotroph.)

Heterozygous (het' er oh zie' gus) [Gr. heteros: different + zygos: joined] • Of a diploid organism having different alleles of a given gene on the pair of homologues carrying that gene. (Contrast with homozygous.)

Hibernation [L. hibernans: winter] • The state of inactivity of some animals during winter; marked by a drop in body temperature and metabolic rate.

Highly repetitive DNA • Short DNA sequences present in millions of copies in the genome, next to each other (in tandem). In a reassociation experiment, denatured highly repetitive DNA reanneals very quickly.

Hippocampus • A part of the forebrain that takes part in long-term memory formation.

Histamine (hiss; tah meen) • A substance released within a damaged tissue by a type of white blood cell. Histamines are responsible for aspects of allergic reactions, including the increased vascular permeability that leads to edema (swelling).

Histology • The study of tissues.

Histone • Any one of a group of basic proteins forming the core of a nucleosome, the structural unit of a eukaryotic chromosome. (See nucleosome.)

hnRNA • See heterogeneous nuclear RNA.

Homeobox • A 180-base-pair segment of DNA found in a few genes (called Hox genes), perhaps regulating the expression of other genes and thus controlling large-scale developmental processes.

Homeostasis (home' ee o sta' sis) [Gr. homos: same + stasis: position] • The maintenance of a steady state, such as a constant temperature or a stable social structure, by means of physiological or behavioral feedback responses.

Homeotherm (home' ee o therm) [Gr. homos: same + therme: heat] • An animal which maintains a constant body temperature by virtue of its own heating and cooling mechanisms. (Contrast with heterotherm, poik-ilotherm.)

Homeotic genes (home' ee ott' ic) • Genes that determine what entire segments of an animal become. Drastic mutations in these genes cause the transformation of body segments in *Drosophila*. Homeotic genes studied in the plant *Arabidopsis* are called organ identity genes.

Homolog (home' o log') [Gr. homos: same + logos: word] • One of a pair, or larger set, of chromosomes having the same overall genetic composition and sequence. In diploid organisms, each chromosome inherited from one parent is matched by an identical (except for mutational changes) chromosome—its homolog—from the other parent.

Homology (ho mol' o jee) [Gr. homologí(a): agreement] • A similarity between two structures that is due to inheritance from a common ancestor. The structures are said to be homologous (Contrast with analogy.)

Homoplasmy (home' uh plaj zee) [Gr. homos: same + plastikos; to mold] • The presence in several species of a trait not present in their most common ancestor. Can result from convergent evolution, reversion, or parallel evolution

Homozygous • Producing a single type of spore that gives rise to a single type of gametophyte, bearing both female and male reproductive organs. (Contrast with heterozygous.)

Homozygous (home' o zie' gus) [Gr. homos: same + zygotes: joined] • Of a diploid

organism having identical alleles of a given gene on both homologous chromosomes. An organism may be a "homozygote" with respect to one gene and, at the same time, a "heterozygote" with respect to another. (Contrast with heterozygous.)

Hormone (hore' mone) [Gr. hormon: excite, stimulate] • A substance produced in one part of a multicellular organism and transported to another part where it exerts its specific effect on the physiology or biochemistry of the target cells.

Host • An organism that harbors a parasite and provides it with nourishment.

Host-parasite interaction • The dynamic interaction between populations of a host and the parasites that attack it.

Hox genes • See homeobox.

Humoral immune system • The part of the immune system mediated by B cells; it is mediated by circulating antibodies and is active against extracellular bacterial and viral infections.

Humus (hew' muss) • The partly decomposed remains of plants and animals on the surface of a soil. Its characteristics depend primarily upon climate and the species of plants growing on the site.

Hyaluronidase (hill yew ron' uh dase) • An enzyme that digests proteoglycans. Found in sperm cells, it helps digest the coatings surrounding an egg so the sperm can penetrate the egg cell membrane.

Hybrid (high' brid) [L. hybrida: mongrel] • The offspring of genetically dissimilar parents. In molecular biology, a double helix formed of nucleic acids from different sources.

Hybridoma • A cell produced by the fusion of an antibody-producing cell with a myeloma cell; it produces monoclonal antibodies.

Hybrid zone • A narrow zone where two populations interbreed, producing hybrid individuals.

Hydrocarbon • A compound containing only carbon and hydrogen atoms.

Hydrogen bond • A chemical bond which arises from the attraction between the slight positive charge on a hydrogen atom

and a slight negative charge on a nearby fluorine, oxygen, or nitrogen atom. Weak bonds, but found in great quantities in proteins, nucleic acids, and other biological macromolecules.

Hydrological cycle • The sum total of movement of water from the oceans to the atmosphere, to the soil, and back to the oceans. Some water is cycled many times within compartments of the system before completing one full circuit.

Hydrolyze (hi' dro lize) [Gr. hydro: water + lysis: cleavage] • To break a chemical bond, as in a peptide linkage, with the insertion of the components of water, -H and -OH, at the cleaved ends of a chain. The digestion of proteins is a hydrolysis.

Hydrophilic [Gr. hydro: water + philia: love] • Having an affinity for water. (Contrast with hydrophobic.)

Hydrophobic [Gr. hydro: water + phobia: fear] • Molecules and amino acid side chains, which are mainly hydrocarbons (compounds of C and H with no charged groups or polar groups), have a lower energy when they are clustered together than when they are distributed through an aqueous solution. Because of their attraction for one another and their reluctance to mix with water they are called "hydrophobic." Oil is a hydrophobic substance; phenylalanine is a hydrophobic amino acid in a protein. (Contrast with hydrophilic.)

Hydrostatic skeleton • The incompressible internal liquids of some animals that transfer forces from one part of the body to another when acted upon by the surrounding muscles.

Hydroxyl group • The —OH group, characteristic of alcohols.

Hyperpolarization • A change in the resting potential of a membrane so the inside of a cell becomes more electronegative. (Contrast with depolarization.)

Hypersensitive response • A defensive response of plants to microbial infection; it results in a "dead spot."

Hypertension • High blood pressure.

Hypertonic [Gk. hyper: above, over] • Having a greater solute concentration. Said of one solution in comparing it to another. (Contrast with hypotonic, isotonic.)

Hypha (high' fuh) (plural: hyphae) [Gr. hyphe: web] • In the fungi, any single filament. May be multinucleate (zygomycetes, ascomycetes) or multicellular (basid-iomycetes).

Hypocotyl [Gk. hypo: beneath, under + kotyledon: hollow space] • That part of the embryonic or seedling plant shoot that is below the cotyledons.

Hypothalamus • The part of the brain lying below the thalamus; it coordinates water balance, reproduction, temperature regulation, and metabolism.

Hypothesis • A tentative answer to a question, from which testable predictions can be generated. (Contrast with theory.)

Hypothetico-deductive method • A

method of science in which hypotheses are erected, predictions are made from them, and experiments and observations are performed to test the predictions.

Hypotonic [Gk. hypo: beneath, under] • Having a greater solute concentration. Said of one solution in comparing it to another. (Contrast with hypotonic, isotonic.)

Imaginal disc • In insect larvae, groups of cells that develop into specific adult organs.

Immune system [L. immunis: exempt] • A system in mammals that recognizes and eliminates or neutralizes either foreign substances or self substances that have been altered to appear foreign.

Immunization • The deliberate introduction of antigen to bring about an immune response.

Immunoglobulins • A class of proteins, with a characteristic structure, active as receptors and effectors in the immune system.

Immunological memory • Certain clones of immune system cells made to respond to an antigen persist. This leads to a more rapid and massive response of the immune system to any subsequent exposure to that antigen.

Immunological tolerance • A mechanism by which an animal does not mount an immune response to the antigenic determinants of its own macromolecules.

Imprinting • (1) In genetics, the differential modification of a gene depending on whether it is present in a male or a female. (2) In animal behavior, a rapid form of learning in which an animal comes to make a particular response, which is maintained for life, to some object or other organism.

Inclusive fitness • The sum of an individual's own fitness (the effect of producing its own offspring: the individual selection component) plus its influence on fitness in relatives other than direct descendants (the kin selection component).

Incomplete dominance • Condition in which the heterozygous phenotype is intermediate between the two homozygous phenotypes.

Incomplete metamorphosis • Insect development in which changes between instars are gradual.

Incus (in' kus) [L. incus: anvil] • The middle of the three bones that conduct movements of the eardrum to the oval window of the inner ear. (See malleus, stapes.)

Independent assortment • The random separation during meiosis of nonhomologous chromosomes and of genes carried on nonhomologous chromosomes.

Individual fitness • That component of inclusive fitness that results from an organism producing its own offspring. (Contrast with kin selection component.)

Indoleacetic acid • See auxin.

Inducer • (1) In enzyme systems, a small molecule which, when added to a growth medium, causes a large increase in the level of some enzyme. (2) In embryology, a substance that causes a group of target cells to differentiate in a particular way.

Inducible enzyme • An enzyme that is present in much larger amounts when a particular compound (the inducer) has been

GLOSSARY

added to the system. (Contrast with constitutive enzyme.)

Inflammation • A nonspecific defense against pathogens; characterized by redness, swelling, pain, and increased temperature.

Inflorescence • A structure composed of several flowers.

Inhibitor • A substance which binds to the surface of an enzyme and interferes with its action on its substrates.

Inhibitory postsynaptic potential • A

change in the resting potential of a postsynaptic membrane in the hyperpolarizing (negative) direction.

Initiation complex • Combination of a ribosomal light subunit, an mRNA molecule, and the tRNA charged with the first amino acid coded for by the mRNA; formed at the onset of translation.

Initiation factors • Proteins that assist in forming the translation initiation complex at the ribosome.

Inositol triphosphate (IP₃) • An intracellular second messenger derived from membrane phospholipids.

Instar (in' star) [L.: image, form] • An immature stage of an insect between molts.

Insulin (in' su lin) [L. insula: island] • A hormone, synthesized in islet cells of the pancreas, that promotes the conversion of glucose to the storage material, glycogen.

Integrase • An enzyme that integrates retroviral cDNA into the genome of the host cell.

Integrated pest management • A method of control of pests in which natural predators and parasites are used in conjunction with sparing use of chemical methods to achieve control of a pest without causing serious adverse environmental side effects.

Integument [L. integumentum: covering] • A protective surface structure. In gymnosperms and angiosperms, a layer of tissue around the ovule which will become the seed coat. Gymnosperm ovules have one integument, angiosperm ovules two.

Intercalary meristem • A meristematic region in plants which occurs not apically, but between two regions of mature tissue. Intercalary meristems occur in the nodes of grass stems, for example.

Intercostal muscles • Muscles between the ribs that can augment breathing movements by elevating and suppressing the rib cage.

Interferon • A glycoprotein produced by virus-infected animal cells; increases the resistance of neighboring cells to the virus.

Interkinesis • The phase between the first and second meiotic divisions.

Interleukins • Regulatory proteins, produced by macrophages and lymphocytes, that act upon other lymphocytes and direct their development.

Intermediate filaments • Fibrous proteins that stabilize cell structure and resist tension.

Internode • Section between two nodes of a plant stem.

Interphase • The period between successive nuclear divisions during which the chromosomes are diffuse and the nuclear envelope is intact. It is during this period that the cell is most active in transcribing and translating genetic information.

Interspecific competition • Competition between members of two or more species.

Intertropical convergence zone • The tropical region where the air rises most strongly; moves north and south with the passage of the sun overhead.

Intraspecific competition • Competition among members of a single species.

Intrinsic protein • A membrane protein that is embedded in the phospholipid bilayer of the membrane. (Contrast with extrinsic protein.)

Intrinsic rate of increase • The rate at which a population can grow when its density is low and environmental conditions are highly favorable.

Intron • A portion of a DNA molecule that, because of RNA splicing, is not involved in coding for part of a polypeptide molecule. (Contrast with exon.)

Invagination • An infolding.

Inversion (genetic) • A rare mutational event that leads to the reversal of the order of genes within a segment of a chromosome, as if that segment had been removed from the chromosome, turned 180°, and then reattached.

Invertebrate • Any animal that is not a vertebrate, that is, whose nerve cord is not enclosed in a backbone of bony segments.

In vitro [L.: in glass] • In a test tube, rather than in a living organism. (Contrast with *in vivo*.)

In vivo [L.: in the living state] • In a living organism. Many processes that occur *in vivo* can be reproduced *in vitro* with the right selection of cellular components. (Contrast with *in vitro*.)

Ion (eye' on) [Gr.: wanderer] • An atom or group of atoms with electrons added or removed, giving it a negative or positive electrical charge.

Ion channel • A membrane protein that can let ions pass across the membrane. The channel can be ion-selective, and it can be voltage-gated or ligand-gated.

Ionic bond • A chemical bond which arises from the electrostatic attraction between positively and negatively charged ions. Usually a strong bond.

Iris (eye' ris) [Gr. iris: rainbow] • The round, pigmented membrane that surrounds the pupil of the eye and adjusts its aperture to regulate the amount of light entering the eye.

Irruption • A rapid increase in the density of a population. Often followed by massive emigration.

Islets of Langerhans • Clusters of hormone-producing cells in the pancreas.

Iso- [Gr.: equal] • Prefix used to denote two separate but similar or identical states of a characteristic. (See isomers, isomorphic, isotope.)

Isolating mechanism • Geographical, physiological, ecological, or behavioral mechanisms that lead to a reduction in the frequency of hybrid matings.

Isomers • Molecules consisting of the same numbers and kinds of atoms, but differing in the way in which the atoms are combined.

Isomorphic (eye' so more' fik) [Gr. isos: equal + morphe: form] • having the same form or appearance, as two isomorphic life stages. (Contrast with heteromorphic.)

Isotonic • Having the same solute concentration; said of two solutions. (Contrast with hypertonic, hypotonic.)

Isotope (eye' so tope) [Gr. isos: equal + topos: place] • Two isotopes of the same chemical element have the same number of protons in their nuclei, but differ in the number of neutrons.

Jasmonates • Plant hormones that trigger defenses against pathogens and herbivores.

Jejunum (jih jew' num) • The middle division of the small intestine, where most absorption of nutrients occurs. (See duodenum, ileum.)

Joule (jool, or jowl) • A unit of energy, equal to 0.24 calories.

Juvenile hormone • In insects, a hormone maintaining larval growth and preventing maturation or pupation.

Karyotype • The number, forms, and types of chromosomes in a cell.

Kelvin temperature scale • See absolute temperature scale.

Keratin (ker' a tin) [Gr. keras: horn] • A protein which contains sulfur and is part of such hard tissues as horn, nail, and the outermost cells of the skin.

Ketone (key' tone) • A compound with a C=O group attached to two other groups, neither of which is an H atom. Many sugars are ketones. (Contrast with aldehyde.)

Keystone species • A species that exerts a major influence on the composition and dynamics of the community in which it lives.

Kidneys • A pair of excretory organs in vertebrates.

Kin selection • The component of inclusive fitness resulting from helping the survival of relatives containing the same alleles by descent from a common ancestor.

Kinase (kye' nase) • An enzyme that transfers a phosphate group from ATP to another molecule. Protein kinases transfer phosphate from ATP to specific proteins, playing important roles in cell regulation.

Kinesis (ki nee' sis) [Gr.: movement] • Orientation behavior in which the organism does not move in a particular direction with reference to a stimulus but instead simply moves at an increasing or decreasing rate until it ends up farther from the object or closer to it. (Contrast with taxis.)

SSAR>

Kinetochore (km not' oh core) [Gr kinetos: moving + khorein: to move] • Specialized structure on a centromere to which microtubules attach.

Koch's postulates • Four rules For establishing that a particular microorganism causes a particular disease.

Krebs cycle • See citric acid cycle.

Lactic acid • The end product of fermentation in vertebrate muscle and some microorganisms.

Lagging strand • In DNA replication, the daughter strand that is synthesized discontinuously.

Lamella • Layer.

Larynx (lar' inks) • A structure between the pharynx and the trachea that includes the vocal cords.

Larva (plural: larvae) [L.: ghost, early stage] • An immature stage of any invertebrate animal that differs dramatically in appearance from the adult.

Lateral • Pertaining to the side.

Lateral gene transfer • The movement of genes from one prokaryotic species to another.

Lateral meristems • The vascular cambium and cork cambium, which give rise to secondary tissue in plants.

Laterization (lat' ur iz ay shun) • The formation of a nutrient-poor soil that is rich in insoluble iron and aluminum compounds.

Law of independent assortment • The random separation during meiosis of nonhomologous chromosomes and of genes carried on nonhomologous chromosomes. Mendel's second law.

Law of segregation • Alleles segregate from one another during gamete formation, Mendel's first law.

Leader sequence • A sequence of amino acids at the N-terminal end of a newly synthesized protein, determining where the protein will be placed in the cell.

Leading strand • In DNA replication, the daughter strand that is synthesized continuously.

Lenticel • Spongy region in a plant's periderm, allowing gas exchange.

Leukocyte (loo' ko sight) [Gr. leukos: clear + kutos: hollow vessel] • A white blood cell.

Lichen (lie' kun) [Gr. leikhn: lick] • An organism resulting from the symbiotic association of a true fungus and either a cyanobacterium or a unicellular alga.

Life cycle • The entire span of the life of an organism from the moment of fertilization (or asexual generation) to the time it reproduces in turn.

Life history • The stages an individual goes through during its life.

Life table • A table showing, for a group of equal-aged individuals, the proportion still alive at different times in the future and the number of offspring they produce during each time interval.

Ligament • A band of connective tissue linking two bones in a joint.

Ligand (lig' and) • A molecule that binds to a receptor site of another molecule.

Lignin • The principal noncarbohydrate component of wood, a polymer that binds together cellulose fibrils in some plant cell

walls.

Limbic system • A group of primitive vertebrate forebrain nuclei that form a network and are involved in emotions, drives, instinctive behaviors, learning, and memory-Limiting resource • The required resource whose supply most strongly influences the size of a population.

Linkage • Association between genetic markers on the same chromosome such that they do not show random assortment and seldom recombine; the closer the markers, the lower the frequency of recombination.

Lipase (lip' ase; lye' pase) • An enzyme that digests fats.

Lipids (lip' ids) [Gr. lipos: fat] • Substances in a cell which are easily extracted by organic solvents; fats, oils, waxes, steroids, and other large organic molecules, including those which, with proteins, make up the cell membranes. (See phospholipids.)

Litter • The partly decomposed remains of plants on the surface and in the upper layers of the soil.

Littoral zone • The coastal zone from the upper limits of tidal action down to the depths where the water is thoroughly stirred by wave action.

Liver • A large digestive gland. In vertebrates, it secretes bile and is involved in the formation of blood.

Lobes • Regions of the human cerebral hemispheres; includes the temporal, frontal, parietal, and occipital lobes.

Locus • In genetics, a specific location on a chromosome. May be considered to be synonymous with "gene."

Logistic growth • Growth, especially in the size of an organism or in the number of organisms that constitute a population, which slows steadily as the entity approaches its maximum size. (Contrast with exponential growth.)

Loop of Henle (hen' lee) • Long, hairpin loop of the mammalian renal tubule that runs from the cortex down into the medulla, and back to the cortex. Creates a concentration gradient in the interstitial fluids in the medulla.

Lophophore • A U-shaped fold of the body wall with hollow, ciliated tentacles that encircles the mouth of animals in several different phyla. Used for filtering prey from the surrounding water.

Lordosis (lor doe' sis) [Gk. lordosis: curving forward] • A posture assumed by females of some mammalian species (especially rodents) to signal sexual receptivity.

Lumen (loo' men) [L.: light] • The cavity inside any tubular part of an organ, such as a piece of gut or a kidney tubule.

Lungs • A pair of saclike chambers within the bodies of some animals, functioning in gas exchange.

Luteinizing hormone • A gonadotropin produced by the anterior pituitary. It stimulates the gonads to produce sex hormones.

Lymph [L. lymphā: water] • A clear, watery fluid that is formed as a filtrate of blood; it contains white blood cells; it collects in a series of special vessels and is returned to the bloodstream.

Lymph nodes • Specialized tissue regions that act as filters for cells, bacteria and foreign matter.

Lymphocyte • A major class of white blood cells. Includes T cells, B cells, and other cell types important in the immune response.

Lysis (lie' sis) [Gr.: a loosening] • Bursting of a cell.

Lysogenic • The condition of a bacterium that carries the genome of a virus in a relatively stable form. (Contrast with lytic.)

Lysosome (lie' so soam) [Gr. lysis: a loosening + soma: body] • A membrane-bounded inclusion found in eukaryotic cells (other than plants). Lysosomes contain a mixture of enzymes that can digest most of the macromolecules found in the rest of the cell.

Lysozyme (lie' so zyme) • An enzyme in saliva, tears, and nasal secretions that attacks bacterial cell walls, as one of the body's nonspecific defense mechanisms.

Lytic • Condition in which a bacterium lyses shortly after infection by a virus; the viral genome does not become stabilized within the bacterial cell. (Contrast with lysogenic.)

Macro- (mack' roh) [Gr. makros: large, long]

• A prefix commonly used to denote something large. (Contrast with micro-.)

Macroevolution • Evolutionary changes occurring over long time spans and usually involving changes in many traits. (Contrast with microevolution.)

Macromolecule • A giant polymeric molecule. The macromolecules are proteins, polysaccharides, and nucleic acids.

Macronutrient • A mineral element required by plant tissues in concentrations of at least 1 milligram per gram of their dry

matter.

Macrophage (mac' roh faj) • A type of white blood cell that endocytoses bacteria and other cells.

Major histocompatibility complex (MHC)

• A complex of linked genes, with multiple alleles, that control a number of immunological phenomena; it is important in graft rejection.

Malignant tumor • A tumor whose cells can invade surrounding tissues and spread to other organs.

Malleus (mal' ee us) [L. malleus: hammer] • The first of the three bones that conduct movements of the eardrum to the oval window of the inner ear. (See incus, stapes.)

Malpighian tubule (mal pee' gy un) • A type of protonephridium found in insects.

GLOSSARY

Mammal [L. mamma: breast, teat] • Any animal of the class Mammalia, characterized by the production of milk by the female mammary glands and the possession of hair for body covering.

Mantle • A sheet of specialized tissues that covers most of the viscera of mollusks; provides protection to internal organs and secretes the shell.

Map unit • In eukaryotic genetics, one map unit corresponds to a recombinant frequency of 0.01.

Mapping • In genetics, determining the order of genes on a chromosome and the distances between them.

Marine [L. mare: sea, ocean] • Pertaining to or living in the ocean. (Contrast with aquatic, terrestrial.)

Marsupial (mar soo' pee al) • A mammal belonging to the subclass Metatheria, such as opossums and kangaroos. Most have a pouch (marsupium) that contains the milk glands and serves as a receptacle for the young.

Mass extinctions • Geological periods during which rates of extinction were much higher than during intervening times.

Mass number • The sum of the number of protons and neutrons in an atom's nucleus.

Mast cells • Typically found in connective tissue, mast cells can be provoked by antigens or inflammation to release histamine.

Maternal effect genes • These genes code for morphogens that determine the polarity of the egg and larva in the fruit fly, *Drosophila melanogaster*.

Maternal inheritance (cytoplasmic inheritance) • Inheritance in which the phenotype of the offspring depends on factors, such as mitochondria or chloroplasts, that are inherited from the female parent through the cytoplasm of the female gamete.

Maturation • The automatic development of a pattern of behavior, which becomes increasingly complex or precise as the animal matures. Unlike learning, the development does not require experience to occur.

Mechanoreceptor • A cell that is sensitive to physical movement and generates action potentials in response.

Medulla (meh dull' luh) [L.: narrow] • (1) The inner, core region of an organ, as in the adrenal medulla (adrenal gland) or the renal medulla (kidneys). (2) The portion of the brain stem that connects to the spinal cord.

Mega- [Gr. megas: large, great] • A prefix often used to denote something large. (Contrast with micro-.)

Megaspore [Gr. megas: large + sporaseed] • In plants, a haploid spore that produces a female gametophyte.

Meiosis (my oh' sis) [Gr.: diminution] • Division of a diploid nucleus to produce four haploid daughter cells. The process consists of two successive nuclear divisions with only one cycle of chromosome replication.

Membrane potential • The difference in electrical charge between the inside and the outside of a cell, caused by a difference in the distribution of ions.

Memory cells • Long-lived lymphocytes produced by exposure to antigen. They persist in the body and are able to mount a rapid response to subsequent exposures to the antigen.

Mendelian population • A local population of individuals belonging to the same species and exchanging genes with one another.

Menopause • The time in a human female's life when the ovarian and menstrual cycles cease.

Menstrual cycle • The monthly sloughing off of the uterine lining if fertilization does not occur in the female. Occurs between puberty and menopause.

Meristem [Gr. meristos: divided] • Plant tissue made up of actively dividing cells.

Mesenchyme (mez' en kyme) [Gr. mesos: middle + enchyma: infusion] • Embryonic or unspecialized cells derived from the mesoderm.

Meso- (mez' oh) [Gr.: middle] • A prefix often used to designate a structure located in the middle, or a stage that appears at some intermediate time. For example, mesoderm, Mesozoic.

Mesoderm [Gr. mesos: middle + derma: skin] • The middle of the three embryonic tissue layers first delineated during gastrulation. Gives rise to skeleton, circulatory system, muscles, excretory system, and most of the reproductive system.

Mesophyll (mez' a fill) [Gr. mesos: middle + phyllon: leaf] • Chloroplast-containing, photo-synthetic cells in the interior of leaves.

Mesosome (mez' o soam') [Gr. mesos: middle + soma: body] • A localized infolding of the plasma membrane of a bacterium.

Messenger RNA (mRNA) • A transcript of one of the strands of DNA, it carries information (as a sequence of codons) for the synthesis of one or more proteins.

Meta- [Gr.: between, along with, beyond] • A prefix used in biology to denote a change or a shift to a new form or level; for example, as used in metamorphosis.

Metabolic compensation • Changes in biochemical properties of an organism that render it less sensitive to temperature changes.

Metabolic pathway • A series of enzyme-catalyzed reactions so arranged that the product of one reaction is the substrate of the next.

Metabolism (meh tab' a lizm) [Gr. metabole: to change] • The sum total of the chemical reactions that occur in an organism, or some subset of that total (as in "respiratory metabolism").

Metamorphosis (met' a mor' fo sis) [Gr. meta: between + morphe: form, shape] • A radical change occurring between one developmental stage and another, as for example from a tadpole to a frog or an insect larva to the adult.

Metaphase (met' a phase) [Gr. meta: between] • The stage in nuclear division at which the centromeres of the highly super-coiled chromosomes are all lying on a plane

(the metaphase plane or plate) perpendicular to a line connecting the division poles.

Metapopulation • A population divided into subpopulations, among which there are occasional exchanges of individuals.

Metastasis (meh tass' tuh sis) • The spread of cancer cells from their original site to other parts of the body.

Methanogen • Any member of a group of Archaeobacteria that release methane as a metabolic product. This group is considered to be an extremely ancient one.

MHC • See major histocompatibility complex.

Micro- (mike' roh) [Gr. mikros: small] • A prefix often used to denote something small. (Contrast with macro-, mega-.)

Microbiology [Gr. mikros: small + bios: life + logos: discourse] • The scientific study of microscopic organisms, particularly bacteria, unicellular algae, protists, and viruses.

Microevolution • The small evolutionary changes typically occurring over short time spans; generally involving a small number of traits and minor genetic changes. (Contrast with macroevolution.)

Microfilament • Minute fibrous structure generally composed of actin found in the cytoplasm of eukaryotic cells. They play a role in the motion of cells.

Micronutrient • A mineral element required by plant tissues in concentrations of less than 100 micrograms per gram of their dry matter.

Micropyle (mike' roh pile) [Gr. mikros: small + pyle: gate] • Opening in the integument(s) of a seed plant ovule through which pollen grows to reach the female gametophyte within.

Microspores [Gr. mikros: small + spora: seed] • In plants, a haploid spore that produces a male gametophyte.

Microtubules • Minute tubular structures found in centrioles, spindle apparatus, cilia, flagella, and other places in the cytoplasm of eukaryotic cells. These tubules play roles in the motion and maintenance of shape of eukaryotic cells.

Microvilli (singular: microvillus) • The projections of epithelial cells, such as the cells lining the small intestine, that increase their surface area.

Middle lamella • A layer of derivative polysaccharides that separates plant cells; a common middle lamella lies outside the primary walls of the two cells.

Migration • The regular, seasonal movements of animals between breeding and nonbreeding ranges.

Mimicry (mim' ik ree) • The resemblance of one kind of organism to another, or to some inanimate object; serves the function of making the organism difficult to find, of discouraging potential enemies or of attracting potential prey (See Batesian mimicry and Mullerian mimicry.)

Mineral • An inorganic substance other than water.

GLOSSAR\

Mineralocorticoid • A hormone produced

by the adrenal cortex that influences mineral ion balance; aldosterone.

Mismatch repair • When a single base in DNA is changed into a different base, or the wrong base inserted during DNA replication, there is a mismatch in base pairing with the base on the opposite strand. A repair system removes the incorrect base and inserts the proper one for pairing with the opposite strand.

Missense mutation • A nonsynonymous mutation, or one that changes a codon for one amino acid to a codon for a different amino acid. (Contrast with frame-shift mutation, nonsense mutation, synonymous mutation.)

Mitochondrial matrix • The fluid interior of the mitochondrion, enclosed by the inner mitochondrial membrane.

Mitochondrion (my' toe kon' dree un) (plural: mitochondria) [Gr. mitos: thread + chondros: cartilage, or grain] • An organelle that occurs in eukaryotic cells and contains the enzymes of the citric acid cycle, the respiratory chain, and oxidative phosphorylation. A mitochondrion is bounded by a double membrane.

Mitosis (my toe' sis) [Gr. mitos: thread] • Nuclear division in eukaryotes leading to the formation of two daughter nuclei each with a chromosome complement identical to that of the original nucleus.

Mitotic center • Cellular region that organizes the microtubules for mitosis. In animals a centrosome serves as the mitotic center.

Moderately repetitive DNA • DNA

sequences that appear hundreds to thousands of times in the genome. They include the DNA sequences coding for rRNAs and tRNAs, as well as the DNA at telomeres.

Modular organism • An organism which grows by producing additional units of body construction (modules) that are very similar to the units of which it is already composed.

Mole • A quantity of a compound whose weight in grams is numerically equal to its molecular weight expressed in atomic mass units. Avogadro's number of molecules: 6.023×10^{23} molecules.

Molecular clock • The theory that macro-molecules diverge from one another over evolutionary time at a constant rate, and that discovering this rate gives insight into the phylogenetic relationships of organisms.

Molecular weight • The sum of the atomic weights of the atoms in a molecule.

Molecule • A particle made up of two or more atoms joined by covalent bonds or ionic attractions.

Molting • The process of shedding part or all of an outer covering, as the shedding of feathers by birds or of the entire exoskeleton by arthropods.

Mono- [Gr. *monos*: one] • Prefix denoting a single entity. (Contrast with *poly*.)

Monoclonal antibody • Antibody produced in the laboratory from a clone of hybridoma cells, each of which produces the same specific antibody.

Monocot (short for monocotyledon) [Gr. *monos*: one + *kotyledon*: a cup-shaped hollow] • Any member of the angiosperm class Monocotyledones, plants in which the embryo produces but a single cotyledon (seed leaf). Leaves of most monocots have their major veins arranged parallel to each other.

Monocytes • White blood cells that produce macrophages.

Monoecious (mo nee' shus) [Gr.: one house] • Organisms in which both sexes are "housed" in a single individual, which produces both eggs and sperm. (In some plants, these are found in different flowers within the same plant.) Examples: corn, peas, earthworms, hydras. (Contrast with dioecious, perfect flower.)

Monohybrid cross • A mating in which the parents differ with respect to the alleles of only one locus of interest.

Monomer [Gr.: one unit] • A small molecule, two or more of which can be combined to form oligomers (consisting of a few monomers) or polymers (consisting of many monomers).

Monophyletic (mon' oh fih leht' ik) [Gk. *monos*: single + *phylon*: tribe] • Being descended from a single ancestral stock.

Monosaccharide • A simple sugar. Oligosaccharides and polysaccharides are made up of monosaccharides.

Monosynaptic reflex • A neural reflex that begins in a sensory neuron and makes a single synapse before activating a motor neuron.

Morphogens • Diffusible substances whose concentration gradients determine patterns of development in animals and plants.

Morphogenesis (more' fo jen' e sis) [Gr. *morphe*: form + *genesis*: origin] • The development of form. Morphogenesis is the overall consequence of determination, differentiation, and growth.

Morphology (more fol' o jee) [Gr. *morphe*: form + *logos*: discourse] • The scientific study of organic form, including both its development and function.

Mosaic development • Pattern of animal embryonic development in which each blastomere contributes a specific part of the adult body. (Contrast with regulative development.)

Motor end plate • The modified area on a muscle cell membrane where a synapse is formed with a motor neuron.

Motor neuron • A neuron carrying information from the central nervous system to an effector such as a muscle fiber.

Motor unit • A motor neuron and the set of muscle fibers it controls.

mRNA • (See messenger RNA.)

Mucosa (mew koh' sah) • An epithelial membrane containing cells that secrete

mucus. The inner cell layers of the digestive and respiratory tracts.

Mullerian mimicry • The resemblance of two or more unpleasant or dangerous kinds of organisms to each other.

Multicellular [L. *multus*: much + *cella*: chamber] • Consisting of more than one cell, as for example a multicellular organism. (Contrast with unicellular.)

Muscle • Contractile tissue containing actin and myosin organized into polymeric chains called microfilaments. In vertebrates, the tissues are either cardiac muscle, smooth muscle, or striated (skeletal) muscle.

Muscle fiber • A single muscle cell. In the case of striated muscle, a syncytial, multinucleate cell.

Muscle spindle • Modified muscle fibers encased in a connective sheath and functioning as stretch receptors.

Mutagen (mute' ah jen) [L. mutare: change + Gr. genesis: source] • Any agent (e.g., chemicals, radiation) that increases the mutation rate.

Mutation • An inherited change along a very narrow portion of the nucleic acid sequence.

Mutation pressure • Evolution (change in gene proportions) by different mutation rates alone.

Mutualism • The type of symbiosis, such as that exhibited by fungi and algae or cyanobacteria in forming lichens, in which both species profit from the association.

Mycelium (my seel' ee yum) [Gr. mykes: fungus] • In the fungi, a mass of hyphae.

Mycorrhiza (my' ka rye' za) [Gr. mykes: fungus + rhiza: root] • An association of the root of a plant with the mycelium of a fungus.

Myelin (my' a lin) • A material forming a sheath around some axons. It is formed by Schwann cells that wrap themselves about the axon. It serves to insulate the axon electrically and to increase the rate of transmission of a nervous impulse.

Myofibril (my' oh fy' bril) [Gr. mys: muscle + L.fibrilla: small fiber] • A polymeric unit of actin or myosin in a muscle.

Myogenic (my oh jen' ik) [Gr. mys: muscle + genesis: source] • Originating in muscle.

Myoglobin (my' oh globe in) [Gr. mys: muscle + L. globus: sphere] • An oxygen-binding molecule found in muscle. Consists of a heme unit and a single globin chain, and carries less oxygen than hemoglobin.

Myosin [Gr. mys: muscle] • One of the two major proteins of muscle, it makes up the thick filaments. (See actin.)

NAD (nicotinamide adenine dinucleotide)

• A compound found in all living cells, existing in two interconvertible forms: the oxidizing agent NAD + and the reducing agent NADH.

NADP (nicotinamide adenine dinucleotide phosphate) • Like NAD, but possessing

.

GLOSSARY

another phosphate group; plays similar roles but is used by different enzymes.

Natural selection • The differential contribution of offspring to the next generation by various genetic types belonging to the same population. The mechanism of evolution proposed by Charles Darwin.

Necrosis (nee roh' sis) • Tissue damage resulting from cell death.

Negative control • The situation in which a regulatory macromolecule (generally a repressor) functions to turn off transcription. In the absence of a regulatory macro-molecule, the structural genes are turned on.

Nekton [Gr. neklein: to swim] • Animals, such as fish, that can swim against currents of water. (Contrast with plankton.)

Nematocyst (ne mat' o sist) [Gr. noun: thread + h/stis: cell] • An elaborate, threadlike structure produced by cells of jellyfish and other cnidarians, used chiefly to paralyze and capture prey.

Nephridium (nef rid' ee um) [Gr. nephros: kidney] • An organ which is involved in excretion, and often in water balance, involving a tube that opens to the exterior at one end.

Nephron (nef ron) [Gr. nephros: kidney] • The basic component of the kidney, which is made up of numerous nephrons. Its form varies in detail, but it always has at one end a device for receiving a filtrate of blood, and then a tubule that absorbs selected parts of the filtrate back into the bloodstream.

Nephrostome (nef ro stome) [Gr. nephros: kidney + stoma: opening] An opening in a nephridium through which body fluids can enter.

Nerve • A structure consisting of many neuronal axons and connective tissue.

Net primary production • Total photosynthesis minus respiration by plants.

Neural plate • A thickened strip of ectoderm along the dorsal side of the early vertebrate embryo; gives rise to the central nervous system.

Neural tube • An early stage in the development of the vertebrate nervous system consisting of a hollow tube created by two opposing folds of the dorsal ectoderm along the anterior-posterior body axis.

Neuromuscular junction • The region where a motor neuron contacts a muscle fiber, creating a synapse.

Neuron (noor' on) [Gr. neuron: nerve, sinew] • A cell derived from embryonic ectoderm and characterized by a membrane potential that can change in response to stimuli, generating action potentials. Action potentials are generated along an extension of the cell (the axon), which makes junctions (synapses) with other neurons, muscle cells, or gland cells.

Neurotransmitter • A substance, produced in and released by one neuron, that diffuses across a synapse and excites or inhibits the postsynaptic neuron.

Neurula (nure' you la) [Gr. neuron: nerve] • Embryonic stage during formation of the dorsal nerve cord by two ectodermal ridges.

Neutral allele • An allele that does not alter the functioning of the proteins for which it codes.

Neutral theory • A view of molecular evolution that postulates that most mutations do not affect the amino acid being coded for, and that such mutations accumulate in a population at rates driven by genetic drift and mutation rates.

Neutron (new' tron) [E.: neutral] • One of the three most fundamental particles of matter, with mass approximately 1 amu and no electrical charge.

Nicotinamide adenine dinucleotide • (See NAD.)

Nicotinamide adenine dinucleotide phosphate • (See NADP.)

Nitrification • The oxidation of ammonia to nitrite and nitrate ions, performed by certain soil bacteria.

Nitrogenase • In nitrogen-fixing organisms, an enzyme complex that mediates the stepwise reduction of atmospheric N₂ to ammonia.

Nitrogen fixation • Conversion of nitrogen gas to ammonia, which makes nitrogen available to living things. Carried out by certain prokaryotes, some of them free-living and others living within plant roots.

Node [L. nodus: knob, knot] • In plants, a (sometimes enlarged) point on a stem where a leaf is or was attached.

Node of Ranvier • A gap in the myelin sheath covering an axons, where the axonal membrane can fire action potentials.

Noncompetitive inhibitor • An inhibitor that binds the enzyme at a site other than the active site. (Contrast with competitive inhibitor.)

Nondisjunction • Failure of sister chromatids to separate in meiosis II or mitosis, or failure of homologous chromosomes to separate in meiosis I. Results in aneuploidy.

Nonpolar molecule • A molecule whose electric charge is evenly balanced from one end of the molecule to the other.

Nonsense (chain-terminating) mutation •

Mutations that change a codon for an amino acid to one of the codons (UAG, UAA, or UGA) that signal termination of translation. The resulting gene product is a shortened polypeptide that begins normally at the amino-terminal end and ends at the position of the altered codon. (Contrast with frame-shift mutation, missense mutation, synonymous mutation.)

Nonspecific defenses • Immunologic responses directed against most or all pathogens, generally without reference to the pathogens' antigens. These defenses include the skin, normal flora, lysozyme, the acidic stomach, interferon, and the inflammatory response.

Nonsynonymous mutation • A nucleotide substitution that changes the amino acid specified (i.e., AGC → AGA, or serine → arginine). (Compare with frame-shift mutation, missense mutation, nonsense mutation.)

Nonsynonymous substitution • The situation when a nonsynonymous mutation becomes widespread in a population. Typically influenced by natural selection. (Contrast with synonymous substitution.)

Nontracheophytes • Those plants lacking well-developed vascular tissue; the liverworts, hornworts, and mosses. (Contrast with tracheophytes.)

Normal flora • The bacteria and fungi that live on animal body surfaces without causing disease.

Norepinephrine • A neurotransmitter found in the central nervous system and also at the postganglionic nerve endings of the sympathetic nervous system. Also called noradrenaline.

Notochord (no' tow kord) [Gr. notos: back + chorde: string] • A flexible rod of gelatinous material serving as a support in the embryos of all chordates and in the adults of tunicates and lancelets.

Nuclear envelope • The surface, consisting of two layers of membrane, that encloses the nucleus of eukaryotic cells.

Nucleic acid (new klay' ik) [E.; nucleus of a cell] • A long-chain alternating polymer of deoxyribose or ribose and phosphate groups, with nitrogenous bases—adenine, thymine, uracil, guanine, or cytosine (A, T, U, G, or C)—as side chains. DNA and RNA are nucleic acids.

Nucleoid (new' klee oid) • The region that harbors the chromosomes of a prokaryotic cell. Unlike the eukaryotic nucleus, it is not bounded by a membrane.

Nucleolar organizer (new klee' o lar) • A region on a chromosome that is associated with the formation of a new nucleolus following nuclear division. The site of the genes that code for ribosomal RNA.

Nucleolus (new klee' oh lus) [from L. diminutive of mix: little kernel or little nut] • A small, generally spherical body found within the nucleus of eukaryotic cells. The site of synthesis of ribosomal RNA.

Nucleoplasm (new' klee o plazm) • The fluid material within the nuclear envelope of a cell, as opposed to the chromosomes, nucleoli, and other particulate constituents.

Nucleosome • A portion of a eukaryotic chromosome, consisting of part of the DNA molecule wrapped around a group of histone molecules, and held together by another type of histone molecule. The chromosome is made up of many nucleosomes.

Nucleotide • The basic chemical unit (monomer) in a nucleic acid. A nucleotide in RNA consists of one of four nitrogenous bases linked to ribose, which in turn is linked to phosphate. In DNA, deoxyribose is present instead of ribose.

Nucleus (new' klee us) [from L. diminutive of mix: kernel or nut] • (1) In chemistry, the dense central portion of an atom, made up of protons and neutrons, with a positive charge. Surrounded by a cloud of negative-

GLOSSAR\

K charged electrons (2) In cells, the central-K located chamber of eukaryotic cells that is bounded by a double membrane and contains the chromosomes. The information center of the cell.

Null hypothesis • [the assertion that an effect proposed by its companion hypothesis does not in fact exist. **Nutrient** • \ food substance; or, in the case of mineral nutrients, an inorganic element required for completion of the life cycle of an organism

Oil • A triglyceride that is liquid at room temperature. (Contrast with fat.)

Okazaki fragments • Newly formed DNA strands making up the lagging strand in DNA replication. DNA ligase links the Okazaki fragments to give a continuous strand.

Olfactory • Having to do with the sense of smell.

Oligomer [Gr.: a few units] • A compound molecule of intermediate size, made up of two to a few monomers. (Contrast with monomer, polymer.)

Oligosaccharins • Plant hormones, derived from the plant cell wall, that trigger defenses against pathogens.

Ommatidium [Gr. omnia: an eye] • One of the units which, collected into groups of up to 20,000, make up the compound eye of arthropods.

Omnivore [L. omnis: all, everything + vorare: to devour] • An organism that eats both animal and plant material. (Contrast with carnivore, detritivore, herbivore.)

Oncogenic (ong' co jen' ik) [Gr. onkos: mass, tumor + genes: born] • Causing cancer.

Oocyte (oh' eh site) [Gr. oon: egg + kytos: cell] • The cell that gives rise to eggs in animals.

Oogenesis (oh' eh jen e sis) [Gr. oon: egg + genesis: source] • Female gametogenesis, leading to production of the egg.

Oogonium (oh' eh go' nee um) • In some algae and fungi, a cell in which an egg is produced.

Operator • The region of an operon that acts as the binding site for the repressor.

Operon • A genetic unit of transcription, typically consisting of several structural genes that are transcribed together; the operon contains at least two control regions: the promoter and the operator.

Opportunity cost • The sum of the benefits an animal forfeits by not being able to perform some other behavior during the time when it is performing a given behavior.

Opsin (op' sin) [Gr. opsis: sight] • The protein portion of the visual pigment rhodopsin. (See rhodopsin.)

Optic chiasm • Structure on the lower surface of the vertebrate brain where the two optic nerves come together.

Optical isomers • Isomers that differ in the configuration of the four different groups attached to a single carbon atom; so named

because solutions of the two isomers rotate the plane of polarized light in opposite directions. The two isomers are mirror images of one another.

Optimality models • Models developed to determine the structures or behaviors that best solve particular problems faced by organisms.

Order • In taxonomy, the category below the class and above the family; a group of related, similar families.

Organ • A body part, such as the heart, liver, brain, root, or leaf, composed of different tissues integrated to perform a distinct function for the body as a whole.

Organ identity genes • Plant genes that specify the various parts of the flower. See homeotic genes.

Organ of Corti • Structure in the inner ear that transforms mechanical forces produced from pressure waves ("sound waves") into action potentials that are sensed as sound.

Organelles (or' gan els) [L.: little organ] • Organized structures that are found in or on cells. Examples: ribosomes, nuclei, mitochondria, chloroplasts, cilia, and contractile vacuoles.

Organic • Pertaining to any aspect of living matter, e.g., to its evolution, structure, or chemistry. The term is also applied to any chemical compound that contains carbon.

Organism • Any living creature.

Organizer, embryonic • A region of an embryo which directs the development of nearby regions. In amphibian early gastrulas, the dorsal lip of the blastopore.

Origin of replication • A DNA sequence at which helicase unwinds the DNA double helix and DNA polymerase binds to initiate DNA replication.

Osmoregulation • Regulation of the chemical composition of the body fluids of an organism.

Osmoreceptor • A neuron that converts changes in the osmotic potential of interstitial fluids into action potentials.

Osmosis (oz mo' sis) [Gr. osmos: to push] • The movement of water through a differentially permeable membrane from one region to another where the water potential is more negative. This is often a region in which the concentration of dissolved molecules or ions is higher, although the effect of dissolved substances may be offset by hydrostatic pressure in cells with semi-rigid walls.

Ossicle (ah' sick ul) [L. os: bone] • The calcified construction unit of echinoderm skeletons.

Osteoblasts • Cells that lay down the protein matrix of bone.

Osteoclasts • Cells that dissolve bone.

Otolith (oh' tun lith) [Gk. otikos: ear + lithos: stone] • Structures in the vertebrate vestibular apparatus that mechanically stimulate hair cells when the head moves or changes position.

Outgroup • A taxon that separated from another taxon, whose lineage is to be inferred, before the latter underwent evolutionary radiation.

Oval window • The flexible membrane which, when moved by the bones of the middle ear, produces pressure waves in the inner ear

Ovary (oh' var ee) • Any female organ, in plants or animals, that produces an egg.

Oviduct [L. ovum: egg + ducere: to lead] • In mammals, the tube serving to transport eggs to the uterus or to outside of the body.

Oviparous (oh vip' uh rus) • Reproduction in which eggs are released by the female and development is external to the mother's body. (Contrast with viviparous.)

Ovulation • The release of an egg from an ovary.

Ovule (oh' vule) [L. ovulum: little egg] • In plants, an organ that contains a gameto-phyte and, within the gametophyte, an egg; when it matures, an ovule becomes a seed.

Ovum (oh' vum) [L.: egg] • The egg, the female sex cell.

Oxidation (ox i day' shun) • Relative loss of electrons in a chemical reaction; either outright removal to form an ion, or the sharing of electrons with substances having a greater affinity for them, such as oxygen. Most oxidation, including biological ones, are associated with the liberation of energy. (Contrast with reduction.)

Oxidative phosphorylation • ATP formation in the mitochondrion, associated with flow of electrons through the respiratory chain.

Oxidizing agent • A substance that can accept electrons from another. The oxidizing agent becomes reduced; its partner becomes oxidized.

P generation • Also called the parental generation. The individuals that mate in a genetic cross. Their immediate offspring are

the F₂ generation.

Pacemaker • That part of the heart which undergoes most rapid spontaneous contraction, thus setting the pace for the beat of the entire heart. In mammals, the sinoatrial (SA) node. Also, an artificial device, implanted in the heart, that initiates rhythmic contraction of the organ.

Pacinian corpuscle • A sensory neuron surrounded by sheaths of connective tissue. Found in the deep layers of the skin, where it senses touch and vibration.

Pair rule genes • Segmentation genes that divide the *Drosophila* larva into two segments each.

Paleomagnetism • The record of the changing direction of Earth's magnetic field as stored in lava flows. Used to accurately date extremely ancient events.

Paleontology (pale' ee on tol' oh jee) [Gr. palaios: ancient, old + logos: discourse] • The scientific study of fossils and all aspects of extinct life.

Pancreas (pan' cree us) • A gland, located near the stomach of vertebrates, that secretes digestive enzymes into the small

GLOSSARY

intestine and releases insulin into the bloodstream.

Pangaea (pan jee' uh) [Gk. pan: all, every] • The single land mass formed when all the continents came together in the Permian period. (Contrast with Gondwana.)

Parabronchi • Passages in the lungs of birds through which air flows.

Paradigm • A general framework within which a scientific or philosophical discipline is viewed and within which questions are asked and hypotheses are developed. Scientific revolutions usually invoke major paradigm changes. (Contrast with hypothesis, theory.)

Parallel evolution • Evolutionary patterns that exist in more than one lineage. Often the result of underlying developmental processes.

Parapatric speciation [Gr. para: beside + patria: fatherland] • Development of reproductive isolation when the barrier is not geographic but is a difference in some other physical condition (such as soil nutrient content) that prevents gene flow between the subpopulations. (Contrast with allopatric speciation, sympatric speciation.)

Paraphyletic taxon • A taxon that includes some, but not all, of the descendants of a single ancestor.

Parasite • An organism that attacks and consumes parts of an organism much larger than itself. Parasites sometimes, but not always, kill the host.

Parasitoid • A parasite that is so large relative to its host that only one individual or at most a few individuals can live within a single host.

Parasympathetic nervous system • A portion of the autonomic (involuntary) nervous system. Activity in the parasympathetic nervous system produces effects such as decreased blood pressure and decelerated heart beat. (Contrast with sympathetic nervous system.)

Parathormone • Hormone secreted by the parathyroid glands. Stimulates osteoclast activity and raises blood calcium levels.

Parathyroids • Four glands on the posterior surface of the thyroid that produce and release parathormone.

Parenchyma (pair eng' kyma) [Gr. para: beside + enchyma: infusion] • A plant tissue composed of relatively unspecialized cells without secondary walls.

Parental investment • Investment in one offspring or group of offspring that reduces the ability of the parent to assist other offspring.

Parsimony • The principle of preferring the simplest among a set of plausible explanations of a phenomenon. Commonly employed in evolutionary and biogeographic studies.

Parthenocarpy • Formation of fruit from a flower without fertilization.

Parthenogenesis (par' then oh jen' e sis) [Gr. parthenos: virgin + genesis: source] • The production of an organism from an unfertilized egg.

Partial pressure • The portion of the barometric pressure of a mixture of gases that is due to one component of that mixture. For example, the partial pressure of oxygen at sea level is 20.9% of barometric pressure.

Patch clamping • A technique for isolating a tiny patch of membrane to allow the study of ion movement through a particular channel.

Pathogen (path' o jen) [Gr. pathos: suffering + gignomai: causing] • An organism that causes disease.

Pattern formation • In animal embryonic development, the organization of differentiated tissues into specific structures such as wings.

Pedigree • The pattern of transmission of a genetic trait in a family.

Pelagic zone (puh ladj' ik) [Gr. pelagos: the sea] • The open waters of the ocean.

Penetrance • Of a genotype, the proportion of individuals with that genotype who show the expected phenotype.

PEP carboxylase • The enzyme that combines carbon dioxide with PEP to form a 4-carbon dicarboxylic acid at the start of C₄ photosynthesis or of Crassulacean acid metabolism (CAM).

Pepsin [Gr. pepsis: digestion] • An enzyme, in gastric juice, that digests protein.

Peptide linkage • The connecting group in a protein chain, -CO-NH-, formed by removal of water during the linking of amino acids, -COOH to -NH-,.

Peptidoglycan • The cell wall material of many prokaryotes, consisting of a single enormous molecule that surrounds the entire cell.

Perennial (per ren' ee al) [L. per. through + annus: a year] • Referring to a plant that lives from year to year. (Contrast with annual, biennial.)

Perfect flower • A flower with both stamens and carpels, therefore hermaphroditic.

Pericycle [Gr. peri: around + kyklos: ring or circle] • In plant roots, tissue just within the endodermis, but outside of the root vascular tissue. Meristematic activity of pericycle cells produces lateral root primordia.

Periderm • The outer tissue of the secondary plant body, consisting primarily of cork.

Period • (1) A minor category in the geological time scale. (2) The duration of a cyclical event, such as a circadian rhythm.

Peripheral nervous system • Neurons that transmit information to and from the central nervous system and whose cell bodies reside outside the brain or spinal cord.

Peristalsis (pair' i stall' sis) [Gr. peri: around + stellein: place] • Wavelike muscular contractions proceeding along a tubular organ, propelling the contents along the tube.

Peritoneum • The mesodermal lining of the coelom among coelomate animals.

Permease • A membrane protein that specifically transports a compound or family of compounds across the membrane.

Peroxisome • An organelle that houses reactions in which toxic peroxides are formed. The peroxisome isolates these peroxides from the rest of the cell.

Petal • In an angiosperm flower, a sterile modified leaf, nonphotosynthetic, frequently brightly colored, and often serving to attract pollinating insects.

Petiole (pet' ee ole) [L. ptiolus: small foot] • The stalk of a leaf.

pH • The negative logarithm of the hydrogen ion concentration; a measure of the acidity of a solution. A solution with pH = 7 is said to be neutral; pH values higher than 7 characterize basic solutions, while acidic solutions have pH values less than 7.

Phage (fayj) • Short for bacteriophage.

Phagocyte • A white blood cell that ingests microorganisms by endocytosis.

Phagocytosis [Gr.: phagein to eat; cell-eating] • A form of endocytosis, the uptake of a solid particle by forming a pocket of plasma membrane around the particle and pinching off the pocket to form an intracellular particle bounded by membrane. (Contrast with pinocytosis.)

Pharynx [Gr.: throat] • The part of the gut between the mouth and the esophagus.

Phenotype (fee' no type) [Gr. phanein: to show] • The observable properties of an individual as they have developed under the combined influences of the genetic constitution of the individual and the effects of environmental factors. (Contrast with genotype.)

Phenotypic plasticity • The fact that the phenotype of an organism is determined by a complex series of developmental processes that are affected by both its genotype and its environment.

Pheromone (feer' o mone) [Gr. phew: carry + hormon: excite, arouse] • A chemical substance used in communication between organisms of the same species.

Phloem (flo' um) [Gr. phloos: bark] • In vascular plants, the food-conducting tissue. It consists of sieve cells or sieve tubes, fibers, and other specialized cells.

Phosphate group • The functional group -OPO₃FT; the transfer of energy from one compound to another is often accomplished by the transfer of a phosphate group.

Phosphodiester linkage • The connection in a nucleic acid strand, formed by linking two nucleotides.

Phospholipids • Cellular materials that contain phosphorus and are soluble in organic solvents. An example is lecithin (phosphatidyl choline). Phospholipids are important constituents of cellular membranes. (See lipids.)

Phosphorylation • The addition of a phosphate group.

Photoautotroph • An organism that obtains energy from light and carbon from carbon

GLOSSARY

dioxide. (Contrast with chemoautotroph, chemoheterotroph, photoheterotroph.)

Photoheterotroph • An organism that obtains energy from light but must obtain it-- carbon from organic compounds. (Contrast with chemoautotroph, chemo-heterotroph, photoautotroph.)

Photon (foe' tohn) [Gr. photos: light] • A quantum of visible radiation; a "packet" of light energy

Photoperiod (foe* tow peer' ee ud) • The duration of a period of light, such as the length of time in a 24-hour cycle in which daylight is present. The regulation of processes such as flowering by the changing length of day (or of night) is known as photoperiodism.

Photoreceptor • (1) A protein (pigment) that triggers a physiological response when it absorbs a photon. (2) A cell that senses and responds to light energy.

Photorespiration • Light-driven uptake of oxygen and release of carbon dioxide, the carbon being derived from the early reactions of photosynthesis.

Photosynthesis (foe tow sin' the sis) [literal-lv, "synthesis out of light"] • Metabolic processes, carried out by green plants, by which visible light is trapped and the energy used to synthesize compounds such as ATP and glucose.

Phototropin • A yellow protein that is the photoreceptor responsible for phototropism.

Phototropism [Gr. photos: light + trope: a turning] • A directed plant growth response to light.

Phylogenetic tree • Graphic representation of lines of descent among organisms.

Phylogeny (fy loj' e nee) [Gr. phylon: tribe, race + genesis: source] • The evolutionary history of a particular group of organisms; also, the diagram of the "family tree" that shows genetic linkages between ancestors and descendants.

Phylum (plural: phyla) [Gr. phylon: tribe, stock] • In taxonomy, a high-level category just beneath kingdom and above the class; a group of related, similar classes.

Physiology (fiz' ee ol' o jee) [Gr. physis: natural form + logos: discourse, study] • The scientific study of the functions of living organisms and the individual organs, tissues, and cells of which they are composed.

Phytoalexins • Substances toxic to fungi, produced by plants in response to fungal infection.

Phytochrome (fy' tow krome) [Gr. phyton: plant + chroma: color] • A plant pigment regulating a large number of developmental and other phenomena in plants; can exist in two different forms, one of which is active and the other is not. Different wavelengths of light can drive it from one form to the other.

Phytoplankton (fy' tow plangk' ton) [Gr. phyton: plant + planktos: wandering] • The autotrophic portion of the plankton, consisting mostly of algae.

Pigment • A substance that absorbs visible light.

Pilus (pill' us) [Lat. pilus: hair] • A surface appendage by which some bacteria adhere to one another during conjugation.

Pinocytosis [Gr.: drinking cell] • A form of endocytosis; the uptake of liquids by engulfing a sample of the external medium into a pocket of the plasma membrane followed by pinching off the pocket to form an intracellular vesicle. (Contrast with phagocytosis and endocytosis.)

Pistil [L. pistillum: pestle] • The female structure of an angiosperm flower, within which the ovules are borne. May consist of a single carpel, or of several carpels fused into a single structure. Usually differentiated into ovary, style, and stigma.

Pith • In plants, relatively unspecialized tissue found within a cylinder of vascular tissue.

Pituitary • A small gland attached to the base of the brain in vertebrates. Its hormones control the activities of other glands.

Also known as the hypophysis.

Placenta (pla sen' ta) [Gr. plax: flat surface] • The organ found in most mammals that provides for the nourishment of the fetus and elimination of the fetal waste products.

Placental (pla sen' tal) • Pertaining to mammals of the subclass Eutheria, a group characterized by the presence of a placenta; contains the majority of living species of mammals.

Plankton [Gr. planktos: wandering] • The free-floating organisms of the sea and fresh water that for the most part move passively with the water currents. Consisting mostly of microorganisms and small plants and animals. (Contrast with nekton.)

Plant • A member of the kingdom Plantae. Multicellular, gaining its nutrition by photosynthesis.

Planula (plan' yew la) [L. planum: something flat] • The free-swimming, ciliated larva of the cnidarians.

Plaque (plack) [Fr.: a metal plate or coin] • (1) A circular clearing in a turbid layer (lawn) of bacteria growing on the surface of a nutrient agar gel. Produced by successive rounds of infection initiated by a single bacteriophage. (2) An accumulation of prokaryotic organisms on tooth enamel. Acids produced by the metabolism of these microorganisms can cause tooth decay.

Plasma (plaz' muh) [Gr. plassein: to mold] • The liquid portion of blood, in which blood cells and other particulates are suspended.

Plasma cell • An antibody-secreting cell that developed from a B cell. The effector cell of the humoral immune system.

Plasma membrane • The membrane that surrounds the cell, regulating the entry and exit of molecules and ions. Every cell has a plasma membrane.

Plasmid • A DNA molecule distinct from the chromosome(s); that is, an extrachromosomal element. May replicate independently of the chromosome.

Plasmodesma (plural: plasmodesmata) [Gr. plasma: formed or molded + desmos: band] • A cytoplasmic strand connecting two adjacent plant cells.

Plasmolysis (plaz mol' i sis) • Shrinking of the cytoplasm and plasma membrane away from the cell wall, resulting from the osmotic outflow of water. Occurs only in cells with rigid cell walls.

Plastid • Organelle in plants that serves for food manufacture (by photosynthesis) or food storage; bounded by a double membrane.

Platelet • A membrane-bounded body without a nucleus, arising as a fragment of a cell in the bone marrow of mammals. Important to blood-clotting action.

Pleiotropy (plee' a tro pee) [Gr. pleion: more] • The determination of more than one character by a single gene.

Pleural membrane [Gk. pleuras: rib, side] • The membrane lining the outside of the lungs and the walls of the thoracic cavity. Inflammation of these membranes is a condition known as pleurisy.

Podocytes • Cells of Bowman's capsule of the nephron that cover the capillaries of the glomerulus, forming filtration slits.

Poikilotherm (poy' kill o therm) [Gr. poikilos: varied + therme: heat] • An animal whose body temperature tends to vary with the surrounding environment. (Contrast with homeotherm, heterotherm.)

Point mutation • A mutation that results from a small, localized alteration in the chemical structure of a gene. Such mutations can give rise to wild-type revertants as a result of reverse mutation. In genetic crosses, a point mutation behaves as if it resided at a single point on the genetic map. (Contrast with deletion.)

Polar body • A nonfunctional nucleus produced by meiosis, accompanied by very little cytoplasm. The meiosis which produces the mammalian egg produces in addition three polar bodies.

Polar molecule • A molecule in which the electric charge is not distributed evenly in the covalent bonds.

Polarity • In development, the difference between one end and the other. In chemistry, the property that makes a polar molecule.

Pollen [L.: fine powder, dust] • The fertilizing element of seed plants, containing the male gametophyte and the gamete, at the stage in which it is shed.

Pollination • Process of transferring pollen from the anther to the receptive surface (stigma) of the ovary in plants.

Poly- [Gr. poly: many] • A prefix denoting multiple entities.

Polygamy [Gr. poly: many + gamos: marriage] • A breeding system in which an individual acquires more than one mate. In polyandry, a female mates with more than one male, in polygyny, a male mates with more than one female.

GLOSSARY

Polygenes • Multiple loci whose alleles increase or decrease a continuously variable phenotypic trait.

Polymer • A large molecule made up of similar or identical subunits called monomers. (Contrast with monomer, oligomer.)

Polymerase chain reaction (PCR) • A technique for the rapid production of millions of copies of a particular stretch of DNA.

Polymerization reactions • Chemical reactions that generate polymers by means of condensation reactions.

Polymorphism (pol' lee mor' fiz um) [Gr. poll/: many + morphe: form, shape] • (1) In genetics, the coexistence in the same population of two distinct hereditary types based on different alleles. (2) In social organisms such as colonial cnidarians and social insects, the coexistence of two or more functionally different castes within the same colony.

Polyp • The sessile, asexual stage in the life cycle of most cnidarians.

Polypeptide • A large molecule made up of many amino acids joined by peptide linkages. Large polypeptides are called proteins.

Polyphyletic group • A group containing taxa, not all of which share the most recent common ancestor.

Polyploid (pol' lee ploid) • A cell or an organism in which the number of complete sets of chromosomes is greater than two.

Polysaccharide • A macromolecule composed of many monosaccharides (simple sugars). Common examples are cellulose and starch.

Polysome • A complex consisting of a threadlike molecule of messenger RNA and several (or many) ribosomes. The ribosomes move along the mRNA, synthesizing polypeptide chains as they proceed.

Polytene (pol' lee teen) [Gr. poly, many + taenia: ribbon] • An adjective describing giant interphase chromosomes, such as those found in the salivary glands of fly larvae. The characteristic, reproducible pattern of bands and bulges seen on these chromosomes has provided a method for preparing detailed chromosome maps of several organisms.

Pons [L. pons: bridge] • Region of the brain stem anterior to the medulla.

Population • Any group of organisms coexisting at the same time and in the same place and capable of interbreeding with one another.

Population density • The number of individuals (or modules) of a population in a unit of area or volume.

Population genetics • The study of genetic variation and its causes within populations.

Population structure • The proportions of individuals in a population belonging to different age classes (age structure). Also, the distribution of the population in space.

Portal vein • A vein connecting two capillary beds, as in the hepatic portal system.

Positive control • The situation in which a regulatory macromolecule is needed to turn transcription of structural genes on. In its absence, transcription will not occur.

Positive cooperativity • Occurs when a molecule can bind several ligands and each one that binds alters the conformation of the molecule so that it can bind the next ligand more easily. The binding of four molecules of O₂ by hemoglobin is an example of positive cooperativity.

Postabsorptive period • When there is no food in the gut and no nutrients are being absorbed.

Postsynaptic cell • The cell whose membranes receive the neurotransmitter released at a synapse.

Predator • An organism that kills and eats other organisms. Predation is usually thought of as involving the consumption of animals by animals, but it can also mean the eating of plants.

Presynaptic excitation/inhibition • Occurs when a neuron modifies activity at a synapse by releasing a neurotransmitter onto the presynaptic nerve terminal.

Prey [L. praeda: booty] • An organism consumed as an energy source.

Primary active transport • Form of active transport in which ATP is hydrolyzed, yielding the energy required to transport ions against their concentration gradients. (Contrast with secondary active transport.)

Primary growth • In plants, growth produced by the apical meristems. (Contrast with secondary growth.)

Primary producer • A photosynthetic or chemosynthetic organism that synthesizes complex organic molecules from simple inorganic ones.

Primary succession • Succession that begins in an area initially devoid of life, such as on recently exposed glacial till or lava flows.

Primary structure • The specific sequence of amino acids in a protein.

Primary wall • Cellulose-rich cell wall layers laid down by a growing plant cell.

Primate (pry' mate) • A member of the order Primates, such as a lemur, monkey, ape, or human.

Primer • A short, single-stranded segment of DNA serving as the necessary starting material for the synthesis of a new DNA strand, which is synthesized from the 3' end of the primer.

Primitive streak • A line running axially along the blastodisc, the site of inward cell migration during formation of the three-layered embryo. Formed in the embryos of birds and fish.

Primordium [L. primordiū: origin] • The most rudimentary stage of an organ or other part.

Principle of continuity • States that because life probably evolved from nonlife by a continuous, gradual process, all postulated stages in the evolution of life should be derivable from preexisting states. (Compare with signature principle.)

Pro- [L.: first, before, favoring] • A prefix often used in biology to denote a developmental stage that comes first or an evolutionary form that appeared earlier than another. For example, prokaryote, prophase.

Probe • A segment of single stranded nucleic acid used to identify DNA molecules containing the complementary sequence.

Procambium • Primary meristem that produces the vascular tissue.

Progesterone [L. pro: favoring + gestare: to bear] • A vertebrate female sex hormone that maintains pregnancy.

Prokaryotes (pro kar' ry otes) [L. pro: before + Gk. karyon: kernel, nucleus] • Organisms whose genetic material is not contained within a nucleus. The bacteria. Considered an earlier stage in the evolution of life than the eukaryotes.

Prometaphase • The phase of nuclear division that begins with the disintegration of the nuclear envelope.

Promoter • The region of an operon that acts as the initial binding site for RNA polymerase.

Proofreading • The correction of an error in DNA replication just after an incorrectly paired base is added to the growing polynucleotide chain.

Prophage (pro' fayj) • The noninfectious units that are linked with the chromosomes of the host bacteria and multiply with them but do not cause dissolution of the cell. Prophage can later enter into the lytic phase to complete the virus life cycle.

Prophase (pro' phase) • The first stage of nuclear division, during which chromosomes condense from diffuse, threadlike material to discrete, compact bodies.

Prostaglandin • Any one of a group of specialized lipids with hormone-like functions. It is not clear that they act at any considerable distance from the site of their production.

Prosthetic group • Any nonprotein portion of an enzyme.

Protease (pro' tee ase) • See proteolytic enzyme.

Protein (pro' teen) [Gr. protos: first] • One of the most fundamental building substances of living organisms. A long-chain polymer of amino acids with twenty different common side chains. Occurs with its polymer chain extended in fibrous proteins, or coiled into a compact macromolecule in enzymes and other globular proteins.

Proteolytic enzyme • An enzyme whose main catalytic function is the digestion of a protein or polypeptide chain. The digestive enzymes trypsin, pepsin, and carboxypeptidase are all proteolytic enzymes (proteases).

Protist • Those eukaryotes not included in the kingdoms Animalia, Fungi, or Plantae.

Protobiont • Aggregates of abiotically produced molecules that cannot reproduce but do maintain internal chemical environments that differ from their surroundings.

Protoderm • Primary meristem that gives rise to epidermis.

Proton (pro' tan) [Gr. protos: first] • One of the three most fundamental particles of matter, with mass approximately 1 amu and an electrical charge of $+1$.

Proto-oncogenes • The normal alleles of genes possessing oncogenes (cancer-causing genes). Proto-oncogenes encode growth factors and receptor proteins.

Protostome • One of the major lineages of animal evolution. Characterized by spiral, determinate cleavage of the egg, and by schizocoelous development. (Compare with deuterostome.)

Prototroph (pro' tow trofe') [Gr. protos: first + tropic: to nourish] • The nutritional wild type, or reference form, of an organism. Any deviant form that requires growth nutrients not required by the prototrophic form is said to be a nutritional mutant, or auxotroph.

Protozoa • A group of single-celled organisms classified by some biologists as a single phylum; includes the flagellates, amoebas, and ciliates. This textbook follows most modern classifications in elevating the protozoans to a distinct kingdom (Protista) and each of their major subgroups to the rank of phylum.

Proximal • Near the point of attachment or other reference point. (Contrast with distal.)

Pseudocoelom • A body cavity not surrounded by a peritoneum. Characteristic of nematodes and rotifers.

Pseudogene • A DNA segment that is homologous to a functional gene but contains a nucleotide change that prevents its expression.

Pseudoplasmodium [Gr. *pseudes*: false + *plasma*: mold or form] • In the cellular slime molds such as *Dictyostelium*, an aggregation of single amoeboid cells. Occurs prior to formation of a fruiting structure.

Pseudopod (soo' do pod) [Gr. *pseudes*: false + *podos*: foot] • A temporary, soft extension of the cell body that is used in location, attachment to surfaces, or engulfing particles.

Pulmonary • Pertaining to the lungs.

Punctuated equilibrium • An evolutionary pattern in which periods of rapid change are separated by longer periods of little or no change.

Pupa (pew' pa) [L: doll, puppet] • In certain insects (the Holometabola), the encased developmental stage that intervenes between the larva and the adult.

Pupil • The opening in the vertebrate eye through which light passes.

Purine (pure' een) • A type of nitrogenous base. The purines adenine and guanine are found in nucleic acids.

Purkinje fibers • Specialized heart muscle cells that conduct excitation throughout the ventricular muscle.

Pyramid of biomass • Graphical representation of the total body masses at different trophic levels in an ecosystem.

Pyramid of energy • Graphical representation of the total energy contents at different trophic levels in an ecosystem.

Pyrimidine (peer im' a deen) • A type of nitrogenous base. The pyrimidines cytosine, thymine, and uracil are found in nucleic acids.

Pyruvate • A three-carbon acid; the end product of glycolysis and the raw material for the citric acid cycle.

Q₁₀ • A value that compares the rate of a biochemical process or reaction over a 10°C range of temperature. A process that is not temperature-sensitive has a Q₁₀ of 1. Values of 2 or 3 mean the reaction speeds up as temperature increases.

Quantum (kwon' turn) [L. *quantus*: how great] • An indivisible unit of energy.

Quaternary structure • Of aggregating proteins, the arrangement of polypeptide sub-units.

R factor (resistance factor) • A plasmid that contains one or more genes that encode resistance to antibiotics.

Radial symmetry • The condition in which two halves of a body are mirror images of each other regardless of the angle of the cut, providing the cut is made along the center line. Thus, a cylinder cut lengthwise down its center displays this form of symmetry. (Contrast with biradial symmetry.)

Radioisotope • A radioactive isotope of an element. Examples are carbon-14 (¹⁴C) and hydrogen-3, or tritium (³H).

Radiometry • The use of the regular, known rates of decay of radioisotopes of elements to determine dates of events in the distant past.

Rain shadow • A region of low precipitation on the leeward side of a mountain range.

Ramet • The repeated morphological units of sessile, modular organisms. (Contrast with genet.)

Random genetic drift • Evolution (change in gene proportions) by chance processes alone.

Rate constant • Of a particular chemical reaction, a constant which, when multiplied by the concentration(s) of reactant(s), gives the rate of the reaction.

Reactant • A chemical substance that enters into a chemical reaction with another substance.

Reaction, chemical • A process in which atoms combine or change bonding partners.

Realized niche • The actual niche occupied by an organism; it differs from the fundamental niche because of the presence of other species.

Receptive field • Of a neuron, the area on the retina from which the activity of that neuron can be influenced.

Receptor potential • The change in the resting potential of a sensory cell when it is stimulated.

Recessive • See dominance.

Reciprocal altruism • The exchange of altruistic acts between two or more individuals. The acts may be separated considerably in time.

Reciprocal crosses • A pair of crosses, in one of which a female of genotype A mates with a male of genotype B and in the other of which a female of genotype B mates with a male of genotype A.

Recognition site (also called a restriction site) • A sequence of nucleotides in DNA to which a restriction enzyme binds and then cuts the DNA.

Recombinant • An individual, meiotic product, or single chromosome in which genetic materials originally present in two individuals end up in the same haploid complement of genes. The reshuffling of genes can be either by independent segregation, or by crossing over between homologous chromosomes. For example, a human may pass on genes from both parents in a single haploid gamete.

Recombinant DNA technology • The

application of genetic tools (restriction endonucleases, plasmids, and transformation) to the production of specific proteins by biological "factories" such as bacteria.

Rectum • The terminal portion of the gut, ending at the anus.

Redox reaction • A chemical reaction in which one reactant becomes oxidized and the other becomes reduced.

Reducing agent • A substance that can donate electrons to another substance. The reducing agent becomes oxidized, and its partner becomes reduced.

Reduction (re duk' shun) • Gain of electrons; the reverse of oxidation. Most reductions lead to the storage of chemical energy, which can be released later by an oxidation reaction. Energy storage compounds such as sugars and fats are highly reduced compounds. (Contrast with oxidation.)

Reflex • An automatic action, involving only a few neurons (in vertebrates, often in the spinal cord), in which a motor response swiftly follows a sensory stimulus.

Refractory period • Of a neuron, the time interval after an action potential, during which another action potential cannot be elicited.

Regulative development • A pattern of animal embryonic development in which the fates of the first blastomeres are not absolutely fixed. (Contrast with mosaic development.)

Regulatory gene • A gene that contains the information for making a regulatory macro-molecule, often a repressor protein.

Releaser • A sensory stimulus that triggers a fixed action pattern.

Releasing hormone • One of several hypothalamic hormones that stimulates the secretion of anterior pituitary hormone.

REM sleep • A sleep state characterized by dreaming, skeletal muscle relaxation, and rapid eye movements.

Renal [L. renes: kidneys] • Relating to the kidneys.

Replication fork • A point at which a DNA molecule is replicating. The fork forms by the unwinding of the parent molecule.

Repressible enzyme • An enzyme whose synthesis can be decreased or prevented by

GLOSSARY

the presence of a particular compound. A repressible operon often controls the synthesis of such an enzyme.

Repressor • A protein coded by the regulatory gene. The repressor can bind to a specific operator and prevent transcription of the operon.

Reproductive isolating mechanism • Any trait that prevents individuals from two different populations from producing fertile hybrids.

Reproductive isolation • The condition in which a population is not exchanging genes with other populations of the same

species.

Resolving power • Of an optical device such as a microscope, the smallest distance between two lines that allows the lines to be seen as separate from one another.

Resource • Something in the environment required by an organism for its maintenance and growth that is consumed in the process of being used.

Resource defense polygamy • A breeding system in which individuals of one sex (usually males) defend resources that are attractive to individuals of the other sex (usually females); individuals holding better resources attract more mates.

Respiration (res pi ra' shun) [L. spvrare: to breathe] • (1) Cellular respiration; the oxidation of the end products of glycolysis with the storage of much energy in ATP. The oxidant in the respiration of eukaryotes is oxygen gas. Some bacteria can use nitrate or sulfate instead of O_2 - (2) Breathing.

Respiratory chain • The terminal reactions of cellular respiration, in which electrons are passed from NAD or FAD, through a series of intermediate carriers, to molecular oxygen, with the concomitant production of ATP.

Resting potential • The membrane potential of a living cell at rest. In cells at rest, the interior is negative to the exterior. (Contrast with action potential, electrotonic potential.)

Restoration ecology • The science and practice of restoring damaged or degraded ecosystems.

Restriction endonuclease • Any one of several enzymes, produced by bacteria, that break foreign DNA molecules at very specific sites. Some produce "sticky ends." Extensively used in recombinant DNA technology.

Restriction map • A partial genetic map of a DNA molecule, showing the points at which particular restriction endonuclease recognition sites reside.

Reticular system • A central region of the vertebrate brain stem that includes complex fiber tracts conveying neural signals between the forebrain and the spinal cord, with collateral fibers to a variety of nuclei that are involved in autonomic functions, including arousal from sleep.

Retina (rett' in uh) [L. rete: net] • The light-sensitive layer of cells in the vertebrate or cephalopod eye.

Retinal • The light-absorbing portion of visual pigment molecules. Derived from (J-carotene).

Retrovirus • An RNA virus that contains reverse transcriptase. Its RNA serves as a template for cDNA production, and the cDNA is integrated into a chromosome of the mammalian host cell.

Reverse transcriptase • An enzyme that catalyzes the production of DNA (cDNA), using RNA as a template; essential to the reproduction of retroviruses.

RFLP (Restriction fragment length polymorphism) • Coexistence of two or more patterns of restriction fragments (patterns produced by restriction enzymes), as revealed by a probe. The polymorphism reflects a difference in DNA sequence on homologous chromosomes.

Rhizoids (rye' zoids) [Gr. rhiza: root] • Hairlike extensions of cells in mosses, liverworts, and a few vascular plants that serve the same function as roots and root hairs in vascular plants. The term is also applied to branched, rootlike extensions of some fungi and algae.

Rhizome (rye' zome) [Gr. rhizoma: mass of roots] • A special underground stem (as opposed to root) that runs horizontally beneath the ground.

Rhodopsin • A photopigment used in the visual process of transducing photons of light into changes in the membrane potential of photoreceptor cells.

Ribonucleic acid • See RNA.

Ribosomal RNA (rRNA) • Several species of RNA that are incorporated into the ribosome. Involved in peptide bond formation.

Ribosome • A small organelle that is the site of protein synthesis.

Ribozyme • An RNA molecule with catalytic activity.

Ribulose 1,5-bisphosphate (RuBP) • The compound in chloroplasts which reacts with carbon dioxide in the first reaction of the Calvin-Benson cycle.

Risk cost • The increased chance of being injured or killed as a result of performing a behavior, compared to resting.

RNA (ribonucleic acid) • A nucleic acid using ribose. Various classes of RNA are involved in the transcription and translation of genetic information. RNA serves as the genetic storage material in some viruses.

RNA polymerase • An enzyme that catalyzes the formation of RNA from a DNA template.

RNA splicing • The last stage of RNA processing in eukaryotes, in which the transcripts of introns are excised through the action of small nuclear ribonucleoprotein particles (snRNP).

Rods • Light-sensitive cells (photoreceptors) in the retina. (Contrast with cones.)

Root cap • A thimble-shaped mass of cells, produced by the root apical meristem, that protects the meristem and that is the organ that perceives the gravitational stimulus in root gravitropism.

Root hair • A specialized epidermal cell with a long, thin process that absorbs water and minerals from the soil solution.

rRNA • See ribosomal RNA.

Rubisco (RuBP carboxylase) • Enzyme that combines carbon dioxide with ribulose bis-phosphate to produce 3-phosphoglycerate, the first product of C₃ photosynthesis. The most abundant protein on Earth.

Rumen (rew' mun) • The first division of the ruminant stomach. It stores and initiates bacterial fermentation of food. Food is regurgitated from the rumen for further chewing.

Ruminant • An herbivorous, cud-chewing mammal such as a cow, sheep, or deer, having a stomach consisting of four compartments.

S phase • In the cell cycle, the stage of interphase during which DNA is replicated. (Contrast with G¹ phase, G₂ phase.)

Saprobe [Gr. sapos: rotten + bios: life] • An organism (usually a bacterium or fungus) that obtains its carbon and energy directly from dead organic matter.

Sarcomere (sark' o meer) [Gr. sark: flesh + mews: a part] • The contractile unit of a skeletal muscle.

Saturated hydrocarbon • A compound consisting only of carbon and hydrogen, with the hydrogen atoms connected by single bonds.

Schizocoelous development • Formation of a coelom during embryological development by a splitting of mesodermal masses.

Schwann cell • A glial cell that wraps around part of the axon of a peripheral neuron, creating a myelin sheath.

Sclereid [Gr. skleros: hard] • A type of sclerenchyma cell, commonly found in nutshells, that is not elongated.

Sclerenchyma (skier eng' kyma) [Gr. skleros: hard + kyinus, juice] • A plant tissue composed of cells with heavily thickened cell walls, dead at functional maturity. The principal types of sclerenchyma cells are fibers and sclereids.

Secondary active transport • Form of active transport in which ions or molecules are transported against their concentration gradient using energy obtained by relaxation of a gradient of sodium ion concentration rather than directly from ATP. (Contrast with primary active transport.)

Secondary compound • A compound synthesized by a plant that is not needed for basic cellular metabolism. Typically has an antiherbivore or antiparasite function.

Secondary growth • In plants, growth produced by vascular and cork cambia, contributing to an increase in girth. (Contrast with primary growth.)

Secondary structure • Of a protein, localized regularities of structure, such as the α helix and the β pleated sheet.

Secondary succession • Ecological succession after a disturbance that does not elimi-

SS \K>

nate all the organisms that originally lived on the site

Secondary wall • Wall layers laid down by a plant cell that has ceased growing; often impregnated with lignin or suberin.

Second law of thermodynamics • States that in any real (irreversible) process, there is a decrease in free energy and an increase in entropy.

Second messenger • A compound, such as cyclic AMP, that is released within a target cell after a hormone or other "first messenger" has bound to a surface receptor on a cell; the second messenger triggers further reactions within the cell.

Secretin (si kreet' in) • A peptide hormone secreted by the upper region of the small intestine when acidic chyme is present. Stimulates the pancreatic duct to secrete bicarbonate ions.

Section • A thin slice, usually for microscopy, as a tangential section or a transverse section.

Seed • A fertilized, ripened ovule of a gymnosperm or angiosperm. Consists of the embryo, nutritive tissue, and a seed coat.

Seed crop • The number of seeds produced by a plant during a particular bout of reproduction.

Seedling • A young plant that has grown from a seed (rather than by grafting or by other means.)

Segmentation genes • In insect larvae, genes that determine the number and polarity of larval segments.

Segment polarity genes • Genes that determine the boundaries and front-to-back organization of the segments in the *Drosophila* larva.

Segregation (genetic) • The separation of alleles, or of homologous chromosomes, from one another during meiosis so that each of the haploid daughter nuclei produced by meiosis contains one or the other member of the pair found in the diploid mother cell, but never both.

Selective permeability • A characteristic of a membrane, allowing certain substances to pass through while other substances are excluded.

Selfish act • A behavioral act that benefits its performer but harms the recipients.

Semelparous organism • An organism that reproduces only once in its lifetime. (Contrast with iteroparous.)

Semen (see' men) [L.: seed] • The thick, whitish liquid produced by the male reproductive organ in mammals, containing the sperm.

Semicircular canals • Part of the vestibular system of mammals.

Semiconservative replication • The common way in which DNA is synthesized. Each of the two partner strands in a double helix acts as a template for a new partner strand. Hence, after replication, each double helix consists of one old and one new strand.

Seminiferous tubules • The tubules within the testes within which sperm production occurs.

Senescence [L. senescere: to grow old] • Aging; deteriorative changes with aging; the increased probability of dying with increasing age.

Sensory neuron • A neuron leading from a sensory cell to the central nervous system. (Contrast with motor neuron.)

Sepal (see' pul) • One of the outermost structures of the flower, usually protective in function and enclosing the rest of the flower in the bud stage.

Septum [L.: partition] • A membrane or wall between two cavities.

Sertoli cells • Cells in the seminiferous tubules that nurture the developing sperm.

Serum • That part of the blood plasma that remains after clots have formed and been removed.

Sessile (sess' ul) [L. sedere: to sit] • Permanently attached; not moving.

Set point • In a regulatory system, the threshold sensitivity to the feedback stimulus.

Sex chromosome • In organisms with a chromosomal mechanism of sex determination, one of the chromosomes involved in sex determination.

Sex linkage • The pattern of inheritance characteristic of genes located on the sex chromosomes of organisms having a chromosomal mechanism for sex determination.

Sexual selection • Selection by one sex of characteristics in individuals of the opposite sex. Also, the favoring of characteristics in one sex as a result of competition among individuals of that sex for mates.

Shoot • The aerial part of a vascular plant, consisting of the leaves, stem(s), and flowers.

Sieve tube • A column of specialized cells found in the phloem, specialized to conduct organic matter from sources (such as photo-synthesizing leaves) to sinks (such as roots). Found principally in flowering plants.

Sieve tube member • A single cell of a sieve tube, containing cytoplasm but relatively few organelles, with highly specialized perforated end walls leading to elements above and below.

Sign stimulus • The single stimulus, or one out of a very few stimuli, by which an animal distinguishes key objects, such as an enemy, or a mate, or a place to nest, etc.

Signal sequence • The sequence of a protein that directs the protein through a particular cellular membrane.

Signal transduction pathway • The series of biochemical steps whereby a stimulus to a cell (such as a hormone or neurotransmitter binding to a receptor) is translated into a response of the cell.

Signature principle • States that because of continuity, prebiotic processes should leave some trace in contemporary biochemistry. (Compare with principle of continuity.)

Silencer • A sequence of eukaryotic DNA that binds proteins that inhibit the transcription of an associated gene.

Silent mutations • Genetic changes that do not lead to a phenotypic change. At the molecular level, these are DNA sequence changes that, because of the redundancy of the genetic code, result in the same amino acids in the resulting protein. See synonymous mutation.

Similarity matrix • A matrix to compare the structures of two molecules constructed by adding the number of their amino acids that are identical or different

Sinoatrial node (sigh' no ay' tree al) • The pacemaker of the mammalian heart.

Sinus (sigh' nus) [L. sinus: a bend, hollow] • A cavity in a bone, a tissue space, or an enlargement in a blood vessel.

Skeletal muscle • See striated muscle.

Sliding filament theory • A proposed mechanism of muscle contraction based on formation and breaking of crossbridges between actin and myosin filaments, causing them to slide together.

Small intestine • The portion of the gut between the stomach and the colon, consisting of the duodenum, the jejunum, and the ileum.

Small nuclear ribonucleoprotein particle (snRNP) • A complex of an enzyme and a small nuclear RNA molecule, functioning in RNA splicing.

Smooth muscle • One of three types of muscle tissue. Usually consists of sheets of mononucleated cells innervated by the autonomic nervous system.

Society • A group of individuals belonging to the same species and organized in a cooperative manner; in the broadest sense, includes parents and their offspring.

Sodium-potassium pump • The complex protein in plasma membranes that is responsible for primary active transport; it pumps sodium ions out of the cell and potassium ions into the cell, both against their concentration gradients.

Solute • A substance that is dissolved in a liquid (solvent).

Solute potential • A property of any solution, resulting from its solute contents; it may be zero or have a negative value.

Solution • A liquid (solvent) and its dissolved solutes.

Solvent • A liquid that has dissolved or can dissolve one or more solutes.

Somatic [Gr. soma: body] • Pertaining to the body, or body cells (rather than to germ cells).

Somite (so' might) • One of the segments into which an embryo becomes divided longitudinally, leading to the eventual segmentation of the animal as illustrated by the spinal column, ribs, and associated muscles.

Spatial summation • In the production or inhibition of action potentials in a postsynaptic neuron, the interaction of depolarizations and hyperpolarizations produced by several terminal boutons.

GLOSSARY

Spawning • The direct release of sex cells into the water.

Speciation (spee' shee ay' shun) • The process of splitting one population into two populations that are reproductively isolated from one another.

Species (spee' shees) [L.: kind] • The basic lower unit of classification, consisting of a population or series of populations of closely related and similar organisms. The more narrowly defined "biological species" consists of individuals capable of interbreeding freely with each other but not with members of other species.

Species diversity • A weighted representation of the species of organisms living in a region; large and common species are given greater weight than are small and rare ones. (Contrast with species richness.)

Species richness • The number of species of organisms living in a region. (Contrast with species diversity)

Specific heat • The amount of energy that must be absorbed by a gram of a substance to raise its temperature by one degree centigrade. By convention, water is assigned a specific heat of one.

Sperm [Gr. sperma: seed] • A male reproductive cell.

Spermatocyte (spur mat' oh site) [Gr. sperma: seed + kytos: cell] • The cell that gives rise to the sperm in animals.

Spermatogenesis (spur mat' oh jen' e sis) [Gr. sperma: seed + genesis: source] • Male gametogenesis, leading to the production of sperm.

Spermatogonia • Undifferentiated germ cells that give rise to primary spermatocytes and hence to sperm.

Sphincter (sfing'k' ter) [Gr. sphinkter: that which binds tight] • A ring of muscle that can close an orifice, for example at the anus.

Spindle apparatus • An array of microtubules stretching from pole to pole of a dividing nucleus and playing a role in the movement of chromosomes at nuclear division. Named for its shape.

Spiracle (spy' rih kel) [L. spirare: to breathe] • An opening of the tracheal respiratory system of terrestrial arthropods.

Spiteful act • A behavioral act that harms both the actor and the recipient of the act.

Spliceosome • An RNA-protein complex that splices out introns from eukaryotic pre-mRNAs.

Splicing • The removal of introns and connecting of exons in eukaryotic pre-mRNAs.

Spontaneous generation • The idea that life is generated continually from nonliving matter. Usually distinguished from the current idea that life evolved from nonliving matter under primordial conditions at an early stage in the history of earth.

Spontaneous reaction • A chemical reaction which will proceed on its own, without any outside influence. A spontaneous reaction need not be rapid.

Sporangium (spor an' gee um) [Gr. spora: seed + angeion: vessel or reservoir] • In plants and fungi, any specialized structure within which one or more spores are formed.

Spore [Gr. spora: seed] • Any asexual reproductive cell capable of developing into an adult plant without gametic fusion. Haploid spores develop into gametophytes, diploid spores into sporophytes. In prokaryotes, a resistant cell capable of surviving unfavorable periods.

Sporophyte (spor' o fyte) [Gr. spora: seed + phyton: plant] • In plants with alternation of generations, the diploid phase that produces the spores. (Contrast with gameto-phyte.)

Stabilizing selection • Selection against the extreme phenotypes in a population, so that the intermediate types are favored. (Contrast with disruptive selection.)

Stamen (stay' men) [L.: thread] • A male (pollen-producing) unit of a flower, usually composed of an anther, which bears the pollen, and a filament, which is a stalk supporting the anther.

Starch [O.E. stearc: stiff] • An or-linked polymer of glucose; used by plants as a means of storing energy and carbon atoms.

Start codon • The mRNA triplet (AUG) that acts as signals for the beginning of translation at the ribosome. (Compare with stop codons. There are a few minor exceptions to these codons.)

Stasis • Period during which little or no evolutionary change takes place within a lineage or groups of lineages.

Statocyst (star' oh sist) [Gk. statos: stationary + kystos: pouch] • An organ of equilibrium in some invertebrates.

Statolith (stat' oh lith) [Gk. statos: stationary + lithos: stone] • A solid object that responds to gravity or movement and stimulates the mechanoreceptors of a statocyst.

Stele (steel) [Gr. stele: pillar] • The central cylinder of vascular tissue in a plant stem.

Stem cell • A cell capable of extensive proliferation, generating more stem cells and a large clone of differentiated progeny cells, as in the formation of red blood cells.

Step cline • A sudden change in one or more traits of a species along a geographical gradient.

Steroid • Any of numerous lipids based on a 17-carbon atom ring system.

Sticky ends • On a piece of two-stranded DNA, short, complementary, one-stranded regions produced by the action of a restriction endonuclease. Sticky ends allow the joining of segments of DNA from different sources.

Stigma [L.: mark, brand] • The part of the pistil at the apex of the style, which is receptive to pollen, and on which pollen germinates.

Stimulus • Something causing a response; something in the environment detected by a receptor.

Stolon • A horizontal stem that forms roots at intervals.

Stoma (plural: stomata) [Gr. stoma: mouth, opening] • Small opening in the plant epidermis that permits gas exchange; bounded

by a pair of guard cells whose osmotic status regulates the size of the opening.

Stop codons • Triplets (UAG, UGA, UAA) in mRNA that act as signals for the end of translation at the ribosome. (See also

start codon. There are a few minor exceptions to these codons.)

Stratosphere • The part of the atmosphere above the troposphere; extends upward to approximately 50 kilometers above the surface of the earth; contains very little water.

Stratum (plural strata) • A layer or sedimentary rock laid down at a particular time in a past.

Striated muscle • Contractile tissue characterized by multinucleated cells containing highly ordered arrangements of actin and myosin microfilaments. Also known as skeletal muscle.

Stroma • The fluid contents of an organelle, such as a chloroplast.

Stromatolite • A composite, flat-to-domed structure composed of successive mineral layers. Some are known to be produced by the action of bacteria in salt or fresh water, and some ancient ones are considered to be evidence for early life on the earth.

Structural formula • A representation of the positions of atoms and bonds in a molecule.

Structural gene • A gene that encodes the primary structure of a protein.

Style [Gr. stylos: pillar or column] • In flowering plants, a column of tissue extending from the tip of the ovary, and bearing the stigma or receptive surface for pollen at its apex.

Sub- [L.: under] • A prefix often used to designate a structure that lies beneath another or is less than another. For example, subcutaneous, subspecies.

Submucosa • (sub mew koe' sah) • The tissue layer just under the epithelial lining of the lumen of the digestive tract. (Contrast with mucosa.)

Substrate (sub' strayte) • (1) The molecule or molecules on which an enzyme exerts catalytic action. (2) The base material on which an organism lives.

Substrate level phosphorylation • ATP formation resulting from direct transfer of a phosphate group to ADP from an intermediate in glycolysis. (Contrast with oxidative phosphorylation.)

Succession • In ecology, the gradual, sequential series of changes in species composition of a community following a disturbance.

Sulcus (plural: sulci) [L. sulcare: to plow] • The valleys or creases between the raised portions of the convoluted surface of the brain. (Contrast to gyrus.)

Sulfhydryl group • The —SH group.

Summation • The ability of a neuron to fire action potentials in response to numerous subthreshold postsynaptic potentials arriving simultaneously at differentiated places on the cell, or arriving at the same site in rapid succession.

SSAR\

Surface area-to-volume ratio • I or an) cell, organism, or geometrical solid, the ratio of surface area to volume; this is an important factor in setting an upper limit on the size a cell or organism can attain.

Surfactant • \ substance that decreases the

surface tension of a liquid. Lung surfactant secreted by cells of the alveoli, is mostly phospholipid and decreases the amount of work necessary to inflate the lungs.

Symbiosis (sim' bee oh' sis) [C.r.: to live together] • The living together of two or more species in a prolonged and intimate ecological relationship. (See parasitism, commensalism, mutualism.)

Symmetry • In biology, the property that two halves of an object are mirror images of each other. (See bilateral symmetry and biradial symmetry.)

Sympathetic nervous system • A division of the autonomic (involuntary) nervous system. Its activities include increasing blood pressure and acceleration of the heartbeat. The neurotransmitter at the sympathetic terminals is epinephrine or norepinephrine. (Contrast with parasympathetic nervous system.)

Sympatric speciation (sim pat' rik) [Gr. si/w: same + patria: homeland] • The occurrence of genetic reproduction isolation and the subsequent formation of new species without any physical separation of the subpopulation. (Contrast with allopatric speciation, parapatric speciation.)

Symplast • The continuous meshwork of the interiors of living cells in the plant body, resulting from the presence of plasmodesmata. (Contrast with apoplast.)

Symport • A membrane transport process that carries two substances in the same direction across the membrane. (Contrast with antiport.)

Synapse (sin' aps) [Gr. syn: together + liap-tcin: to fasten] • The narrow gap between the terminal bouton of one neuron and the dendrite or cell body of another.

Synapsis (sin ap' sis) • The highly specific parallel alignment (pairing) of homologous chromosomes during the first division of meiosis.

Synaptic vesicle • A membrane-bounded vesicle, containing neurotransmitter, which is produced in and discharged by the presynaptic neuron.

Syngamy (sing' guh mee) [Gr. sun-: together + gamos: marriage] • Union of gametes. Also known as fertilization.

Synonymous mutation • A mutation that substitutes one nucleotide for another but does not change the amino acid specified (i.e., UUA → UUG, both specifying leucine). (Compare with frame-shift mutation, mis-sense mutation, nonsense mutation.)

Synonymous substitution • The situation when a synonymous mutation becomes widespread in a population. Typically not influenced by natural selection, these substitutions can accumulate in a population. (Contrast with nonsynonymous substitution.)

Systematics • The scientific study of the diversity of organisms.

Systemic circulation • The part of the circulatory system serving those parts of the body other than the lungs or gills.

Systemin • The only polypeptide plant hormone; participates in response to tissue damage.

Systole (sis' tuh lee) [Gr.: contraction] • Contraction of a chamber of the heart, driving blood forward in the circulatory system.

T cell • A type of lymphocyte, involved in the cellular immune response. The final stages of its development occur in the thymus gland. (Contrast with B cell; see also cytotoxic T cell, helper T cell, suppressor T cell.)

T cell receptor • A protein on the surface of a T cell that recognizes the antigenic determinant for which the cell is specific.

T tubules • A system of tubules that runs throughout the cytoplasm of muscle fibers, through which action potentials spread.

Target cell • A cell with the appropriate receptors to bind and respond to a particular hormone or other chemical mediator.

Taste bud • A structure in the epithelium of the tongue that includes a cluster of chemoreceptors innervated by sensory neurons.

TATA box • An eight-base-pair sequence, found about 25 base pairs before the starting point for transcription in many eukaryotic promoters, that binds a transcription factor and thus helps initiate transcription.

Taxis (tak' sis) [Gr. taxis: arrange, put in order] • The movement of an organism in a particular direction with reference to a stimulus. A taxis usually involves the employment of one sense and a movement directly toward or away from the stimulus, or else the maintenance of a constant angle to it. Thus a positive phototaxis is movement toward a light source, negative geotaxis is movement upward (away from gravity), and so on.

Taxon • A unit in a taxonomic system.

Taxonomy (taks on' oh me) [Gr. taxis: arrange, classify] • The science of classification of organisms.

Telomeres (tee' lo merz) [Gr. telos: end] • Repeated DNA sequences at the ends of eukaryotic chromosomes.

Telophase (tee' lo phase) [Gr. telos: end] • The final phase of mitosis or meiosis during which chromosomes became diffuse, nuclear envelopes reform, and nucleoli begin to reappear in the daughter nuclei.

Template • In biochemistry, a molecule or surface upon which another molecule is synthesized in complementary fashion, as in the replication of DNA. In the brain, a pattern that responds to a normal input but not to incorrect inputs.

Template strand • In a stretch of double-stranded DNA, the strand that is transcribed.

Temporal summation • In the production or inhibition of action potentials in a postsynaptic neuron, the interaction of depolarizations or hyperpolarizations produced by rapidly repeated stimulation of a single point.

Tendon • A collagen-containing band of tissue that connects a muscle with a bone.

Terrestrial (ter res' tree al) [L. terra: earth] • Pertaining to the land. (Contrast with aquatic, marine.)

Territory • A fixed area from which an animal or group of animals excludes other members of the same species by aggressive behavior or display.

Tertiary structure • In reference to a protein, the relative locations in three-dimensional space of all the atoms in the molecule. The overall shape of a protein. (Contrast with primary, secondary, and quaternary structures.)

Test cross • A cross of a dominant-phenotype individual (which may be either heterozygous or homozygous) with a homozy-

gous-recessive individual.

Testis (tes' tis) (plural: testes) [L.: witness] • The male gonad; that is, the organ that produces the male sex cells.

Testosterone (tes toss' tuhr own) • A male sex steroid hormone.

Tetanus [Gr. tetanos: stretched] • (1) In physiology, a state of sustained, maximal muscular contraction caused by rapidly repeated stimulation. (2) In medicine, an often-fatal disease ("lockjaw") caused by the bacterium *Clostridium tetani*.

Thalamus • A region of the vertebrate fore-brain; involved in integration of sensory input.

Thallus (thai' us) [Gr.: sprout] • Any algal body which is not differentiated into root, stem, and leaf.

Theory • An explanation or hypothesis that is supported by a wide body of evidence. (Contrast with hypothesis, paradigm.)

Thermoneutral zone • The range of temperatures over which an endotherm does not have to expend extra energy to thermoregulate.

Thermoreceptor • A cell or structure that responds to changes in temperature.

Thoracic cavity • The portion of the mammalian body cavity bounded by the ribs, shoulders, and diaphragm. Contains the heart and the lungs.

Thorax • In an insect, the middle region of the body, between the head and abdomen. In mammals, the part of the body between the neck and the diaphragm.

Thrombin • An enzyme that converts fibrinogen to fibrin, thus triggering the formation of blood clots.

Thrombus (throm' bus) [Gk. thrombos: clot] • A blood clot that forms within a blood vessel and remains attached to the wall of the vessel. (Contrast with embolus.)

GLOSSARY

Thylakoid • A flattened sac within a chloroplast. The membranes of the numerous thylakoids contain all of the chlorophyll in a plant, in addition to the electron carriers of photophosphorylation. Thylakoids stack to form grana.

Thymine • A nitrogen-containing base found in DNA.

Thymus • A ductless, glandular portion of the lymphoid system, involved in development of the immune system of vertebrates.

Thyroid [Gr. thyreos: door-shaped] • A two-lobed gland in vertebrates. Produces the hormone thyroxine.

Thyrotropic hormone • A hormone that is produced in the pituitary gland of amphibia such as frogs and transported in the bloodstream to the thyroid gland, inducing the thyroid gland to produce the thyroid hormone that regulates metamorphosis from tadpole to adult frog.

Tight junction • A junction between epithelial cells, in which there is no gap whatever between the adjacent cells. Materials may get through a tight junction only by entering the epithelial cells themselves.

Tissue • A group of similar cells organized into a functional unit and usually integrated with other tissues to form part of an organ such as a heart or leaf.

Tonus • A low level of muscular tension that is maintained even when the body is at rest.

Totipotency • In a cell, the condition of possessing all the genetic information and other capacities necessary to form an entire individual.

Toxigenicity [L. toxicum: poison] • The ability of a bacterium to produce chemical substances injurious to the tissues of the host organism.

Trachea (tray' kee ah) [Gr. trakhoia: a small tube] • A tube that carries air to the bronchi of the lungs of vertebrates, or to the cells of arthropods.

Tracheid (tray' kee id) • A distinctive conducting and supporting cell found in the xylem of nearly all vascular plants, characterized by tapering ends and walls that are pitted but not perforated.

Tracheophytes [Gr. trakhoia: a small tube + phyton: plant] • Those plants with xylem and phloem, including psilophytes, club mosses, horsetails, ferns, gymnosperms, and angiosperms. (Contrast with nontracheophytes.)

Trait • One form of a character: Eye color is a character; brown eyes and blue eyes are traits.

Transcription • The synthesis of RNA, using one strand of DNA as the template.

Transcription factors • Proteins that assemble on a eukaryotic chromosome, allowing RNA polymerase II to perform

transcription.

Transduction • (1) Transfer of genes from one bacterium to another, with a bacterial virus acting as the carrier of the genes. (2) In sensory cells, the transformation of a

stimulus (e.g., light energy, sound pressure waves, chemical or electrical stimulants) into action potentials.

Transfection • Uptake, incorporation, and expression of recombinant DNA.

Transfer cell • A modified parenchyma cell that transports solutes from its cytoplasm into its cell wall, thus moving the solutes from the symplast into the apoplast.

Transfer RNA (tRNA) • A category of relatively small RNA molecules (about 75 nucleotides). Each kind of transfer RNA is able to accept a particular activated amino acid from its specific activating enzyme, after which the amino acid is added to a growing polypeptide chain.

Transformation • Mechanism for transfer of genetic information in bacteria in which pure DNA extracted from bacteria of one genotype is taken in through the cell surface of bacteria of a different genotype and incorporated into the chromosome of the recipient cell.

Transgenic • Containing recombinant DNA incorporated into its genetic material.

Translation • The synthesis of a protein (polypeptide). This occurs on ribosomes, using the information encoded in messenger RNA.

Translocation • (1) In genetics, a rare mutational event that moves a portion of a chromosome to a new location, generally on a nonhomologous chromosome. (2) In vascular plants, movement of solutes in the phloem.

Transpiration [L. spirare . to breathe] • The evaporation of water from plant leaves and stem, driven by heat from the sun, and providing the motive force to raise water (plus ions) from the roots.

Transposable element • A segment of DNA that can move to, or give rise to copies at, another locus on the same or a different chromosome.

Triglyceride • A simple lipid in which three fatty acids are combined with one molecule of glycerol.

Triplet • See codon.

Triplet repeat • Occurrence of repeated triplet of bases in a gene, often leading to genetic disease, as does excessive repetition of CGG in the gene responsible for fragile-X syndrome.

Triploblastic • Having three cell layers. (Contrast with diploblastic.)

Trisomic • Containing three, rather than two members of a chromosome pair.

tRNA • See transfer RNA.

Trochophore (troke' o fore) [Gr. troches: wheel + phoreus: bearer] • The free-swimming larva of some annelids and mollusks, distinguished by a wheel-like band of cilia around the middle, and indicating an evolutionary relationship between these two groups.

Trophic level • A group of organisms united by obtaining their energy from the same part of the food web of a biological community.

Tropic hormones • Hormones of the anterior pituitary that control the secretion of hormones by other endocrine glands.

Tropism [Gr. tropos: to turn] • In plants, growth toward or away from a stimulus such as light (phototropism) or gravity (gravitropism).

Tropomyosin (troe poe my' oh sin) • A protein that, along with actin, constitutes the thin filaments of myofibrils. It controls the interactions of actin and myosin necessary for muscle contraction.

Troposphere • The atmospheric zone reaching upward approximately 17 km in the tropics and subtropics but only to about 10 km at higher latitudes. The zone in which virtually all the water vapor in the atmosphere is located.

Trypsin • A protein-digesting enzyme. Secreted by the pancreas in its inactive form (trypsinogen), it becomes active in the duodenum of the small intestine.

T-tubules • A set of transverse tubes that penetrates skeletal muscle fibers and terminates in the sarcoplasmic reticulum. The T-system transmits impulses to the sacs, which then release Ca²⁺ to initiate muscle contraction.

Tube nucleus • In a pollen tube, the haploid nucleus that does not participate in double fertilization. (Contrast with generative nucleus.)

Tubulin • A protein that polymerizes to form microtubules.

Tumor • A disorganized mass of cells, often growing out of control. Malignant tumors spread to other parts of the body.

Tumor suppressor genes • Genes which, when homozygous mutant, result in cancer. Such genes code for protein products that inhibit cell proliferation.

Twitch • A single unit of muscle contraction.

Tympanic membrane [Gr. tympanum: drum] • The eardrum.

Umbilical cord • Tissue made up of embryonic membranes and blood vessels that connects the embryo to the placenta in eutherian mammals.

Understory • The aggregate of smaller plants growing beneath the canopy of dominant plants in a forest.

Unicellular (yoon' e sell' yer ler) [L. unus: one + cella: chamber] • Consisting of a single cell; as for example a unicellular organism. (Contrast with multicellular.)

Uniport • A membrane transport process that carries a single substance. (Contrast with antiport, symport.)

Unsaturated hydrocarbon • A compound containing only carbon and hydrogen atoms. One or more pairs of carbon atoms are connected by double bonds.

Upwelling • The upward movement of nutrient-rich, cooler water from deeper layers of the ocean.

SAIN

Urea • A compound serving as the main excreted form of nitrogen by many animals, including mammals.

Ureotelic • Describes an organism in which the final product of the breakdown of nitrogen-containing compounds (primarily proteins) is urea. (Contrast with ammonotelic, uricotelic.)

Ureter (your* uh tur) [Gr. ouron: urine] • A long duct leading from the vertebrate kidney to the urinary bladder or the cloaca.

Urethra (you ree' thra) [Gr. ouron: urine] • In most mammals, the canal through which urine is discharged from the bladder and which serves as the genital duct in males.

Uric acid • A compound that serves as the main excreted form of nitrogen in some animals, particularly those which must conserve water, such as birds, insects, and reptiles.

Uricotelic • Describes an organism in which the final product of the breakdown of nitrogen-containing compounds (primarily proteins) is uric acid. (Contrast with ammonotelic, ureotelic.)

Urinary bladder • A structure that receives urine from the kidneys via the ureter, stores it, and expels it periodically through the urethra.

Urine (you' rin) [Gk. ouron: urine] • In vertebrates, the fluid waste product containing the toxic nitrogenous by-products of protein and amino acid metabolism.

Uterus (yoo' ter us) [L.: womb] • The uterus or womb is a specialized portion of the female reproductive tract in certain mammals. It receives the fertilized egg and nurtures the embryo in its early development.

Vaccination • Injection of virus or bacteria or their proteins into the body, to induce immunization. The injected material is usually attenuated (weakened) before injection.

Vacuole (vac' yew ole) [Fr.: small vacuum] • A liquid-filled cavity in a cell, enclosed within a single membrane. Vacuoles play a wide variety of roles in cellular metabolism, some being digestive chambers, some storage chambers, some waste bins, and so forth.

Vagina (vuh jine' uh) [L.: sheath] • In female mammals, the passage leading from the external genital orifice to the uterus; receives the copulatory organ of the male in mating.

van der Waals interaction • A weak attraction between atoms resulting from the interaction of the electrons of one atom with the nucleus of the other atom. This attraction is about one-fourth as strong as a hydrogen bond.

Variable regions • The part of an immunoglobulin molecule or T-cell receptor that includes the antigen-binding site.

Vascular (vas' kew lar) • Pertaining to organs and tissues that conduct fluid, such as blood vessels in animals and phloem and xylem in plants.

Vascular bundle • In vascular plants, a strand of vascular tissue, including conducting cells of xylem and phloem as well as thick-walled fibers.

Vascular ray • In vascular plants, radially oriented sheets of cells produced by the vascular cambium, carrying materials

laterally between the wood and the phloem.

Vascular tissue system • The conductive system of the plant, consisting primarily of xylem and phloem. (Contrast with dermal tissue system, ground tissue system.)

Vasopressin • See antidiuretic hormone.

Vector • (1) An agent, such as an insect, that carries a pathogen affecting another species. (2) A plasmid or virus that carries an inserted piece of DNA into a bacterium for cloning purposes in recombinant DNA technology.

Vegetal hemisphere • The lower portion of some animal eggs, zygotes, and embryos, in which the dense nutrient yolk settles. The vegetal pole refers to the very bottom of the egg or embryo. (Contrast with animal hemisphere.)

Vegetative • Nonreproductive, or nonflowering, or asexual.

Vein [L. vena: channel] • A blood vessel that returns blood to the heart. (Contrast with artery.)

Ventral [L. venter, belly, womb] • Toward or pertaining to the belly or lower side. (Contrast with dorsal.)

Ventricle • A muscular heart chamber that pumps blood through the body.

Vernalization [L. vernalis: belonging to spring] • Events occurring during a required chilling period, leading eventually to flowering.

Vertebral column • The jointed, dorsal column that is the primary support structure of vertebrates.

Vertebrate • An animal whose nerve cord is enclosed in a backbone of bony segments, called vertebrae. The principal groups of vertebrate animals are the fishes, amphibians, reptiles, birds, and mammals.

Vessel [L. vasculum: a small vessel] • In botany, a tube-shaped portion of the xylem consisting of hollow cells (vessel elements) placed end to end and connected by perforations. Together with tracheids, vessel elements conduct water and minerals in the plant.

Vestibular apparatus (ves tib' yew lar) [L. vestibulum: an enclosed passage] • Structures associated with the vertebrate ear; these structures sense changes in position or momentum of the head, affecting balance and motor skills.

Vestigial (ves tij' ee al) [L. vestigium: footprint, track] • The remains of body structures that are no longer of adaptive value to the organism and therefore are not maintained by selection.

Vicariance (vye care' ee unce) [L. vicus: change] • The splitting of the range of a taxon by the imposition of some barrier to dispersal; its members.

Vicariant distribution • A distribution resulting from the disruption of a formerly continuous range by a vicariant event.

Villus (viT lus) (plural: villi) [L.: shaggy hair] • A hairlike projection from a membrane; for example, from many gut walls.

Virion (veer' e on) • The virus particle, the minimum unit capable of infecting a cell.

Viroid (vye' roid) • An infectious agent consisting of a single-stranded RNA molecule with no protein coat; produces diseases in plants.

Virus [L.: poison, slimy liquid] • Any of a group of ultramicroscopic infectious particles constructed of nucleic acid and protein (and, sometimes, lipid) that can reproduce only in living cells.

Visceral mass • The major internal organs of a mollusk.

Vitamin [L. vita: life] • Any one of several structurally unrelated organic compounds that an organism cannot synthesize itself, but nevertheless requires in small quantity for normal growth and metabolism.

Viviparous (vye vip' uh rus) [L. vivus: alive] • Reproduction in which fertilization of the egg and development of the embryo occur inside the mother's body. (Contrast with oviparous.)

Waggle dance • The running movement of a working honey bee on the hive, during which the worker traces out a repeated figure eight. The dance contains elements that transmit to other bees the location of the food.

Water potential • In osmosis, the tendency for a system (a cell or solution) to take up water from pure water, through a differentially permeable membrane. Water flows toward the system with a more negative water potential. (Contrast with osmotic potential, turgor pressure.)

Water vascular system • The array of canals and tubelike appendages that serves as the circulatory system, locomotory system, and food-capturing system of many echinoderms; is in direct connection with the surrounding sea water.

Wavelength • The distance between successive peaks of a wave train, such as electromagnetic radiation.

Wild type • Geneticists' term for standard or reference type. Deviants from this standard, even if the deviants are found in

the wild, are said to be mutant.

Xanthophyll (zan' tho fill) [Gr. xanthos: yellowish-brown + phyllon: leaf] • A yellow or orange pigment commonly found as an accessory pigment in photosynthesis, but found elsewhere as well. An oxygen-containing carotenoid.

X-linked (also called sex-linked) • A character that is coded for by a gene on the X chromosome.

Xerophyte (zee' row fyte) [Gr. xerox: dry + pkyton: plant] • A plant adapted to an environment with a limited water supply.

Xylem (zy' lum) [Gr. xylon: wood] • In vascular plants, the woody tissue that conducts water and minerals; xylem consists, in various plants, of tracheids, vessel elements, fibers, and other highly specialized cells.

GLOSSARY

Yeast artificial chromosome • A laboratory-made DNA molecule containing sequences of yeast chromosomes (origin of replication, telomeres, centromere, and selectable markers) so that it can be used as a vector in yeast.

Yolk • The stored food material in animal eggs, usually rich in protein and lipid.

Z-DNA • A form of DNA in which the molecule spirals to the left rather than to the right.

Zooplankton (zoe' o plang ton) [Gr. zoon: animal + planktos: wandering] • The animal portion of the plankton.

Zoospore (zoe' o spore) [Gr. zoon: animal + spora: seed] • In algae and fungi, any swimming spore. May be diploid or haploid.

Zygote (zye' gote) [Gr. zygos: yoked] • The cell created by the union of two gametes, in which the gamete nuclei are also fused. The earliest stage of the diploid generation.

Zymogen • An inactive precursor of a digestive enzyme secreted into the lumen of the gut, where a protease cleaves it to form the active enzyme.
